If a state permitting authority believes that the intake structure at a Phase III facility needs to be regulated before EPA promulgates the Phase III rule, and if that state has a state law that authorizes imposition of requirements on cooling water intake structures, then under Clean Water Act section 510 the state would be able to impose those more stringent requirements. States do not, however, have any authority to come up with their own, case-by-case interpretation of the regulations EPA is developing under section 316(b). The BPJ language of the Phase II proposal suggests that they do.

Another aspect of BPJ authority provided by proposed 40 C.F.R. §125.94(e) is the provision to authorize the permit writer to: “establish more stringent requirements as best technology available (BTA) for minimizing adverse environmental impact” if the permit writer determines that compliance with the technology requirements of the Phase II rule “would not meet the requirements of other applicable Federal, State, or Tribal law.” Again, this provision is both confusing and unnecessary. It makes no sense to suggest that a given set of technologies for minimizing adverse environmental impact from a cooling water intake structure constitutes BTA unless use of that technology would not meet the requirements of some other applicable law. While there may be some other law that requires imposition of more stringent conditions on a particular cooling water intake structure, those more stringent conditions would not be determinative of BTA; rather, they would be imposed by the other law as a requirement in addition to the BTA requirement of CWA section 316.

At a minimum, EPA should delete language suggesting that BTA may be dictated by other statutes, rather than the requirements of section 316(b) and EPA’s implementing regulations. It would be preferable, however, to remove this provision altogether, which raises more questions than it answers and is not necessary for proper operation of the Phase II regulations.

EPA Response

The final rule provides that existing facilities that are not expressly subject to this (Subpart J – Requirements Applicable to Cooling Water Intake Structures for Phase II Existing Facilities Under Section 316(b)) or another subpart of Part 125, must meet the requirements of section 316(b) of the CWA as determined by the Director on case-by-case, best professional judgment (BPJ) basis. EPA included this provision to ensure that section 316(b) requirements are implemented as necessary and appropriate at those existing facilities that use a cooling water intake structure but do not meet the applicability criteria of the phase II existing facility rule. Such facilities could include, but are not limited to, existing facilities with flows below the Phase II threshold or that do not meet the requirement that 25 percent of water intake be used for cooling. In each case, consistent with 316(b), such facilities would have to have one or more cooling water intake structures that withdraw cooling water from waters of the U.S., be a point source subject to NPDES permit, and be subject to 301 or 306 standards. Under the CWA, EPA is not at liberty to categorically exclude facilities from regulation that otherwise meet the applicability criteria of the Act. Moreover, given that this final regulation is not an effluent limitation guideline, EPA believes that it is it is appropriate to specifically include the BPJ requirements in the rule language.

EPA expects that in determining BPJ permit conditions for cooling water intake structures the Director will consider those factors identified in 316(b) and applicable NPDES program regulations. Such factors include, but may not be limited to, the adverse environmental impact posed by a facility, the control technologies that reduce these impacts, relative technology efficacy in minimizing impacts, and the availability of different control technologies. EPA may develop further guidance regarding the development of 316(b) BPJ permit conditions if the Agency deems it necessary following the completion of the 316(b) rulemakings.

Authority for BPJ determinations is in part found in 402(a)(1), which generally provides that prior to full implementation of specified CWA requirements (including sections 301 and 306 of the Act), the permitting authority may issue permits that include conditions necessary to carry out the Act. Section 316(b) requires that standards established pursuant to sections 301 and 306 of the CWA and applicable to a point source meet specified levels of performance. Given that some existing facilities that meet the applicability criteria of section 316(b) are not subject to the phase II existing facility rule, EPA has authority to issue BPJ-based permit conditions to these facilities according to the terms of section 316(b) to fully implement that section. A similar BPJ provision is included as part of the Phase I 316(b) final rule. (See, §125.80(c)).

EPA recognizes that following the effective date of the Phase II rule and prior to the effective date of the Phase III rule, this BPJ provision could potentially be used to address existing facilities that may ultimately be subject to Phase III requirements. The Agency fully expects that any BPJ permit conditions will continue to be developed based on the case-by-case characteristics of the relevant facility and will, thus, fully consider and appropriately address the specific characteristics of such facilities (including, small power producers or manufacturers as necessary and appropriate). Given the timing of these rulemakings and the implementation workload associated with the Phase II rule becoming effective, EPA believes that the permitting focus will remain predominantly on in-scope Phase II facilities pending the final Phase III rule.

With regard to proposed § 125.94(e), which is applicable under this rule but not under BPJ-based permits, this provision has been redesignated as § 125.94(f) and reworded to provide that "The Director may establish more stringent requirements as best technology available for minimizing adverse environmental impact if the Director determines that your compliance with the applicable requirements of paragraphs (b) and (c) of this section would not meet the requirements of applicable State and Tribal law, or other Federal law." This provision is intended to allow consideration as appropriate for the fact that State and Tribes may have addition or more stringent requirements applicable to Phase II existing facilities, as well as for the fact that other Federal laws also may be applicable when determining the permit conditions that fulfill this rule. EPA does not intend this provision to alter the national requirements for BTA under section 316(b), only for Directors to retain the ability to supplement them where appropriate.

Subject Matter Code 7.02
Performance standards

The rule must be revised so the “calculation baseline” is not the only surrogate measure for the threshold of adverse environmental impact; the rule must provide for use of alternative performance standards [e.g. expanding 125.94(c) beyond just cost considerations] that allow demonstrating that the existing intake structure is not adversely impacting populations of aquatic life in the area.

The “calculation baseline” is used in the proposed rule essentially as a threshold for determining when adverse environmental impact begins. It calls for an “estimate of impingement mortality and entrainment that would occur at your site assuming you had a shoreline cooling water intake structure with an intake capacity commensurate with a once-though cooling water system and with no impingement and/or entrainment reduction controls.” (Section 125.93). We are not aware of any scientifically supportable way to make this estimate, particularly at an existing facility site where the populations and ecosystem have equilibrated to the presence of the existing intake structure. Performance standards based on the calculation baseline are essentially making the performance standard a volume reduction requirement based on reducing intake capacity to that of a cooling tower system.

EPA Response

The calculation baseline provides a standard intake configuration by which facilities can determine relative reductions in impingement and entrainment. EPA acknowledges the numerous comments on the proposed definition and has refined the definition to provide more clarity in implementing this concept. For example, the definition in the proposed rule incorporated a shoreline intake structure. In the final rule, the definition has been clarified to specify a 3/8 inch mesh traveling screen at a shoreline intake structure. Based on available data that indicate this is a common intake structure configuration at Phase II existing facilities, EPA designated a 3/8 inch screen as the standard mesh size against which reductions will be calculated. Similarly, the assumption of no impingement or entrainment controls in the definition in the proposed rule has been clarified to describe an intake where the baseline operations do not take into consideration any procedures to reduce impingement or entrainment. EPA recognizes that some facilities may have control technologies in place that already reduce impingement or entrainment and that the final calculation baseline would allow credit for such reductions. Additionally, EPA further clarified the definition to include the potential data sources that may be used in defining the calculation baseline, such as historical data, data collected at nearby locations, or data collected at the facility. EPA is permitting the use of existing biological data in determining the calculation baseline to minimize the impacts to facilities, provided that the data are representative of current conditions and were collected using appropriate quality control procedures.

EPA chose not to incorporate operating capacity into the calculation baseline, as the definition is not dependent upon intake flow volumes. EPA has adopted an "as built" component to the calculation baseline definition in today's rule.

EPA recognizes that this definition cannot address the variety of intake configurations and other conditions at all facilities and therefore cannot define the calculation baseline in all settings. However, EPA believes that the calculation baseline in the final rule is clear and straightforward to implement, and allows for proactive facilities (i.e., those with control technologies, operational procedures, or restoration measures already in place) to take credit for existing measures.

Subject Matter Code 3.01

Definition: Existing Facility

RG&E questions the definition of "existing facility", as presented in Sect 125.93 and discussed in Section II.A. of the Supplementary Information of the proposed rule. Within the proposed definition of existing facility, increased intake design capacities and flows are not precluded for either facility modifications or the addition of a unit (for the same industrial application). Therefore, in the case of an electric generating station, increased intake capacities and flows resulting from plant modifications or even the addition of another generating unit would meet the definition of an existing facility. However, a facility constructed in place of an existing facility (a replacement facility) cannot be included as an existing facility if intake flows are increased. This presents an apparent incongruity in that, for example, the addition of another generating unit at a single unit site could increase intake flows by 100% and meet the existing facility definition, while a replacement facility may increase intake flows by a much lesser amount (e.g., 25%), and yet not meet the existing facility definition. RG&E believes that the determination regarding the regulatory program to which a facility is subject (i.e. new vs existing facility), should turn on the fact that a new facility would result in entirely new impacts upon a source Waterbury, whereas, the existing facility (which would include replacement facilities) would merely result in increased flows that would be a continuation of existing impacts. This is because the impacts of a replacement facility, even with a modest increase in intake flow, more closely resemble an existing facility than a new facility, and should be evaluated accordingly.

RG&E therefore recommends that the existing facility definition criteria include all types of facility modifications, up to and including the construction of a replacement facility, qualified with a limit upon any increase in intake capacity and flow. While a doubling of intake flows would seem excessive to be included as an existing facility, a maximum limitation of 25% increase in capacity and/or or flow seems reasonable.

EPA Response

See section II of the preamble to the final rule. In the final rule (§ 125.93), EPA has defined the term “existing facility” to mean any facility that commenced construction, as described in 40 CFR 122.29(b)(4), on or before January 17, 2002; and any modification of, or any addition of a unit at such a facility that does not meet the definition of a new facility at § 125.83.

Under this rule, the definition of “existing facility” is based on several factors, including EPA’s recognition that existing power generating facilities can and do make changes to their facilities and cooling water intakes in the course of operation, the nature and magnitude of such changes within the technology-forcing approach framework contained in the NPDES permitting portions of the CWA, the environmental impacts associated with changes to an existing facility, and existing regulations, including existing NPDES program new source and new discharger definitions (e.g., 40 CFR 122.2 and 122.29), as well as the Phase I regulatory definition of new facility. EPA has considered each of these factors in establishing a reasonable demarcation between new and existing facilities subject to section 316(b) requirements.

In the final rule, EPA is not determining which facilities are new versus those that are existing facilities based solely on whether a facility poses entirely new versus existing environmental impacts, as the comment suggests. Such an approach is not consistent with the technology-based framework for environmental protection specified in the CWA, under which new facilities are required to meet the most stringent CWA standards because such facilities have the greatest ability to adopt highly effective environmental protection technologies. EPA's existing NPDES regulations recognize this and clarify when changes to an existing facility may result in the facility being defined and regulated as a new source (e.g., 40 CFR 122.29). The new facility definition in 125.83, which is referenced in this rule, also is consistent with this approach.

Defining new facilities as only those with entirely new environmental impacts raises the difficult issue of defining what constitute new impacts (i.e., must impacts be different than existing impacts, increased levels of existing impacts, or totally new?) and, depending on the approach, could result in all changes to existing facilities being regulated under the Phase II existing facility rule regardless of the scope or nature of the change. EPA does not believe such an approach, or an approach under which EPA would establish a maximum limit on the increase in capacity or flow, is consistent with existing relevant NPDES regulations or the technology-forcing framework contained in the NPDES permitting portions of the CWA

EPA's definition of "existing facility" in this final rule reasonably balances the need of existing facilities to make changes with their ability, when changes are substantial, to upgrade to the level of best technology required at new facilities, while being consistent with existing regulations.

Option: Site-specific determination of BTA

RG&E supports the concept of site-specific evaluation and determination for implementing 316(b) regulations and reiterates comments of the Edison Electric Institute (EEI) in their 316(b) Phase II comment letter to docket:

"The single most important lesson learned from [these] 25 years of experience is that the site-specific variations in facility operations and affected ecosystems makes site-specific technology selection the most efficient and effective means of minimizing adverse environmental impact. A structured site-specific approach makes it possible to select and install the technology that maximizes the net benefits to society. EEI members maintain that a rule embodying such a structured site-specific approach represents the best approach to addressing any adverse environmental impacts that may result from the operation of cooling water intake structures at member facilities."

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Role of States and Tribes (alt./equiv. programs)

In Section VII.F. of the Supplementary Information of the proposed rule, EPA has invited comments on the role of "functionally equivalent" State programs in the implementation of these proposed regulations. RG&E strongly supports this concept of functionally equivalent programs and urges EPA to allow States maximum flexibility within their individual programs to achieve site-specific determinations of best technology available to minimize adverse environmental impacts. The State, as the primary stakeholder of its natural resources, is best suited to ensure the proper implementation of the proposed 316(b) concepts in a manner that conforms with the individual State's economic and environmental goals. For example, in New York State, the Department of Environmental Conservation is responsible for both fisheries management (within all waters of the State) and SPDES Permits, thus NYS fisheries management goals have always been considered in assessing power plant operations and associated impacts. This results in SPDES operating permit requirements which include minimizing intake impacts. RG&E believes that this approach has been successfully applied for nearly thirty years, and should be continued.

EPA Response

In today's final rule, EPA has provided for approval of State programs that meet specific requirements (125.90(d)). See response to 316bEFR.023.001 for details.

Option 3--Site-specific determination

Author Name Kevin Hylton

Organization Rochester Gas & Electric Corp

The EPA proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that impact the technical practicability of meeting the proposed standards. Specifically, the costs of compliance may exceed those anticipated by the agency. In those instances the proposal provides the facility with the opportunity to justify an alternative technology selection.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.064.009

Author Name Kevin Hylton

Organization Rochester Gas & Electric Corp

Subject Matter Code 7.01.03

Option 3--Site-specific determination

The EPA proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that indicate that the costs of meeting the performance standards are not warranted by the projected benefits at that facility. The rule allows facilities to select an alternative level of compliance in cases where the costs of compliance with the EPA's performance levels would be significantly greater than the expected benefits derived from achieving levels. This approach explicitly recognizes the site-specific variations in the ecology of source water bodies and can account for controls already in place at many facilities.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.064.010

Author Name Kevin Hylton

Organization Rochester Gas & Electric Corp

Subject Matter Code 7.02

Performance standards

The EPA proposal provides a flexible approach to compliance that allows facilities to meet the performance standards through a number of options, including creation or restoration of habitats and other non-traditional approaches. This does not freeze compliance in time by relying on today's technologies and allows for continued innovation in addressing the potential adverse environmental impacts associated with impingement and entrainment. This also leaves significant discretion in determining how best to comply with the standards to State permitting authorities and facilities managers who have developed extensive expertise on these issues.

EPA Response

EPA agrees with the commenter and has accorded considerable discretion to the Director in implementing the requirements of today's rule.

RFC: Appropriateness of "significantly greater"

Author Name Kevin Hylton

Organization Rochester Gas & Electric Corp

EPA's failure to define significantly greater for either of its cost tests creates unnecessary uncertainty in the rule.

EPA Response

See response to 316bEFR.006.003.

Comment ID 316bEFR.064.013

Author Name Kevin Hylton

Organization Rochester Gas & Electric Corp

Subject Matter Code 7.01.02

Option 2--Implement performance requirements

EPA should provide a much simpler implementation path for facilities that choose to install one of the EPA approved technologies. The EPA proposal does too little to reduce the costs of implementation for facilities and State permitting authorities. Much of the information necessary to implement a purely site-specific approach, (e.g., calculation of baseline losses, estimation of technology effectiveness, post compliance monitoring, etc.,) must be generated despite its not being used to improve the technology selection decision.

EPA Response

EPA agrees that streamlined implementation is a worthy goal and notes that facilities using approved design and construction technologies (such as a wedge-wire screen in certain freshwater river environments) may demonstrate compliance with the rule under § 125.94(a)(4) or may request that the Director approve additional technologies under § 125.99(b). Please refer to the response to comment 316bEFR.072.045 for more information.

Comment ID 316bEFR.064.014

Author Name Kevin Hylton

Organization Rochester Gas & Electric Corp

Subject Matter Code 10.1

General: cost tests

Rule must retain consideration of site-specific variations in cost. This is currently embodied in both the new facility standards and the proposed rule as a test of the cost of compliance against the costs considered by the Agency in establishing the standards. This is referred to as the cost-cost test. Rule should provide guidance on proper and reasonable interpretation of significance for the cost-cost test. The company suggests that to be deemed "significantly greater than," costs should not exceed the costs considered by the agency by some factor between zero and one. In no case by more than 100 percent of the cost considered by the Agency in establishing the standards as this would result in costs that were not only significantly greater but wholly disproportionate.

EPA Response

The cost-cost test is retained in the final rule. Therefore, this recommendation from the commenter has been met.

The Agency does not necessarily agree with the commenter’s assertion that costs exceeding 100 percent of the cost considered by the Agency should be termed “wholly disproportionate.” The Agency notes that the commenter provides no basis for this designation (neither anecdotal nor historical). Hence, the Agency prefers to differ to the Director applying the standard for their locality in order to determine what is “significantly greater.”

Comment ID 316bEFR.064.015

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

Rule must retain consideration of site-specific variations in benefits. This is currently embodied in the proposed rule to as a test of the cost of compliance against the expected benefits of compliance. This is referred as the benefit-cost test. The decision criteria for the benefit-cost test should be the maximization of net benefits.

EPA Response

EPA does not agree that decisions must be made based on maximization of net benefits in cases such as this where benefits cannot be completely monetized. For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Comment ID 316bEFR.064.016

Author Name Kevin Hylton

Organization Rochester Gas & Electric Corp

Subject Matter Code 21.05

Role of States and Tribes (alt./equiv. programs)

In order to reduce implementation costs, speed permitting and prevent unnecessary permit backlog for both facilities and the States, the EPA should allow State permitting agencies to waive the requirement for baseline monitoring, study and modeling for facilities that install or currently utilize any of the technologies referenced by the EPA in establishing the standards. Likewise, post-compliance monitoring should be limited to that which is necessary to demonstrate proper operation of the technologies.

EPA Response

Much flexibility has been added to today's final rule to assist in speeding implementation and reducing application burden. For example, under 125.94(b)(4), a facility may demonstrate that it has installed and properly operates and maintains an approved design and construction technology in accordance with 125.99(a) or (b); or the facility may install and properly operate wedgewire screens in accordance with 125.99(a). Under this compliance alternative, facilities only need to submit the Design and Construction Technology Plan (125.95(b)(4)(i)) and the Verification Monitoring Plan (125.96(b)(7)). Facilities may also opt to comply using the Technology Installation and Operation Plan (125.94(d)(1)) and/or Restoration Plan (125.94(c)) which allows a facility to comply with conditions of the respective plan in lieu of having compliance based on meeting performance standards (see section 9 of the preamble for more discussion). Under today's final rule, monitoring must be performed in accordance with the Verification Monitoring Plan, the Technology Installation and Operation Plan (125.95(b)(4)(ii)), as appropriate, and, if applicable, the Restoration Plan (125.95(b)(5)). Additional monitoring requirements may be specified the Director. EPA is also allowing the use of historical data where it is still reflective of existing conditions for use in baseline calculations. EPA believes that these measures, and other measures in the final rule, will provide flexibility for the facility and the Director.

Implications for nuclear facilities

Finally, with respect to impacts upon the Nuclear Industry and our Ginna Nuclear Power Station, RG&E supports the 316(b) Phase II Comments submitted by the Nuclear Energy Institute, and summarized below.

It is imperative that nuclear power plants be provided flexibility in how they meet Cooling Water Intake Structure (CWIS) requirements because costs for the nuclear industry will be higher for installation of new equipment/technologies due to a constant need for cooling water and to ensure that any changes do not adversely impact plant safety and increase the risk to the health and safety of the public.

The inclusion of 125.94 (f), which concerns the resolution of potential safety issues by the NRC resulting from 316(b) compliance, must remain in the rule to ensure that considerations of human health and safety of the people at and around nuclear power plants remain the paramount determining factor.

EPA Response

EPA has provided several different compliance alternatives that facilities can use to meet today's requirements in the most cost-effective way possible. In addition, EPA agrees with Rochester Gas and Electric Corporation on the importance of human health and safety considerations. Therefore, today's final rule allows for a site-specific determination of best technology available if requirements conflict with Nuclear Regulatory Commission safety requirements (see § 125.94(f)).

Comment ID 316bEFR.064.018

Author Name Kevin Hylton

Organization Rochester Gas & Electric Corp

Subject Matter Code SUP

General statement of support

Rochester Gas and Electric supports the U.S. EPA's overall proposal, though it believes that these regulations may be improved to provide an adaptable, technology-neutral, site specific approach that yields optimal, cost effective, and scientifically sound protection of the environment as indicated by the comments provided. With these improvements, EPA's proposed rule regarding Section 316(b) permitting can result in a consistent decision-making framework that continues to provide flexibility to the states.

EPA Response

Today's final rule maintains the desired flexibility for both the permittee and the Director to determine the most appropriate and cost-effective means for meeting the requirements of today's rule. EPA also notes that compliance alternative 5 allows a site-specific determination to be made based on cost-cost and cost-benefit considerations.

Monroe

It is not apparent to DE why the EPA selected the Monroe facility, along with some Ohio River facilities, as having cooling water intake structures (CWIS) that are presumably representative of all CWIS located on freshwater lakes and rivers, exclusive of the Great Lakes. (It should be noted that the Monroe facility is located at the confluence of the River Raisin and Lake Erie and while a portion of the cooling water flow is withdrawn from the River Raisin, the majority of the flow is withdrawn from Lake Erie.) The EPA does not describe the methodology (e.g., random or stratified sampling using variables such as capacity, intake design and/or data availability) used for selecting the facilities for case studies. Consequently, one has to question the appropriateness of the selection of Monroe as a case study facility if the basis is not known for its selection.

EPA Response

EPA based its use of I&E data for the Monroe facility and other facilities on a number of factors, including data availability and facility location in relation to other in scope facilities. However, EPA notes that it was unable to conduct statistically-based selection procedures such as random or stratified sampling due to the lack of I&E data for most of the over 550 facilities in scope of the Phase II rule. See also responses to Comment 316bEFR.072.055 on sample size and representativeness and Comment 316bEFR.041.041 on EPA's extrapolation approach.

Comments on Part I: Monroe Facility Case Study
EPA's Proposed Section 316(b) Phase II Rule

Chapter I1: Background

1. Each unit has three, not four, circulating water pumps.

2. The cooling water discharge does not empty into Plum Creek; rather it is discharged into Lake Erie via a discharge canal.

3. EPA identifies alewife and burbot as being "most frequently" impinged and entrained at the Monroe facility. However, alewife comprised only 0.001% of the University of Michigan (UM) impingement estimate (Jude et al. 1983) and 0.03% of the Michigan Department of Natural Resources (MDNR) impingement estimate (A. Nuhfer, unpublished data) and none were identified in the UM entrainment estimate (Jude et al. 1983). No burbot were identified in either impingement estimate and the species comprised only 0.06% of the entrainment estimate.

4. EPA lists species of special concern found in the River Raisin. It should be noted that none of these species are listed in EPA's Table I3-1: Species Vulnerable to I&E by Monroe.

5. Introduction of nonnative species. In addition to the zebra mussel mentioned in the case study, the round goby (Neogobius melanostomus), a species native to Eastern Europe, was discovered in Lake Erie in 1994 and has increased in abundance. This species is a threat to indigenous species as it displaces them from their habitat through competition for food and predation on eggs and young. Neither the UM study or MDNR study collected this species because they were conducted prior to its introduction.

6. Commercial fisheries. As indicated in Tables I1-4 and I1-5, total catch and total revenue were unusually high in 1985 because of the large harvest of gizzard shad. They were harvested to determine suitability for use as crayfish bait, a market that did not develop (Darl Komomy, commercial fisherman, personal communication). These fish were harvested in mid-winter (January-March) because Detroit Edison gave permission to seine at the mouth of the Monroe discharge canal that is ice-free and where shad are concentrated during winter. This catch would have been impossible under other circumstances. Therefore, 1985 should be excluded from estimates of annual average commercial catch (expressed either as pounds or revenue) for gizzard shad and the whole fishery (all species combined).

Chapter I2: Technical Description of Monroe

1. The capacity utilization values in Table I2-1 were recalculated (as capacity factors) using a net rated capacity of 750 MW for each unit as reported in EIA-860. The recalculated values are 71.0%, 55.3%, 72.4% and 79.9% for Units 1, 2, 3, and 4, respectively.

2. The heated water does not return to the River Raisin; rather it is discharged into Lake Erie via a discharge canal.

3. Operation of the fish pump and return system was discontinued in 2001 because of chronic fouling of collectors by zebra mussels.

Chapter I3: Evaluation of I&E Data

1. The EPA includes alewife in its evaluation of impingement and entrainment (I&E) data even though it comprises less than EPA's criteria of 1% of the total I&E estimates. (Alewives comprised only 0.001% of the TIM impingement estimate and 0.03% of the MDNR impingement estimate and none were identified in the UM entrainment estimate.)

2. While there is limited commercial harvest of adult gizzard shad, young-of-the-year shad are a major prey item for predator fish species, particularly the walleye. It is unclear why EPA has classified longnose gar as a forage species. It would be more appropriate to classify this species as recreational and commercial because of, albeit limited, harvests in these categories.

3. It should be noted that nearly one third of the UM estimate of gizzard shad impingement was based on a collection made during one unusual episodic event on December 13, 1982 when an estimated 1.3 million shad were impinged. Multiplying this estimate by 7 brought the estimated weekly total to 9.3 million. During the prior week an estimated 285,000 gizzard shad were impinged for a weakly estimate of nearly 2 million fish. The week following December 13 an estimated 438,000 fish were impinged for a weekly estimate of 3.1 million fish. Thus, because of the inclusion of this unusual episodic event data, the UM impingement estimate is not representative of annual impingement losses.

4. Most of the impinged gizzard shad do not represent power plant-induced mortality. Gizzard shad, primarily young-of-the-year (y-o-y), are subject to winter mortality when water temperature falls below 4 C (Miller 1961, flames 2000). Trautman (1981) reported that gizzard shad "winter-killed readily, especially the young". Most of the impinged shad are less than 1 year old (99%) and most of the impingement of fish subject to winter mortality (80%) occurs in December and January (Jude et al. 1983). Historically, condition of fish (e.g., live-dead ratios or other assessments) was not routinely assessed as part of impingement studies. However, White et al. (1986) noted that many of the gizzard shad impinged at some Ohio power plants were dying or dead. LaJeone and Monzingo (2000) reported that large numbers of gizzard shad were either dead or moribund prior to entrapment on the screens of a power plant on the Mississippi River. Assessment of the condition of impinged fish must be an integral part of all future studies.

5. Section I3-4 identifies white bass as one of four species that "dominated" impingement and entrainment collections. In fact, the related species, white perch, comprised a higher percentage of the impingement collections for the two studies. In the UM study nearly twice as many white perch were estimated to have been impinged than white bass, while for the MDNR study the white perch estimate was over four times greater. The investigators did not differentiate between the two species in the UM entrainment study. Also, the EPA combined the impingement estimates for the two species in Table I3-2 and identified the estimate as white bass. This is a noteworthy inaccuracy because the white perch is a less desirable recreational and commercial species.

6. In Section I3-4 EPA states that impingement rates are about 4-5 times the entrainment rates. In examining Table I3-10 only the age 1 equivalents and fishery yield for impingement have higher values than the corresponding entrainment values and the differences are 3 times and 2 times, respectively.

7. In Table I3-2 [impingement] EPA combines trout-perch with unrelated logperch and identifies the combined estimate as logperch even though the estimate for logperch was a fraction of the estimate for trout-perch. The UM estimate for trout-perch was over 13 times greater than the estimate for logperch and in the MDNR study the entire estimate reported in Table I3-2 was for logperch. The same misrepresentation error occurs in Table I3-6 [entrainment] where nearly four times as many trout-perch larvae were estimated to have been entrained as logperch. However, both species were considered forage so it appears that this error does not affect the overall valuation estimate.

8. In Table I3-3, EPA indicates in a footnote that the impingement losses expressed as age 1 equivalents are larger than the “raw losses” because the ages of impinged individuals are assumed to be distributed across the interval between the start of year 1 and start of year 2, and then the losses are normalized back to the start of year 1 by accounting for mortality during this interval. However, as indicated in the text and the length frequency distributions in the appendices of the UM report, the majority of fish for several of the major species (gizzard shad (99%), white perch (91%), white bass (94%) and walleye (95%)) were less than one year old. Thus the number of age 1 equivalents should be less, not more, than the “raw” numbers.

Chapter I4: Economic Value of I&E Losses Based on Benefits Transfer Techniques

Questions/comments 1, 2 and 3 were submitted to the EPA on June 4, 2002 by DTE Energy and on June 5, 2002 and June 11, 2002 (prioritized) by the Utility Water Act Group (UWAG). (UWAG’s submittals contained questions/comments from UWAG members, attorneys and consultants.) EPA sent responses to these questions to UWAG on July 2, 2002 (Appendix 1). These responses were considered unsatisfactory as they simply (1) restated what was already in the text of the Monroe facility case study and (2) in general, referred the reader to Chapter A5 with no further explanation.

1. Tables I4-2 and I4-3: The data in the column titled “Total Catch (#) appear to be harvestable catch data, but no explanation or reference is given to the source of the data.

2. Table I4-11: identify actual references in AFS (1993) from which came the “Hatchery costs ($/lb)”. Addendum: I also need to know where the EPA got the poundage for the three species that were multiplied times the hatchery costs to get the annual replacement costs.

3. Table I4-12: explain how this table was compiled, in particular, how the annual loss values were apportioned/calculated for each species. For example, how were the $673,405 and $1,133,734 low and high [production foregone] values, respectively, for whitefish derived?

4. Values of lost recreational and commercial yields because of impingement are overestimated. When estimates of the number of age 1 equivalent fish impinged at Monroe are corrected for predominance of fish less than 1 year old, estimated value of lost yield decreases dramatically. For example, the value of lost commercial yield of gizzard shad decreased from $203,222 to $71,146.

(Calculations used to revise the estimate of the value of lost yield of gizzard shad at the end of this section. The table summarizes the revision of the number of age 1 equivalent gizzard shad impinged.)

5. It is not appropriate to assign full value to lost yield for species like gizzard shad where lost yield (474,300 pounds, corrected for predominance of fish less than 1 year old) greatly exceeds annual harvest (9760 pounds, average excluding 1985 and years of no harvest). Commercial harvest of shad is not limited by yield (supply) but by demand which is low because of poor flesh quality.

6. Because whitefish larvae were collected on only one date and because juvenile and adult whitefish are not impinged at Monroe (Jude et al. 1983), presence of whitefish larvae in plankton is spurious. Additionally, it is unclear how an estimated annual entrainment of 190,000 whitefish (Table 13-6) results in an allocation that generates production foregone valued at $1.1 million (Table 14-12).

7. Additional comments on this chapter are provided in the report prepared by Resource Econometrics (Appendix 2).

Calculations used to revise the estimate of the value of lost yield of gizzard shad. Revision of the number of age 1 equivalent shad impinged is summarized in the table below.

[see hard copy for table]

EPA estimated that the number of age 1 equivalent shad impinged at Monroe was 34,323,242 (Table I3-3). Estimated lost yield to the commercial fishery was 1,354,816 lbs (Table I3-4). At $0.15/lb, lost yield was worth $203,222. Detroit Edison's corrected estimate of the number of age 1 equivalent shad impinged was 12,016,169. By proportion, this resulted in a lost yield of 474,305 lbs that at $0.15/lb, was worth $71,146. (If the $0.041 /lb reported in Appendix 2 is used this lost yield is worth $19,447.)

Chapter I5: Streamlined HRC Valuation of I&E Losses at the Monroe Facility.

1. The habitat-based replacement cost (HRC) analysis, particularly the "streamlined" version, is an unproven methodology for monetizing I&E losses. RRC was originally devised to monetize habitat damage/loss. Its application to I&E is a stretch that goes something like this. There is a need to address impacts beyond reductions in yield, particularly the very nebulous "ecological services" provided by fish (see also Comment 5, below). Ecosystem services are by-products of energy flow and material cycling that are habitat/ecosystem based. Therefore, to provide ecosystem services suitable habitat is required. EPA treats HRC analysis as though its validity is self-evident even though the appropriateness and/or efficacy of HRC has not been demonstrated for monetizing I&E losses.

2. Choosing shoreline wetland as the basis for the Monroe HRC analysis was arbitrary. No documentation (peer-reviewed scientific publications) was offered to support this decision. (This exemplifies the overall lack of credible information needed to conduct an HRC analysis despite EPA's repeated assertion that such information is readily available.) By choosing a single habitat type to estimate replacement cost, EPA assumes all species have the same habitat preferences/requirements. Absent documentation, this choice also assumes shoreline wetlands contribute substantially to recruitment of all species. Neither of the latter two assumptions can be verified with appropriate documentation (peer-reviewed literature). A "complete" HRC analysis may

have identified more appropriate alternatives.

3. Estimated annualized HRC at Monroe was $1.1 -14.4 million with a total cost of $22-288 million (20 year amortization). This is the estimated cost of constructing enough shoreline wetland to offset 50-90% of I&E. Replacement of 100% would require construction of 26,900 acres of wetland at a total cost of $828 million. This amount of wetland (41 square miles) would double the amount of wetland in U.S. waters of Lake Erie and is equivalent to a band (100 yards wide) extending 726 miles around the 860 mile long shoreline of Lake Erie. The large amount of wetland needed to replace 100% of I&E strongly suggests that the required mitigation was overestimated.

4. Large areas of wetlands are needed to replace species that arc abundant in I&E and uncommon or rare in wetlands. Low abundance in wetlands most often reflected preference for other habitats (e.g., logperch, trout-perch, smelt, gizzard shad, walleye and small mouth bass). EPA made no effort to take into account that shoreline wetlands were not suitable habitat for these species. By failing to do so, the high estimated cost of replacing I&E becomes an important driver of proposed reductions in I&E.

5. Part of the rationale for HRC was the perceived need to monetize, among other things, the "ecological services" provided by fish. Worldwide ecosystem services are valued at $33 trillion per year. Contributions of Lake Erie and adjacent wetlands to worldwide services were estimated based on the contribution of lakes/streams and swamps/marshes to annual worldwide net primary production and on area of Earth's surface these habitats/ecosystems represent (Table 1). This assumes ecosystem services are by-products of ecosystem processes like primary production. Estimated value of ecosystem services from lakes is $196/acre and from wetlands $1571/ acre (Table 1). If the contribution of fish to system energy flow is 10%, then services provided by the whole fish fauna are worth about $20/acre in lakes and $157/acre in wetlands. If I&E resulted in a 15% reduction in fish stocks, the value of lost ecosystem services is $3/acre in lakes and $24/acre in wetlands. This exercise demonstrates that HRC greatly exaggerates valuation of ecological services provided by fish.

[see hard copy for table]

Table 1. Area, annual net primary production and estimated value of ecosystem services (expressed three ways) for two habitats/ecosystems and the whole Earth (i.e., biosphere).

6. EPA does not provide any guidance on a verification program for habitat restoration plans.

Chapter I6: Benefits Analysis for the Monroe Facility

The errors noted in the other chapters will require revisions to the values reported in this chapter.

Chapter I7: Conclusions

The errors noted in the other chapters will require revisions to the values reported in this chapter.

Additional Comments

1. A societal benefit that has been established at the Monroe facility is the recreational fishing that occurs in the warm water discharge canal. Since the plant began commercial operation, the discharge canal has been accessible to boat anglers. In 1997 ten fishing piers were built to provide access from shore for fishing. The piers proved to be so popular that the Michigan Department of Natural Resources requested that the seasonal access to the piers be increased. The company agreed to the increase.

2. KJ. Hartman stated in his comments on the proposed rule (prepared for UWAG) that productivity in Lake Erie has declined due to nutrient abatement activities in the mid-1980's and invasion of the lake by zebra mussels in the late 1980's and 1990's. As a consequence, there has been a decline in fish production and thus a reduction in the availability of fish to I&E. This trend is contrary to EPA's assertion that improvements in water quality have resulted in increases in fish populations and thus increases in I&E since the period when many of the original I&E studies were conducted.

Conclusions

The Monroe case study is offered as a "science-based" assessment of the value of impingement and entrainment (I&E) losses at the plant. Ostensibly the large monetized values of I&E at Monroe (and the Ohio River facilities) projected to estimate the value of I&E losses for all cooling water intakes located in freshwater (exclusive of the Great Lakes), inappropriately provides strong support for proposed reductions of I&E.

I&E were monetized using two basic approaches. Valuation based on the benefits transfer technique quantified losses in terms of impacts on commercial and recreational fisheries and included assessment of non-use values of fish and impacts on forage species that support predator stocks. Using this, more or less, traditional method, estimated annualized value of I&E losses was $800,000-3.2 million. Revisions suggested in comments presented in the foregoing sections would reduce this estimate substantially.

Valuation of I&E was also based on estimation of habitat-based replacement cost (HRC). Application of HRC analysis to monetize I&E losses is new. There is no indication that this method was subject to peer-review prior to publication of the Phase II Rules (Chapter All of the case study document). Moreover, no peer-reviewed documentation based on field study is provided to validate this method. The failure to provide objective valuation-of HRC is important because the estimated annualized value of I&E losses at Monroe was $1.1 -14.4 million. Because valuation based on HRC was greater than valuation based on the benefits transfer technique, HRC also becomes the basis for estimating the benefits of reduced I&E at Monroe and possibly other cooling water intakes in freshwater locations, including the Great Lakes basin.

In this case study, I&E were used directly to monetize impacts. This deviates philosophically from traditional environmental impact assessments where the impacts of I&E are recognized primarily by quantifiable reductions in fish stocks. This latter approach recognizes that the rapid renewal capacity of resources like fish can mitigate losses like I&E. EPA made no attempt to assess impacts of I&E on fish stocks in Lake Erie.

Fish populations exhibit considerable capacity to offset natural and anthropogenic mortality. If they did not, even small increases in mortality from angling would cause population extinction. When mortality increases, population size is maintained by compensation. Compensation is an increase in recruitment (addition of sexually mature individuals to population) mediated though changes in life-history parameters such as survival rate, growth rate and age at maturation. Ability to adjust life-history parameters, called compensatory reserve, is not unlimited and varies among species. Increased mortality causes reduction in population size only after compensatory reserve is depleted. There is no evidence that I&E has depleted compensatory reserve or reduced fish stocks in Lake Erie.

EPA avoided consideration of compensation in this case study. (Compensation is only mentioned briefly in regard to life history parameters (Chapter A5-2.3)), This is unfortunate because compensation is not only an integral part of environmental impact assessment but also a mechanism for assessing whether reduction of I&E by intake modification or mitigation of I&E by habitat construction will achieve desired results. Considering the cost involved, some assessment and assurance of efficacy appears warranted.

EPA Response

The Background chapter and Technical Description of the facility are no longer included in EPA's final analysis or the Regional Analysis Document (DCN # 6-0003) presented in support of the final rule.

Regarding I&E estimates for Monroe, these data are used only as part of the total Great Lakes regional I&E estimate and are not used for a facility-specific estimate. A total of 3 facilities were used to estimate I&E in the Great Lakes. Please see response to Comment 316bEFR.041.041 for a discussion of EPA's regional extrapolation approach.

Regarding benefits transfer, please see EPA's response to Comment 316bEFR.075.504.

For information on replacement costs and the HRC method and its uses, please refer to EPA's responses to Comment 316bEFR005.035 and Comment 316bEFR.029.113 and the document entitled "Habitat-based Replacement Cost Method" (Docket #6-1003).

Regarding compensation, please see EPA's response to Comment 316bEFR.025.015.

DTE Energy Questions

1. Chapter I4 of Part I of the Case Study Document (DCN 4-0003) refers the reader to Section I3-4 of Chapter I3 for data sources. The chapter also explains that foregone recreational yield in pounds was converted to numbers of fish for valuation purposes. Details on how yield in pounds was derived from annual I&E loss rates are provided in Chapter A5 of Part A of the Case Study Document (DCN 4-0003).

2. All AFS (1993) values are derived from a 1989-1990 survey of public, private, and tribal hatcheries.

3. The methods for converting forage species to species which may be commercially or recreationally valued are described in Chapter A5 of Part A of the Case Study Document (DCN 4-0003).

4. This question is in the nature of a comment on the record or the proposed rule. EPA will address this question in its responses to public comments if it is included in public comments on the proposal.

DTE Energy Questions – Monroe Case Study

1. Tables I4-2 and I4-3: The data in the column titled "Total Catch (#) appear to be harvestable catch data, but no explanation or reference is given as to the source of the data.

2. Table I4-1l: identify actual references in APS (1993) from which came the "Hatchery costs ($/lb)". Addendum: 1 also need to know where the EPA got the poundages for the three species that were multiplied times the hatchery costs to get the annual replacement costs.

3. Table I4-12: explain how this table was compiled, in particular, how the annual loss values were apportioned/calculated for each species. For example, how were the $673,405 and $1,133,734 low and high values, respectively, for whitefish derived?

4. Is implementation and verification of the HRC methodology, particularly the "streamlined" version, practical? Combining steps 2 - 4 and limiting the data gathering raises some real concerns about the credibility of, essentially, an unproven methodology

EPA Response

1) See response to comment 316bEFR.041.824 on Tables I4-2 and I4-3.

2) See response to comment 316bEFR.041.825 on Table I4-11.

3) The valuation methods used to generate this range were not used in EPA's analysis for the final

Phase 2 rule.

4) The HRC method was not used in EPA's analysis for the final Phase 2 rule. For additional information, please see the document entitled "Habitat-based Replacement Cost Method" (DCN# 6-1003) and EPA's response to Comment 316bEFR.005.035.

Organization Great River Energy

Subject Matter Code 10.07.02
RFC: Appropriateness of "significantly greater"

"Significantly Greater":

The proposal provides for a site-specific determination of the "best technology available" if the costs of compliance at a site would be "significantly greater" than either the benefits of meeting the performance standards or the cost of what the agency considered. EPA must provide a clear definition of what is meant by "significantly greater." To maximize net benefits to society, economic theory would dictate that this should be interpreted to mean any cost benefit ratio greater that 1:1. This reflects the most cost-effective, performance-based outcome.

EPA Response

RFC: Use of previous demonstration studies

Application to Existing Facilities:

The proposal should include a process for approving existing intake technologies as "best available" if it can be shown that the facility is not causing adverse environmental impact or the technologies have been deemed "best available" by the state. Such a process is reasonable since Section 316(b) has been in effect since 1972 and has been implemented case-by-case at many sites. There are many electric generating facilities for which there is already a high degree of confidence that the facility is not causing adverse environmental impact or that it has already installed the best technology available. In addition, if the facility has data indicating that the amount of entrainment and impingement is so small that there is no significant harm to the aquatic community or the environmental impact is of so little economic and environmental significance that the costs of a comprehensive 316(b) study would be significantly greater than its benefits, then there should be no need for either further studies or for additional intake technology.

EPA Response

Performance standards

Compliance Assessment:

Since there is such variability in biological systems, it is not practical to require the permittee to meet a specific numerical reduction in affected organisms. The proposed performance criteria should not be directly implemented as enforceable permit limitations. Rather, when the existing technology is not the "best available", the permit should require the installation of technology identified collaboratively by the permittee and the state. Then compliance with the permit would be based on installation, operation and maintenance of the selected technology.

EPA Response

Permit applications/implementation schedule

Author Name Erik Silvola

Organization Great River Energy

Compliance Timelines:

Some consideration should be given to facilities currently engaged in the re-permitting process. Again due to the variability of biologic systems in terms of weather cycles, seasonal changes, population dynamics, and a host of other factors large amounts of data over significant periods of time are required to establish baseline conditions. Those facilities currently engaged in re-permitting may not be able to supply adequate data to determine a baseline reflective of current conditions for use in determining the "best available" technology at the time of permit renewal.

EPA Response

In recognition of the situation described by the commenter, EPA has clarified timing requirements for the submittal of the required studies. See response to comment 316bEFR.034.066 for a discussion.

Subject Matter Code 17.08

Option: UWAG's recommended approach

Framework of EPA's proposed rule. As stated above, NRECA supports the approach UWAG advocates for the 316(b) regulations. UWAG's stresses that the regulations must be site-specific, and that they should apply only if a facility's cooling water intake structure (CWIS) is having an adverse environmental impact. UWAG has outlined a detailed regulatory proposal that we believe would be the optimum way to structured these regulations. It would provide real environmental protection, economically, without imposing undue administrative burdens on regulatory agencies or on permittees. An important benefit of the UWAG approach is that it uses a risk management approach to quickly identify facilities that are not having a significant adverse environmental impact allowing them to be removed from further consideration. NRECA strongly advocates the UWAG approach rather than the framework EPA has proposed.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Subject Matter Code 7.01

RFC: Three-option framework for determining BTA

Author Name James F. Stine

Organization National Rural Electric Cooperative Association

However, NRECA appreciates the efforts EPA has made to propose a regulation that has many favorable aspects to it. While it may not be the best approach, EPA's approach could be workable if certain modifications as suggested by UWAG and NRECA are adopted. The overall framework of EPA's proposal is good. In particular it allows a cost benefit test to insure that appropriate technology is identified as the "best available". However, in contrast to the UWAG approach, many facilities that are not having an adverse environmental impact will still have to incur significant costs to gather data and to develop certain studies (the costs of which EPA underestimates considerably). The UWAG proposal, using sound scientific principles and an environmentally protective approach, helps insure that facilities that are not having an adverse environmental impact are removed from the process, thereby reducing study costs and easing administrative burdens. If EPA decides to adopt the rule framework as proposed in the Phase II regulations, then NRECA urges EPA to make the modifications detailed in the UWAG comments as well as those suggested by NRECA below.

EPA Response

Please refer to the preamble for a discussion of the framework of today's rule. EPA appreciates the commenter's support of the regulatory approach in the proposal, and notes that the final rule uses a similar approach, including the use of a cost-benefit test.

EPA disagrees, for the reasons set forth in the preamble and elsewhere in the record to the final rule, that a determination of whether an adverse environmental impact is occurring is a preliminary step in implementing 316(b).

Performance standards

Author Name James F. Stine

Organization National Rural Electric Cooperative Association

Performance criteria. NRECA believes that EPA's proposed performance criteria would not be suitable for direct insertion into NPDES permits as enforceable limitations. Biological populations are extremely variable, temporally and spatially, and technologies are simply not capable of providing the extremely high levels of control that would be necessary (on a daily basis, for example) to insure full time compliance and to avoid penalties including possible imprisonment for violating limits that were directly based on the performance criteria. That is not to say that the performance criteria can serve no useful purpose or that it is impossible to identify technologies that can meet the criteria on a long term basis.

NRECA believes that EPA has correctly determined that certain technologies (i.e., wedge-wire screens, aquatic fabric filter barriers, fine mesh traveling screens with fish returns, and barrier nets) are highly effective and produce significant reductions in impingement and entrainment in some cases. Those technologies cannot be applied in every case, however. Even where they can be applied, they may not achieve the ambitions reductions EPA anticipates in all cases.

Thus, the performance criteria should be bench-marks for the permittee and their states to use to identify the appropriate technology or combination of technologies, operational measures or mitigation that must be applied at a particular site. The installation of the technology or other agreed upon control strategy should be the permit requirement, not the performance criteria. Then, if necessary, this can be followed by an extended period of performance monitoring (to account for natural variability) with the recognition that more may need to be done if the approach selected is insufficient. Also, this can only -work if EPA retains the site specific cost/benefit test for technology selection as currently proposed in the rule.

In short, if EPA implements the regulatory framework they have proposed, they should structure the rule to insure that the most effective and economical (cost beneficial) technology is identified and implemented at each particular site -- and this could include in-place technology The "effectiveness" of the technology would be judged against the performance standards EPA has established.

EPA Response

EPA agrees with this comment and others like it. While EPA has retained the national performance standards in the final rule and continues to believe they reflect levels of reduction that can be achieved using available, practicable technologies, EPA also recognizes that it could be difficult ensure consistent attainment of those standards because of the type of variability the commenter describes. Because failing to achieve compliance with a numeric permit limitation customarily subjects a NPDES permittee to civil or even criminal penalties and performance standards are expressed in relation to the ambient environment, EPA has decided to authorize a Technology Installation and Operation Plan to be used, at the Director's discretion, as a compliance strategy for meeting the requirements of today's rule.

Performance standards

Baseline for assessing performance. If EPA decides not to use the performance criteria as enforceable permit limitations but rather as federal criteria that the permittee and their state use to select the best technology for a site, the rule will be much easier to implement. This approach will relieve problems associated with establishing a baseline or a point of reference for measuring attainment of the criteria. If the criteria are enforceable permit limitations, the issue of what levels of entrainment and impingement the criteria are measured against will be critically important. However, NRECA's members have strong concerns about how the theoretical performance of a non-existent intake structure could be assessed with the degree of accuracy necessary for anchoring enforceable performance criteria.

However, using the criteria as a basis for selecting technology would greatly relieve these problems. As long as permit limits are not an issue, in many cases, one could simply assume (as EPA has suggested in discussions) that the level of protection of the baseline facility is zero. By using zero for the baseline, the state and the permittee could focus directly on the more straight forward problem of identifying the technology needed to -bring current performance up to the levels required by EPA. If a permittee wanted to take credit for in-place technology, only then would he have to do a performance study. And in this instance he would be studying existing technology and would not even have to do the study unless the credit for in-place technology was likely to outweigh the study costs.

EPA Response

For discussions on the basis for and implementation of the calculation baseline, please see response to comments 316bEFR.308.014 and 316bEFR.063.022, as well as the preamble to today's rule.

Definition: Waters of the U.S.

Cooling Lakes and Ponds. EPA should exclude ponds or lakes created specifically for cooling purposes from the definition of “Waters of the United States.” This is an important issue for many of NRECA’s members. We refer EPA to UWAG’s discussion of this issue in their comments on the Phase II rule. NRECA is not aware of any significant CWIS impacts on cooling lakes or ponds. Further, as UWAG points out, cooling lakes and ponds are treatment systems. They should not be considered “Waters of the United States”.

Even if cooling ponds and lakes are not excluded as treatment systems, EPA should consider them closed-cycle cooling systems that satisfy § 316(b). In the rule, EPA states that one can meet the entrainment and impingement standards if you “reduce your intake capacity to a level commensurate with the use of a closed-cycle, recirculating cooling system.” EPA defines a closed-cycle recirculating system as a system with minimized makeup and blowdown flow that (usually) sends the water to a cooling canal or channel, lake, pond, or tower (67 Fed. Reg. 17130 col. 2). EPA uses wet cooling towers or ponds as examples of recirculating wet cooling systems (67 Fed. Reg. 17142 col.2, 17154 col. 3, italics added).

Many of NRECA’s members use cooling lakes or ponds; some specifically constructed to achieve compliance with NPDES permit requirements (for heat discharge) obviating the need to install cooling towers to reduce heat loads. There are many similarities between cooling lakes / ponds and cooling towers. Both are intended to reduce heat loads to the environment, both recirculate the cooling water and thereby withdraw less water from off-site water resources than comparable once-through designs. Plants that already have cooling towers satisfy the new regulations if they can demonstrate that they already meet the performance requirements in the regulations (although EPA needs to clarify how this demonstration would be made). NRECA believes that whether or not they are considered “Waters of the United States”, plants with closed, recirculating cooling lakes / ponds (allowing for a limited amount of make-up and blowdown) should also be considered to satisfy the 316(b) requirements.

Subject Matter Code 14.01

RFC: 5% threshold and supporting documents

Flow Threshold. If a facility's flow is greater than 5% of the mean annual flow of a freshwater river or stream, it must meet the 60-90% entrainment reduction standard. NRECA believes that the threshold should apply to both impingement and entrainment. That is if the facility withdraws less that the threshold amount, the Section 316(b) requirements should not apply. Several of NRECA's facilities are located on very large rivers, including the Missouri. One facility withdraws less than even 1% of the river flow. Even when the intakes are near the 5% threshold, we do not see evidence of adverse effect on aquatic life in the river.

NRECA believes the threshold, whether it is 5% or larger, should be based on the mean annual flow of the river or stream, as proposed. Moreover, if at a particular site a facility withdraws more than 5% but is demonstrably not causing adverse environmental impact, the permit writer should be allowed to establish that whatever percent of the river or stream is withdrawn, the § 316(b) requirements do not apply.

EPA Response

EPA believes it has presented ample evidence demonstrating a significant decrease in the level of entrainment when intake flow is minimized in relation to the flow of the source waterbody. The documents DCN# 2-013L-R15 and 2-013J support the proposition that flow is related to entrainment. EPA believes the intake capacity standard established under today's final rule minimizes the entrainment impacts of cooling water intake structures. See also the preamble to today's final rule for a discussion of site-specific determinations and other compliance alternatives.

EPA disagrees that the 5% flow threshold should apply to impingement standards as well. Rates of impingement, although influenced by cooling water withdrawals, are not as directly attributable to percentage flows as are rates of entrainment.

Subject Matter Code 21.01.01

Source water physical data

Spatial Extent of Biological Studies. Section 122.2 1(4) describes the Source Water Baseline Biological Characterization Data and says, “This information is required to characterize the biological community in the vicinity of the CWIS”. It also notes that this information can be used later to determine if the Design and Construction Technology Plan “should be revised”. EPA adds that, “The study area should include, at a minimum, the area of influence of the cooling water intake structure,” The phrase “in the vicinity of” is also used in the Comprehensive Demonstration Study, Section 125.95 (b)(3)(ii)…"a description of the abundance and temporal/spatial characteristics [of species] in the vicinity of" the CWIS.

NRECA is concerned about how the phrase "in the vicinity of" will be interpreted. We believe EPA should clarify that under the rule framework EPA has proposed, it is up to the permittee to decide on the appropriate spatial extent of the required studies.

Especially when biological populations are reasonably discrete (such as in a lake or isolated water body) a permittee should be allowed to put entrainment and impingement data collected around his intake in context with larger populations in the waterbody itself. However there may be times when a simple characterization within, say, the “hydrological zone of influence” would be sufficient and more cost effective than extensive population studies. EPA should make it clear that it is up to the permittee to decide on an appropriate extent for these studies.

EPA Response

EPA believes that the Director is best suited to define the scale of studies. The facility may propose a study scale in the Proposal for Information Collection and include a rationale for the scale. However, the Director will have the final determination on the scale of studies including defining the phrases "in the vicinity of" and "the hydrological zone of influence" as necessary.

RFC: Will I&E study supply sufficient information?

What Species Must Be Studied. The proposed rule says that you must reduce impingement mortality and entrainment of "all life stages of fish and shellfish." "All life stages" are defined to mean "eggs, larvae, juveniles, and adults." But the proposed rule is largely silent as to whether this means all species present at the site, or a smaller set of 'representative' species, as industry has recommended. It is clear that we will have to address impingement mortality and entrainment of "species of concern," including any species that is designated as such by a fish and wildlife or environmental agency, and we will have to be concerned about disrupting the migration path of migratory species. Also, EPA's proposal says, with respect to monitoring, that companies will have to take enough samples to give an accurate representation of losses for "all commercial, recreational, and forage-based fish and shellfish species and their life stages" (preamble p. 117). Within these constraints, companies should be required to study only a limited set of representative and important species in the waterbody as agreed to by the state and the permittee. Otherwise the requirement would simply be too open-ended. Please refer to UWAG's more detailed comments on this issue.

Definition: Waters of the U.S.

Cooling Lakes and Ponds

EPA should consider cooling lakes and ponds to constitute a treatment system, and not "waters of the United States". Even if EPA decides not to designate them as treatment systems, EPA should determine that such a cooling system constitutes a "closed-cycle recirculating cooling system" and is therefore exempt from the 316(b) rules.

EPA Response

Definition: Waters of the U.S.

Cooling Lakes and Ponds

In certain cases, a fishing, boating and recreational resource is present only because a dam and reservoir were constructed for cooling purposes. The fish population and diversity in such an established reservoir generally greatly exceed what was present before a reservoir was created. The impacts of impingement and entrainment in these settings is minimal compared to the overall benefit the facility has on the fishery.

To conduct costly studies to gather data on such reservoirs is unwarranted. Likewise, to assign costly retrofits in these settings because the structure itself may not meet "best available technology" is not warranted.

EPA Response

See responses to 316bEFR.006.001 and 316bEFR.063.011. See also the preamble to the final rule regarding site-specific and other compliance alternatives.

RFC: Cost: benefit ratio for site-specific BTA?

Cost-Benefit Test

A cost-benefit test is the key to successful implementation of this rule. Specifically, a “site specific” cost benefit test would allow facilities and their permit writers the flexibility to choose the alternative that provides the greatest net benefit at each individual facility. Barring that, facilities should be allowed to choose an alternative approach to the “significantly greater than” test if they can demonstrate that the net benefit would be greater than meeting the levels presented in the rule. If EPA adopts their framework as proposed, rather than including a site-specific approach, it is essential that this test be included in the final rule and given the same significance it has in the proposed rule.

EPA Response

EPA has included a specific-specific compliance option based on cost-benefit considerations. For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Option: Site-specific based 1977 Draft Guidance

EPA's Attempt to Cover All Situations with a "One-Size Fits All" is Costly

In EPA's attempt to cover all situations regarding cooling water intake structures (CWIS) with a broad sweeping, one-size fits all rule, the result will be a more complicated and costly program to State agencies, utilities, and their customers. Just as there are many types of aquatic ecosystems in the U.S. waters, so are there different CWIS. One-size does not fit all.

A structured, site-specific approach is the only way to accurately choose the best technology for each CWIS. Many states have existing programs, which should be utilized by EPA to provide the greatest amount of protection, while implementing the best technology for each site. EPA should not try to rewrite what the States have already accomplished. Rather, they should codify that expertise into a flexible system that will meet all needs. Revamping the entire program would be very costly to State agencies.

Sound science is also necessary for complete evaluation of each site. Not all sites have the same potential for impact on aquatic life. This is yet another reason why a site-specific approach is the best approach.

The 1977 Draft Guidance for Evaluating the Adverse Impact of Cooling Water Intake Structures on the Aquatic Environment: Section 316 b) P.L. 92-500 (US. EPA, 1977) states that the best technology available for intake design, location, construction, and capacity must be made on a case-by-case basis. This is stated in the proposed rule's Preamble.] This Draft Guidance should be the basis for the 316(b) Phase II requirements. Since each state may have very different water issues based on climate and other water uses, the States have more knowledge of what is needed to protect the aquatic environment in their particular region. One-size-fits-all may be the easiest approach, but the costs will most likely not justify the benefits to the environment.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Performance standards

Compliance Assessment

Since there is such variability in biological systems, it is not practical to require the permittee to meet a specific numerical reduction in affected organisms. The proposed performance criteria should not be directly implemented as enforceable permit limitations. Rather, when the existing technology is not the “best available”, the permit should require the installation of technology identified collaboratively by the permittee and the state. Then compliance with the permit would be based on installation, operation and maintenance of the selected technology.

EPA Response

Author Name John W. Dwyer

Organization Lignite Energy Council

Subject Matter Code 3.06.01

Withdrawal threshold of 50 MGD

De minimis Criteria

The preamble (pp 17162) refers to comments by Utility Water Activities Group (UWAG) regarding "use of de minimus criteria to exempt small cooling water users that pose no appreciable risk of causing adverse environmental impact because only a small amount of cooling water is withdrawn from a water body at a location that does not require special protection".

The LEC concurs that certain small volume cooling water intakes at locations not requiring special protection should be exempted. It would be appropriate to apply de minimus criteria to other small volume cooling water intakes which are present at a facility that has at least one cooling water intake structure with a design intake capacity of 50 MGD. Some facilities have smaller cooling water intakes that would be regulated by the Phase II rulemaking only because they exist at a facility that has one with over 50 MGD capacity.

The Phase I rule established requirements applicable to the location, design, construction, and capacity of cooling water intake structures at new facilities that withdraw at least two million gallons per day. The LEC suggests that facilities regulated by Phase II that have intakes with less than two million gallons per day capacity be exempt from the Phase II regulations.

EPA Response

Today's rule is applicable to facilities that, among other criteria, have a total facility capacity of 50 MGD or more and are classified as a point source discharger and either have, or are required to obtain, an NPDES permit. A facility subject to the NPDES program is considered in its entirety, not as the commenter suggests in a piecemeal fashion. Therefore, today's rule does not exempt small volume intakes from 316(b) regulations, if those intakes are part of a facility that meets the criteria of a Phase II existing facility. Facilities will be able to propose to their Directors for review and approval, technologies and operational measures they have in place and/or have selected to meet the requirements in § 125.94 as part of the Design and Construction Technology Plan. Therefore, a facility may propose technologies or operational measures that are appropriate for each of its intakes, for review and approval by the Director. Please see the final rule preamble for an explanation of how the Phase II final rule is applied to facilities, and what constitutes a "Phase II existing facility."

Organization Lignite Energy Council

Subject Matter Code 3.04.01

RFC: Application to "unique" facilities

EPA Lacks Authority to Apply 316(b) to Facilities Subject Only to a NPDES Storm Water Permit

EPA is proposing to apply section 316(b) to all facilities that are covered by NPDES permits, including those subject only to NPDES storm water permits. The Federal Water Pollution Control Act Amendments Section 316 Thermal Discharges paragraph (b) states the following:

"Any standard established pursuant to section 301 or section 306 of this Act and applicable to a point source shall require that the location, design, construction, and capacity of cooling water intake structure reflect the best technology available for minimizing adverse environmental impact."

Section 301 establishes the requirement for adoption of effluents limitations for all point sources. Section 306 establishes requirements for best demonstrated control technology and a list of source categories that must comply with standards of performance for new sources within the category. Those standards were subsequently adopted and implemented as the Steam Electric Point Source Effluent Guidelines in 40 CFR Part 423.

Thus, the 316(b) requirements apply to only to those facilities that are subject to sections 301 and 306 and not to facilities that are required to have storm water permits under section 402.

Furthermore, the LEC does not believe that EPA has the authority under section 402 to issue a general NPDES permit that would include Section 316(b) requirements. Nor does it have the authority to amend existing individual or general storm water permits to include section 316(b) requirements without amending the storm water rules and corresponding permit requirements.

EPA Response

See responses to 316bEFR.035.001 and 041.127.

Author Name John W. Dwyer

Organization Lignite Energy Council

Subject Matter Code 7.02

Performance standards

EPA's Operational Performance Standards Penalize Certain Geographical Regions

EPA is proposing to establish performance standards in section 125.94(b) that would offer facility owners several options for compliance including the option to reduce "intake capacity to a level commensurate with the use of closed-cycle, recirculating cooling system;.. ."

The LEC is concerned that the existing performance standard does not offer sufficient latitude to accommodate all closed-cycle, recirculating facilities in all geographical regions. Some facilities that are located in more arid regions have on-site cooling ponds and pumping facilities that are designed to appropriate large amounts of water from waters of the U. S. over a limited time period (for example, during spring run-off). Such facilities have a higher pumping capacity, but the pumps would operate for only a portion of any calendar year.

States have considered and mitigated possible impacts by limiting pumping based on site-specific permit conditions.

It is unreasonable for EPA to establish performance standards based strictly on an intake capacity comparison with closed-cycle, recirculating cooling systems while ignoring the annual amount of water pumped.

EPA Response

EPA believes the compliance alternative allowing a facility to demonstrate a flow reduction commensurate with a closed-cycle system is reasonable and expansive enough to address the situation discussed by the commenter.

Brayton Point

Production foregone or biomass lost due to impingement and entrainment (I&E) is a critical component of USEPA's analysis and plays an important role in USEPA's justification of the proposed 316(b) rule for existing facilities. One of the case studies used by USEPA is the Brayton Point Station. PG&E NEG and its consultants recently completed their own detailed analysis of production lost due to I&E at the Brayton Point Station in support of a permit application. USEPA states they got much of the biological information they used to compute production lost from the documents prepared and submitted by PG&E NEG.

PG&E NEG and its consultants who prepared the documents relied on by USEPA carefully reviewed the production lost calculations performed by USEPA for the Brayton Point Station Case Study. Based on correspondence with USEPA and attempts to reconstruct USEPA's results, PG&E NEG concludes that USEPA made two major errors in their calculations of production lost. The errors by USEPA resulted in production lost estimates being overestimated for 14 of the sixteen fish species analyzed. For several species, USEPA's estimates of production lost were hundreds of time higher than the correct values.

Production lost is commonly used to quantify the losses due to I&E. Production is addition of biomass to the population. Biomass at any given time is the sum of the weights of all individuals alive at that time. Because the weights of all individuals at a given time are often not known, biomass is often computed as the number alive times the mean weight of an individual. Production is the rate at which biomass is added to a population, and is the net result of individuals dieing over time while surviving individuals increase their body weight. Production forgone or lost is the amount of biomass that would have been added to the population if the individuals had not been entrained or impinged. These individuals would have grown in body weight, while eventually dieing from other causes. There is a well-known formula for taking the numbers of individuals entrained or impinged of a given age class or life stage, and computing the future production of these individuals over their life time Unfortunately, USEPA incorrectly implemented this formula.

The production lost formula uses information on the initial biomass of individuals and on growth and mortality rates. USEPA made two mistakes in their implementation of the production lost formula. The first mistake arose because US EPA used mean weights of individuals at the midpoint of life stages to compute the growth rate used in the formula, and used midpoint weights to compute initial biomass. The correct use of the formulas compute growth rate from the initial and final weights of the life stage, and use initial weight of the life stage to compute initial biomass. USEPA's implementation of the production lost formula is biologically wrong and mathematically incorrect. The second mistake made by USEPA was their estimates of mean weight at the midpoint of early life stages were too heavy, sometimes thousands of times too heavy, for many species.

The combined effect of these two errors by USEPA is frequent overestimation, sometimes by hundreds of times, of the production lost due to I&E for the Brayton Point Case Study. USEPA must reevaluate its production lost calculations and mean weights, replace their existing estimates of production lost with correct values, and determine how the revised estimates affect the 316(b) rule.

EPA methods: age 1 equiv, yield, prod foregone

Review of EPA's Application of Production Foregone Model2

Introduction

In support of its new Section 316(b) regulations, USEPA developed a series of case studies. As an example of a power plant located on an estuarine system, Part F of the "Case Study Analysis for the Proposed Section 3 16(b) Phase II Existing Facilities Rule" document addresses the Brayton Point Station (BPS), located on Mount Hope Bay, Massachusetts. The owner of BPS, PG&E NEG, and its consultants have recently completed their own Section 3 16(b) assessment of this facility and are thoroughly familiar with the methods and data used by USEPA. Based on this familiarity, we note several problems with the USEPA assessment, in particular with the findings of the Production Foregone Model application (pages A5-6 through A5-7 and F4-8).

The Production Foregone Model (PPM) is a procedure for quantifying the amount of production that would have resulted had individuals not been lost through entrainment and impingement. Production is defined as the total addition of biomass that would occur during a specified period of time, and is based on individuals increasing their body weight via growth rate and dieing through time. Mathematically, production (P) is calculated as:

[see hard copy for equation]
Equation 1

where:
P=expected production
G=the instantaneous growth rate
B=the average biomass during the time period

The instantaneous growth rate (G) is defined as,

[see hard copy for equation]
Equation 2

where W<1> and W<2> are the start and end weights, respectively, of an individual over the time period t<j> to t<2>. If delta-t = 1, then Equation 2 may be expressed as,

[see hard copy for equation]
Equation 3

An estimate of the mean biomass, B, may be obtained in several different ways; in principle it is the total weight of the population divided by the number of individuals alive at the time. As both weight and number of individuals change over time, both functions need to be integrated with respect to time.

Ricker (1973), among other authors, gives the following:

[see hard copy for equation]
Equation 4

where,
Z=instantaneous mortality rate
B<0>=average biomass at start of time period, t = t<1>
The instantaneous mortality rate (Z) is defined as,

[see hard copy for equation]
Equation 5

where N<1> and N<2> are the number of individuals at the start (t<j>) and end (t<2>), respectively, of the time period t. If delta-t = 1, then Equation 5 may be expressed as,

[see hard copy for equation]
Equation 6

Because G and Z change over the life of a fish, accurate estimation of P requires that the calculations be carried out separately for a particular age class or size class. This can be noted by adding a subscript to Equation 1 to denote a specific age or size class,

[see hard copy for equation]
Equation 7

Further, as Rago (1984) notes, we are interested in the production foregone by the entrainment and impingement of fish. In other words, given that an entrained or impinged fish is of age j (or life stage j), what would that fish have produced over its remaining life span? To address this, Equation 7 may be recast as the sum of production from the current age or life stage to the final age or life stage,

[see hard copy for equation]
Equation 8

where t<max> = maximum age (or stage) obtained by the species of fish.

Our examination of the USEPA analysis suggests two serious flaws in their approach to estimating production foregone. First, we believe that USEPA incorrectly computed the instantaneous growth rate (G) and mean biomass (B) used in Equation 1. Second, USEPA used biologically unrealistic values for early life stage weights. Each of these points is addressed in detail below.

Incorrect Application of Average Weight

USEPA, after Rago (1984), used the following formula for computing production losses:

[see hard copy for equation]

Equation 9

Note that N<i>W<i> (the average biomass) is substituted for B<0> (the initial biomass) of Equation 4. For entrainment and impingement calculations, W<i> and N<i> are computed recursively,

[see hard copy for equation]
Equation 10

and

[see hard copy for equation]
Equation 11

Our attempts to reconstruct USEPA's production foregone estimates using Equation 9 were unsuccessful. In response to our written comments, we were provided with communications (ca. 6/17/02) which indicated that USEPA had used the average weight between successive life stages to obtain the instantaneous growth rate, i.e.,

[see hard copy for equation]
Equation 12

and where [see hard copy for equation]. The average weights, [see hard copy for equation] are the start weights of life stages i, i+l and i+2. Inspections of their results also suggest that W<i> was also used for the initial biomass. Thus, USEPA used W<i> in two places in Equation 9: to compute G and in N<i>W<i> to estimate B. For example, if a larva was entrained, USEPA computed the average weight of the larva (W<i>) as the average of the predicted mean weight at the beginning of the larval stage and the predicted mean weight at the end of the larval life stage. To obtain the average weight for the subsequent life stage, i.e., W<i>, the average of the predicted mean weight at the beginning of the juvenile stage (= weight at end of larval stage) and the predicted mean weight at the end of the juvenile life stage were averaged. The resulting value of W<i> was inserted into Equation 9 and the values of [see hard copy for equation] were used to compute G via Equation 12. This is incorrect. The correct calculation would use the starting and ending weights of the larval stage to compute G, and the starting weight of the larval stage asW<i>. USEPA's erroneous use of mean weights, in some cases, greatly inflated the resulting values of production lost. Average biomäss based on the weight of an individual observed at the midpoint of a life stage will invariably be greater than the weight at the inception of the life stage, and instantaneous growth rate (G) based on the midpoint weights of a life stage and the next life stage is biologically incorrect.

If this is what was actually used, then there is potential for serious error in the production loss estimates. Depending on the relative magnitude of the instantaneous growth and mortality rates, both to each other and to the preceding life stage, the resulting estimates may be substantially over- or under-estimated. (It should be noted that, because we could not reproduce USEPA 's results even after their explanation, we cannot say with any certainty how they actually did the calculations. We have requested further clarification, but to date have not received any response to our request;)

Biologically Unrealistic Weights

USEPA made a series of unrealistic assumptions for the weights of individuals in the early life stages that are then used in the Production Foregone Model and USEPA failed to make use of available scientific literature. For almost all early life stages, USEPA overestimated, sometimes grossly, the average weight of the individuals at the midpoint of life stages. This, in turn, led to highly inflated estimates of lost production.

Production estimates are highly sensitive to the average weight of an individual selected for each life stage. Yet, for eggs and early larval stages these values are not readily available in a form directly usable in the PFM. Scientific studies rarely report the average wet-weight of any egg or larvae. Such weights would be difficult to measure accurately due to the overwhelming contribution of moisture. Weights for these small organisms are generally reported as dry-weight, i.e., the organisms have been dried to remove all moisture. These weights are no longer comparable to the wet-weights reported for larger organisms. It is not entirely clear how USEPA overcame this lack of comparable wet-weight data. Tables F1-l through F1-18 of the Case Study provides wet-weights and cites the PG&E NEG’s Brayton Point Station 316(b) Demonstration as the source, yet PG&E NEG did not provide wet-weights in their Demonstration.

There are several methods, however, that can yield reasonable estimates of early life stage wet-weights, particularly for eggs. These include (1) volume of the organism coupled with the assumption that the biological material has nearly the same weight as water, (2) that dry-weight is a constant proportion of the wet-weight, or (3) compute the average wet-weight by dividing the ovary wet-weight by the total number of eggs present. Additional computational details for the three methods follow.

Method #1
For eggs, volume (V) may be calculated as [see hard copy for equation]. For spherical eggs this reduces to [see hard copy for equation]. The volume of small fish larvae may similarly be computed by multiplication of length x depth x width. The volume may be expressed as weight assuming that 1 cm<3> = 1 gram.

Method #2
Wet weight can be calculated from dry weight based on the fact that dry weight is approximately 20% of the wet-weight (McGurk 1986). Our analysis (see below) is in close agreement with this figure, yielding 19.3%.

Method #3
By dividing the ovary wet weight by the total number of eggs, the average egg wet weight may be obtained. The information necessary for this method is often available from studies of fish fecundity. Some allowance should be made for the weight of the ovary tissues other than eggs. In the following example, we have assumed 10% for this weight.

An example of all three of these methods is presented in Table 1.

TABLE 1
Winter Flounder Egg Weight

	Buckley et al. (1991b)	Calculated

Ovary Wgt(g)	Egg DryWgt (g)	Fecundity	Wet Wgt*(g)	Dry/WetRatio (%)
82.5	0.000054	192,240	0.000386	14.0%
335.6	0.0000542	1,035,653	0.000292	18.6%
66.9	0.0000459	222,491	0.000271	17.0%
188.0	0.0000407	832,196	0.000203	20.0%
368.1	0.0000487	1,390,495	0.000238	20.4%
190.8	0.0000412	896,455	0.000192	21.5%
116.8	0.0000511	369,831	0.000284	18.0%
146.8	0.0000473	568,533	0.000232	20.4%
134.4	0.0000366	616,280	0.000196	18.6%
139.4	0.0000382	614,823	0.000204	18.7%
322.7	0.0000479	1,131,404	0.000257	18.7%
152.6	0.0000469	679,486	0.000202	23.2%
202.0	0.000045	753,385	0.000241	18.6%
230.6	0.000046	822,999	0.000252	18.2%
114.1	0.0000357	619,677	0.000166	21.5%
82.9	0.0000403	364,602	0.000205	19.7%
237.6	0.0000508	902,800	0.000237	21.4%

* Method #3, assuming total ovary weight is made up of 90% ova weight and 10% connective tissue.
Average Wet-Weight (Method #1) = 0.000268 grams
Average Wet-Weight (Method #2) = 0.000225 grams
Average Wet-Weight (Method #3) 0.000239 grams
Average Dry/Wet Weight Ratio = 19.3%

Using the average weight from all three methods, the expected weight of a single winter flounder egg is 0.000244 grams or 0.000000538 lbs.USEPA's reported value in Table Fl-18 was 0.0022 lbs, or over 4,000 times heavier than the actual weight!

As newly hatched larvae do not feed exogenously, but rely on yolk reserves, it is expected that the initial yolk-sac larvae weight will be similar to that of the egg stage. As the yolk-sac is absorbed, larval weight may actually decrease somewhat. For winter flounder, data from Buckley (1982) illustrate this point (Table 2).

TABLE 2
Winter Flounder Yolk-Sac Larvae Weight

Stage	Wet Weight(grams)	Comments
Egg	0.000244	From above calculations
Eggs on Day of Hatch	0.000157*	Buckley 1982, average, 3 tests
YSL on Day of Hatch	0.000131	Buckley 1982, average, 4 tests
YSL at yolk-sac absorption	0.000122	Buckley 1982, average, 4 tests
YSL at first feeding	0.000113	Buckley 1982, average, 3 tests

* Converted to wet weight from protein weight by 1 .626x protein to dry ratio (based on Buckley et al. 1991a) and 5x dry to wet ratio.

Buckley et al. (199lb) reported that the initial average weight of laboratory reared winter flounder yolk-sac larvae from upper Narragansett Bay was 29.7 ug, while those from lower Narragansett Bay averaged 25.6 ug. Assuming that dry weight is 20% of wet weight, corresponding wet weights would be 0.000160 g and 0.000128 g, (or 3.53x10<7> and 2.82x10<7> lbs) respectively. USEPA assumed an average weight of 0.00441 lbs for Stage 1 (= yolk-sac larvae). This is approximately 12,500 to 15,600 times heavier than the actual weight.

Weight at length relationships for post yolk-sac winter flounder larvae are available from several sources, including Laurence (1979), Beyer and Laurence (1980), and Rose et al. (1996). Using the relationship from Laurence (1979), the expected weights for post yolk-sac larvae (ca. 3.1 to 8.2 mm) may be calculated and compared to the values assumed by USEPA (Table 3).

[see hard copy for table]
TABLE 3
Winter Flounder Post Yolk-Sac Larvae Weight

The comparison in Table 3 demonstrates that USEPA grossly overestimated the weights for all post yolk-sac larvae stages of winter flounder. The largest discrepancy is for the Stage 2 larvae, surpassing the discrepancy for the yolk-sac larvae (Stage 1).

By re-arrangement of Rose et al.'s Equation 9, the expected weight for juvenile winter flounder (ca. 9 to 137 mm) may be obtained:

W<mg> wet = 0.000209 L<mm>3.57l

This equation yields an expected weight for an averaged size juvenile (ca. 73 mm) of 0.942g or 0.00208 lbs. The USEPA value of 0.033 lbs is 15.8 times greater than the actual value.

Discrepancies in early life stage weights are not restricted to winter' flounder, but appear in nearly all species. Below (Table 4) are several examples of this problem in other species (winter flounder is sometimes included for comparisons).

[see hard copy for table]
TABLE 4
Comparison of Expected Egg Weight with Values Assumed by USEPA

Of the eighteen species modeled by USEPA, egg weights for fifteen (83%) were overestimated. In some cases, such as the previously examined winter flounder and tautog, this overestimation was by several orders of magnitude. Only butterfish, silver hake, and striped killifish egg weights were underestimated.

Larval stages were also overestimated. For example, the expected weight for tautog larvae is shown in Table 5.

[see hard copy for table]
TABLE 5
Tautog Larvae Weight

Assuming an average size of approximately 15mm (size range is 2.2 mm at hatch to 30 mm TL at end of PYSL), the average weight is 0.000233 lbs (the average of 10 mm and 20 mm weights in Table 5).

The weight used by USEPA, 0.022 lbs, is almost 95 times heavier that the actual weight.

A similar analysis may be conducted for scup larvae (Table 6):

[see hard copy for equation]
TABLE 6

Scup hatch at about 2 mm in length and become juveniles at about 20 mm in length. Assuming an average size of approximately 11 mm for larvae, Laurence's equation predicts an average weight of 0.0 163 g or 0.000036 lbs. The assumed USEPA weight of 0.0011 lbs for scup larvae is 30 times heavier. (Even assuming the weight for the 20 mm individual, the USEPA weight is over 3 times heavier.)

USEPA needs to re-evaluate its Production Foregone estimates with biologically realistic measures of mean weights of individuals.

Combined Influence of Errors

The two errors by USEPA combine to yield an overestimate of the production losses resulting from BPS. To demonstrate the magnitude of this overestimation, we have computed production losses using the correct weights in the production formula and biologically realistic values for weights at midpoints of life stages. As can be seen in Table 7, USEPA overstated total production losses by at least 300 times!

For 14 of the sixteen species, the incorrect calculations used by USEPA resulted in overestimation of the production lost. For several species, USEPA's estimate of production lost was hundreds of times higher than the production lost based on realistic weights and the correct use of the production formula.

TABLE 7
Comparison of USEPA and LMS 1974-83 Average ProductionForegone Estimates for Brayton Point Station

Species	USEPAPFMlbs.wet	LMSPFMlbs.wet	USEPA ÷LMS
Alewife	584	42	13.8x
Atlantic Menhaden	546,168	22,850	23.9x
American Sand Lance	1,737	5,074	0.3x
Atlantic Silverside	8,748	2,154	4.1 x
Bay Anchovy	1,501,808	14,953	100.4x
Hogchoker	81,576	550	148.3x
Rainbow Smelt	4,276	1,656	2.6x
Scup	1,708	297	5.8x
Seaboard Goby	894	5,305	0.2x
Silver Hake	108	1	108.4x
Tautog	60,371,893	89,277	676.2x
Threespine Stickleback	28	8	3.5x
Weakfish	2,440,664	1,971	1,238.4x

White Perch	72	1	60.2x
Windowpane	181,291	1,547	117.2x
Winter Flounder 3	4,380,576	82,290	53.2x.
Total	69,522,131	227,976	305.0x

Note: Winter flounder numbers may change based on use of 1993-1999 data and possible revision of life history parameters.

Conclusion

USEPA must reevaluate its calculations of production lost and its estimates of mean weights, replace their existing estimates of production lost with correct values, and determine how the revised estimates affect the 316(b) rule.

Brayton Point

Development of Long-term Indices of Post-larval Finfish Abundance in Narragansett Bay

We considered five data sources for development of long-term indices of post-larval finfish abundance within Narragansett Bay and/or Mount Hope Bay:

1. Manchester Street Station Impingement Survey

2. Marine Research Inc., Standard Trawl Index (MRI)

3. Brayton Point Station Impingement Survey (BPS)

4. Rhode Island Department of Fish and Wildlife Spring/Fall Trawl Survey (RIDFW)

5.University of Rhode Island Graduate School of Oceanography Trawl Survey (URIGSO)

The Manchester Street Station index is of limited value to the expanded analysis for two reasons: 1) the index covers the shortest time period (1982-2001) of all the available indices; and 2) four years of index data (1982, 1991, 1994, 1995) are either missing or represent incomplete collections due to significant periods of Station outage (3+ months). For these reasons, the Manchester Street Station is not considered further in this document.

The sections that follow describe each of the remaining four sampling programs and the methods used to generate the indices of abundance. Indices of abundance were calculated (and provided in Tables 1-6) for the following species: hogchoker, scup, tautog, windowpane flounder, and winter flounder.

Marine Research Inc., Standard Trawl Index (MRI)

MRI Survey Background

A standard otter trawl has been used in upper Mount Hope Bay since late 1971 to assess the relative spatial distribution and abundance of post-larval finfish. The standard otter trawl used to sample Mount Hope Bay is 11.4 m (37.5 ft) long. It has a 7.6-m (25-ft) head rope, 11-m (36-ft) foot rope, 120.6-mm (4.75-in) stretched mesh in the body, and 38.1-mm (1.5-in) stretched mesh in the cod end. Except for the purchase of replacement nets in 1986, 1987, 1994, and 2001 the gear and vessel have remained unchanged.

Beginning in late 1971, standard otter trawl tows were performed along transects located at five fixed stations within Mount Hope Bay: Spar, Cole River, Lee River, Intake and Crossleg. In 1979, three additional stations were added: Taunton River, Discharge, and Mid-Bay. In January 1986, the Crossleg and Mid-Bay stations were eliminated, bringing to six the number of fixed stations included in the standard otter trawl sampling program. Spar, Cole River, Lee River, and Intake have been sampled continuously since late 1971; the Taunton River and Discharge stations have been sampled continuously since 1979. The Discharge tow was perpendicular to the plume from 1979 — December 1985 and was reoriented inline with the plume beginning in January 1986. Figure 1 shows the eight fixed stations sampled at various times in MRI's finfish trawl program (only the post-1985 Discharge station is shown).

Duplicate tows were made twice each month until 1979, when tows were changed from duplicate to single. Tow frequency was reduced to once per month at the eight fixed stations in October 1980. Trawls are towed for 15 minutes along the established transects, except for the pre-1985 Discharge tows, which were 3 minutes in duration. (Transects are located with reference to land-based bearings and differential Global Positioning System longitude and latitude coordinates). Occasionally, tow duration exceeds 15 minutes because tidal-driven currents increase the time required to cover the established transect. This occurs most often on Taunton River transects, where currents are strongest.

For more detail on the standard otter trawl program, see Section F of USGEN (2000) and page E-12— E-13 of the (USGEN 2001).

MRI Index Calculation

The MRI CPUE index was calculated by Marine Research, Inc. using all fixed station data collected within a given year. The annual CPUE values are the delta mean catch per tow. The delta mean was used because it has substantially lower variance compared with the arithmetic mean when the data set consists of many zero tows. The MRI fixed station CPUE indexes fish abundance in approximately the upper 1/3 of Mount Hope Bay (from Spar Island north) (Figure 1).

Brayton Point Station Impingement Survey (BPIS)

BPIS Survey Background

The objective of the Brayton Point Impingement Survey, conducted by Marine Research Inc., is to determine the number of fish impinged per unit flow at the Units 1, 2, and 3 intake traveling screens (Figure 2). To assess impingement, field personnel divert screenwash to special collection tanks, where the impinged finfish are evaluated.

Units 1, 2, and 3 traveling screens are equipped with 9.5-mm (0.375-in) square mesh panels. To reduce impingement of horseshoe crabs (Limulus polyphemus), fixed screens with larger mesh —38 mm2 (1.5 in2) at Units 1 and 2 and 25 mm2 (1 in2) at Unit 3—are used in front of the traveling screens from May through October, when horseshoe crabs are most abundant. The fixed screens are mesh panels that drop down in the stop-log slots in front of the trash racks.

The traveling screens at Units 1, 2, and 3 have been run continuously since 1997 to minimize the amount of time fish are impinged and therefore their likelihood of injury or mortality due to impingement.

The Units 1, 2, and 3 traveling screens are connected to in-line collection tanks. During impingement sampling, water is diverted for a fixed period of time to collection tanks, where fishes are collected and processed. Diverted screenwash can be sampled over any time period, but algae and debris must be cleaned from the sides of the collection tank periodically so that overflow and subsequent loss of diverted material does not occur. Prior to arrival at the station, the biologist performing the assessment requests that the collection tanks be opened to accept screenwash at a specified time. The duration of collection periods typically is in the range of 4 to 8 hours. All fish captured are identified, counted, and measured for total length to the nearest millimeter.

If an impingement rate of more than 25 fish per hour is recorded, standard procedure requires that certain Brayton Point Station personnel and selected state agencies be notified, and that impingement measurement continue until a rate of less than seven fish per hour is recorded.

Assessment of impingement at the Units 1, 2, and 3 traveling screens has been performed since 1972. Before 1997, screenwash cycles typically were 8 or 12 hours, and sampling was done three times a week. Since 1997, when continuous screen travel began, sampling has been done daily to reduce the probability that occasions of high fish impingement will be missed.

For more detail on the BPS impingement program, see Section F of USGen (2000) and page E29 - E-30 of the (USGen 2001).

BPIS Index Calculation

The BPIS index, calculated by Lawler, Matusky, and Skelly Engineers Inc. (LMS), is the annual average number of organisms impinged per million m3 of intake water. The index was calculated by dividing the total number of fish of a given species captured during each year in the impingement sampling program by the total intake volume sampled during that year. The annual value was then converted to the number that would be impinged in 1 million m3 of intake water. The BPIS CPUE indexes fish abundance in the vicinity of the Station's Units 1, 2, and 3 intake in upper MHB (Figure 2).

Rhode Island Department of Fish and Wildlife Spring/Fall Trawl Survey (RIDFW)

MDFW Survey Background

The RIDFW spring and fall trawl program has monitored fish populations in Narragansett Bay, Rhode Island Sound, and Block Island Sound since 1979. The core program consists of stratified (by depth) random sampling conducted throughout the three areas. The sample areas and strata are shown in Figures 3, 4, and 5. Note that the area covered in Narragansett Bay does not include Massachusetts waters (i.e. upper portions of Mount Hope Bay). The Narragansett Bay survey was augmented in 1990 with the addition of 13 stratified fixed stations (Figure 6). Two of the fixed stations are located in, Mount Hope Bay: Roger Williams College and Spar Island. The 16-m (54-ft) (foot-rope) trawl has a 2.4-3 m (8—10 ft) rise and has 38-mm (1.5-in) mesh in the cod-end, with a 10-mm (GA-in) liner. Tow durations are 20 minutes.

An average of 93 trawl tows has been made annually in the random program since inception (range: 59 to 138). Sampling was generally conducted during April — May (spring) and September — October (fall), though some tows have been made during June, July, and November. Most tows are made in Narragansett Bay (which includes Mount Hope Bay) (60%) followed by Block Island Sound (25%) and Rhode Island Sound (15%). Fixed stations have been sampled each month since 1990.

RIDFW Index Calculation

LMS used data from the RIDFW spring and fall random and fixed surveys to generate annual indices of abundance of finfish in two areas: Lower Mount Hope Bay (LMHB), and Narragansett Bay exclusive of Mount Hope Bay (NB exclusive of MHB). In the calculation of the LMHB CPUE, lower Mount Hope Bay was defined to the north by the Rhode Island/Massachusetts state border and to the south by the Mt. Hope and Sakonnett Bridges (Figure 6). The NB exclusive of MHB CPUE was calculated with data from all Narragansett Bay tows, except those defined as being in Lower Mount Hope Bay. To generate the annual index for each area, all fish captured in the random and fixed station tows made in that area were summed together and divided by the total number of random and fixed tows made in that area in that year. In generating the indices, April - May and September - October fixed station tows were used because these time periods were sampled consistently throughout the duration of the random program. The Rhode Island Sound fixed station was not included in the calculation of the NB exclusive of MHB index because the objective was to index abundance in Narragansett Bay independent of the coastal population.

The LMHB CPUE indexes fish abundance in Rhode Island waters of MHB (lower 2/3 of MHB). The NB exclusive of MHB CPUE indexes fish, abundance in all of Narragansett Bay except waters in MHB (i.e., approximately 90% of NB) (Figure 7).

University of Rhode Island Graduate School of Oceanography (URIGSO)

UIRIGSO Survey Background

The University of Rhode Island Graduate School of Oceanography (URIGSO) trawl sampling program is the oldest in the state. The program, which has been ongoing since 1959, conducted monthly bottom trawl sampling until 1965 and weekly sampling thereafter at two fixed stations in Rhode Island waters (M. Scherer, personal communication, Marine Research Inc., Falmouth, MA). One station is located in the West Passage of Narragansett Bay (Fox Island) and the other is in Rhode Island Sound waters at the mouth of Narragansett Bay (Whale Rock) (Figure 8). The program's 10-m (33-fl) (foot-rope) net has a 1.2-m (4-fl) rise and 51-mm (2-in) mesh. There is no cod-end liner and tow duration is 30 minutes.

RIDFW Index Calculation

The URIGSO index is from USGEN (2000). The index is the annual geometric mean catch per tow at the Fox Island station, calculated from all tows made within a given year. Scup and tautog were the exception, with the annual geometric mean catch per tow being based on May through October and May through November tows only, respectively. The hogchoker index was not published for reasons unknown. The URIGSO Fox Island CPUE indexes fish abundance in the West Passage of Narragansett Bay (Figure 8).

[see hard copy for figures and tables]

EPA Response

EPA did not evaluate trends in fish populations in Mt. Hope Bay for its benefits analysis for the final 316b Phase 2 rule. However, EPA notes the commenter's listing of the available indices of post-larval finfish abundances in Narragansett Bay.

REPORT

TRENDS IN THE ABUNDANCE OF FIVE FISH SPECIES IN MOUNT HOPE BAY:
A RESPONSE TO M. GIBSON'S ASSESSMENT OF THE EFFECT OF BRAYTON POINT STATION
ON FISH STOCKS IN MOUNT HOPE BAY

1 July 2002

Joseph DeAlteris, Ph.D.
DEALTERIS ASSOCIATES INC.
Jamestown, RI 02835

EXECUTIVE SUMMARY

In recent years, there has been a great deal of debate and controversy about trends in the abundance of certain fish populations in Mount Hope Bay. A series of reports (1996, 2000, 2002a, 2002b) prepared by Mark Gibson of the Rhode Island Division of Fish and Wildlife (RIDFW) have been at the heart of this debate. In these reports, Gibson concluded that Brayton Point Station has negatively impacted fish stocks in Mount Hope Bay (MHB). As will be shown in detail in this report, the weight of the evidence flatly 'contradicts Gibson's conclusions for some fish species and casts doubt about his conclusion for other species. Indeed, there is limited evidence that several bottom-dwelling species have fared better in Upper Mount Hope Bay (UMHB) near Brayton Point Station than they have fared in Narragansett Bay (NB), just as there is also limited evidence that other species have fared worse in UIVIHB than they have fared in NB.

Gibson's conclusion derives from two major errors in his use of data. First, he erroneously characterized data that was collected exclusively from the upper 1/3 of MHB (the MRI and BPIS data) as representative of all of MHB. That is not the case. RIDFW has collected data from Lower Mount Hope Bay (LMHB) and NB for many years, and my analysis of this data demonstrates conclusively that trends in fish abundance in the lower 2/3 of MHB are not different from those in NB. Note that it is widely agreed that Brayton Point Station has no impact on NB. A second major flaw in Gibson's use of data is that he compares data collected from coastal waters. (Rhode Island and Block Island Sounds) with data collected in UMHB (the MRI and BPIS) to support his conclusions. That comparison is biased and not appropriate. When the coastal data is removed from the analysis, it is immediately apparent that there are minimal differences between fish abundance trends in MHB and NB. Finally, in his 2002a report, Gibson only considered a single species -- winter flounder -- but improperly extrapolated his conclusion to two other bottom-dwelling species, windowpane flounder and tautog.

I have utilized all of the available data collected over a three decade period to evaluate trends in the abundance of five fish species in MHB. The purpose of my analysis and report was to undertake a critical and comprehensive examination of the data and of the validity of Gibson's conclusions. I have done this by using Gibson's (2002a) methodology, but included additional species, areas, and time periods. I evaluated four demersal species (winter flounder, windowpane flounder, hogchoker and tautog) and one pelagic species (scup). Like winter flounder, these have also been identified as species of concern in Mount Hope Bay. In addition, these species are present in the MRI trawl survey, and are also sampled in the Brayton Point impingement studies. RIDFW collects data on fish abundance in LMHB, NB, and the surrounding estuarine and coastal waters using a trawl survey. The survey includes stations in LMHB, and data from these stations were grouped to form an index of abundance representative of LMHB. I analyzed these abundance indices by standardizing them against two different long-term series for NB, the RIDFW and URIGSO trawl surveys. I considered three time periods: 1972-1985, 1986-2000 and 1972-2000, so as to correspond with the various Gibson analyses. I analyzed a total of 81 individual cases (see Table 13, page 34 of this report for a summary of the results of the trend analyses). Based on the results of these analyses, I then evaluated the trends in abundance of the five fish species in MHB to evaluate the potential effect of the Brayton Point Station. (I have not taken into account other potential stressors on abundance.) Conclusions for individual species are based on the results of the majority of the cases investigated, so as to provide clear and convincing interpretation of the analyses.

The results of my analyses are detailed below and are summarized as follows. There is limited evidence of a differential decline of winter flounder in UMHB but it is not as far-reaching, striking or as definitive as Gibson's reports suggest. Notably, as for windowpane flounder, hogchoker, and tautog, the weight of the evidence indicates that abundance trends in both UMHB and LMHB are similar to NB, but there is also limited evidence that these species fared better in UMHB than NB. As for scup, in LMHB the abundance trend is similar to NB, and there is only limited evidence of a differential decline of scup in UMHB. The clear weight of the evidence eliminates Brayton Point Station as a factor in the declines of all five species in the lower 2/3 of MHB. It also casts serious doubt on claims that the Station has seriously impacted the five species in UMHB.

More specifically as to winter flounder, all the short-term series for UMHB have slopes that are not significantly different from zero (8 of 8 cases). The long-term series trends have significant negative slopes in 2 of 4 cases, a significant positive slope in 1 of 4 cases, and a slope not significantly different from zero in 1 of 4 cases. The results of the analysis of the LMHB series clearly indicate that the abundance of winter flounder in LMHB is following a similar trend to the reference series for NB (6 of 6 cases). These results clearly refute the Gibson's conclusion that winter flounder are declining at a greater rate in the entire MHB system. in fact, it appears that the trends in abundance in LMHB are similar to NB, and that in UMHB the rate of decline is greater than NB in only 2 of 12 cases analyzed. In summary, while there may be some evidence of a greater differential decline in winter flounder in UMHB than in Narragansett Bay in some of the data series, it is neither definitive nor compelling as suggested by Gibson (2002a).

The results of the analyses of the data for windowpane flounder, hogchoker and tautog in UMHB as described by the MRI and BPI standardized series clearly indicate abundance trends for these species are similar to NB (23 of 30 cases). In fact, the analyses indicate that in the, remaining 7 of 30 cases, abundance trends for these species are significantly positive relative to NB. In LMHB the analyses indicate that abundance trends for these species are also similar to NB (15 of 15 cases). Again, results of analyses for these species clearly refute the conclusion drawn by Gibson (2002b).

The results of the analyses of the data for scup are also equivocal with respect to UMHB. The shorter term series indicate that the abundance trend is similar to NB (8 of 8 cases), while the long-term series (1972-2000) indicates that scup have declined at a greater rate than NB in 3 of 4 cases. The analyses of the LMHB standardized series indicate that the abundance trend for scup is not significantly different from NB (6 of 6 cases).

BACKGROUND

Fishery resource abundance patterns in Rhode Island estuarine and coastal waters have experienced dramatic changes in the last three decades due to the effects of overfishing selected species, global climate warming and other factors (DeAlteris et al. 2000). Quantifying the relative importance of individual causal factors associated with changes in the abundance of individual fish stocks is very difficult when multiple stressors are simultaneously acting on the fish stock (Hilborn and Walters 1992). A recent report from RI Division of fish and Wildlife, entitled “Winter Flounder Abundance near Brayton Point Station, Mount Hope Bay Revisited: Separating Local from Regional Impacts Using Long Term Abundance Data” (Gibson 2002a) states that the abundance of winter flounder, in Mount Hope Bay (MHB) is anomalously low compared to other areas inside and outside Narragansett Bay (NB). The Gibson conclusion is based on comparative analyses of abundance trends for winter flounder from two data sources in Mount Hope Bay (MHB), that are individually compared to five other long-term series from NB and the surrounding offshore areas for the period 1972 to 1985.

The two MHB data sources are the MRI trawl survey conducted by the operators of Brayton Point Station, and the Brayton Point impingement screen (BPIS) data from the cooling water intakes for that power plant. The other long-term data series are the RIDFW trawl survey of NB, Rhode Island Sound, and Block Island Sound, the URIGSO trawl survey West Passage in NB, the NMFS trawl survey for Block Island Sound, NMFS landings data for statistical area 539 which includes NB and the coastal water south of Rhode Island, and the Manchester Street power station screen impingement data for Upper Narragansett Bay. In this report, Gibson (2002a) incorrectly ascribed the representative area for the MRI trawl survey and BPIS data to the entire area of MHB (about 15 square miles), rather than to the upper 1/3 of MHB (about 5 square miles) where the data was in fact collected.

In a related report, Gibson (2002b) suggested that similar population declines have occurred in MHB for windowpane flounder and tautog, and then presented the results of a foregone production model that estimates a monetary value for the loss of all these species. However, there is no data or analysis to demonstrate that the abundance trends of windowpane flounder and tautog are in fact declining faster in MHB than in NB, and therefore he offers no scientific evidence to support his conclusions, other than citing to individual stock assessments for these species that indicate overall declines in abundance in RI waters. Gibson interprets the results of his analyses and states “that the operation of units 1-3 [at Brayton Point Station] during the period 1972-1985 was sufficient to induce a decline in the winter flounder stock”. He further states that “the conversion of unit 4 to open cycle cooling accelerated the decline” post 1986, and “led to. the complete collapse of the stock”. This latter conclusion was based on a previous analysis (Gibson 1996) that suggested a post 1986 power plant effect based on a parsimony hypothesis. This analysis correlated the post 1986 decline in MHB fish stocks with an increase in the heat flow from the power plant, associated with the conversion of unit 4 to open cycle cooling. However, it did not utilize other long-term reference abundance trends for NB to standardize the MHB series, as Gibson later considered them in the 2002a report.

The purpose of my analysis and this report was to undertake a critical and comprehensive examination of the data and an assessment of the validity of Gibson's conclusions. I have done this by conducting analyses utilizing the identical methods to Gibson 2002a, but including additional areas, time periods, and species.

QUESTIONS RAISED BY THE GIBSON REPORTS

1. Using the Gibson 2002a data for winter flounder, I evaluated standardized abundance trends for the periods 1972-1985, 1986-2000, and 1972-2000. My analyses addressed the following questions:

a. Are the results of Gibson 2002a for the period 1972-1985 reproducible?
b. Is there evidence of a post 1986 "collapse" (1986-2000) of the winter flounder stock in MHB?
c. Do the Gibson results and conclusions for the period 1972-1985, hold for the entire period 1972-2000?

2. Using available data for five finfish species (winter flounder, windowpane flounder, tautog, hogchoker and scup) for UMHB (MN trawl survey and BP1S), and LMHB (RIDFW stations in LMHB), I evaluated the abundance trends for these species and areas by standardizing these series with the long term series from RIDFW for NB only and URIGSO for West Passage of NB for the periods 1972-1985, 1986-2000, 1972-2000. My analyses addressed the following questions:

a. For winter flounder, are the standardized abundance trends for UMHB and LMHB increasing, decreasing or following the same trend as the other long term series in NB for the various time periods?
b. For the other species, windowpane flounder, hogchoker, tautog, and scup, are the standardized abundance trends increasing, decreasing, or following the same trend as the long-term series in NB for the three time periods?

Based on the results of the aforementioned analyses (six standardized abundance series evaluated for five species in three time periods for a total of 81 cases studied), I then considered the trends in abundance of these finfish species in MHB to evaluate the effect of the Brayton Point Station.

METHODS AND DATA SOURCES

Following the control-impact methodology (Underwood 1994) outlined and data presented in Gibson (2002a), I first standardized the MRI and BPIS series for upper Mount Hope Bay (UMHB) with the other five long-term data series (NMFS Block Island Sound, URIGSO for West Passage of Narragansett Bay (NB), RIDFW for NB and adjacent coastal waters, statistical area 539 landings, and Manchester Street screen impingement) (Manley 2001). I then plotted the natural log (LN) of the standardized index for each of the time series. Using linear regression in EXCEL, I estimated the slope of the entire series, the 1972-1985 series and the 1986-2000 series. Finally, I statistically evaluated the null hypothesis, that the slope of the regression was not significantly different from zero (?= 0.05). If the null hypothesis ,is accepted, this implies that the standardized series follows a similar trend to the reference long-term series. If the null hypothesis is rejected, then the standard series is either significantly increasing (+) more than or significantly decreasing (-) more than the reference long-term series (Netter et al. 1983).

An identical procedure was followed using data from the above sources tabulated by LMS (2002) for winter flounder, windowpane flounder, tautog, hogchoker and scup for UMHB, lower Mount Hope Bay (LMHB) and NB. The UMHB data series are the MRI trawl survey and Brayton Point screen impingement data. The LMHB series is based on the RIDFW trawl survey locations situated in LMHB. The NB series are the RIDFW data for stations exclusively in NB, and the URIGSO series in West Passage of NB. The analysis periods are 1972-1985, 1986-2000 and 1972-2000 as data were available, so as to correspond with the Gibson analyses. The hypotheses evaluated are identical to those identified previously, but the standardized series evaluated are MRI, BPIS and LMHB.

RESULTS

The raw data used in all the analyses are listed in Tables 1-6, and this section is divided into three parts: the reanalysis of the Gibson data for winter flounder (Table 7 and Figure 1), the analysis of the LMS data for winter flounder (Table 8 and Figure 2), and the analysis of LMS data for windowpane flounder, hogchoker, tautog, and scup (Tables 9-12 and Figures 3-6).

The, first analysis replicates Gibson's use of data. The results for winter flounder are shown in Figure 1 and are summarized in Tables 7a and 7b. For winter flounder, the MRI standardized series has a significant negative slope in 3 of 5 cases for the period 1972-1985, 4 of 5 cases for the period 1986-2000, and 5 of 5 cases for the period 1972-2000. For winter flounder, the standardized BPI series has a significant negative slope in 4 of 5 cases for the period 1972-1985, 3 of 5 cases for the period 1986-2000, and 4 of 5 cases for the period 1972-2000.

The second set of analyses evaluates standardized series for UMHB (MN trawl survey and Brayton Point impingement screen data) and LMHB (RIDWF trawl). The results of the analyses for winter flounder are shown in Figure 2 and summarized in Tables 8a, 8b, and 8c. For the periods 1972-1985 and 1986-2000, the slopes of the standardized MRI and BPI series representing UMHB are not significantly different from zero in 8 of 8 cases. However, for the longer period 1972-2000, the Mill standardized series has a significant negative slope in 2 of 2 cases, while the BPI standardized series has a significant positive slope in I case, and a slope not significantly different from zero in the other case. In LMHB the slopes of the standardized series are not significantly different from zero for any time periods (6 of 6 cases).

The results of the analyses for windowpane flounder are shown in Figure 3 and summarized Tables 9a, 9b, and 9c. For both the MRI and BPI standardized series representing UMHB for all time periods, the slopes of the series are not significantly different from zero, with the exception of the period 1986-2000 where 2 of 4 cases indicate a significant positive slope. For the standardized LMHB series in all cases and all time periods, the slopes are not significantly different from zero (6 of 6 cases).

The results of the analyses for hogchoker are shown in Figure 4 and summarized in Tables l0a, l0b, and l0c. For both the MN and BPI standardized series representing UMHB, the slopes are significantly positive for the period 1972-1985 (2 of 2 cases), and are not significantly different from zero for the periods 1986-2000, and 1972-2000 (4 of 4 cases). The slopes of LMHB standardized series is not significantly different from zero for any time periods (3 of 3 cases).

The results of the analyses for tautog are shown in Figure 5 and summarized in Tables 11a, 11b &

11c. For both the MRI and BPI standardized series representing UMHB, the slopes are significantly positive in 2 of 4 cases, and not significantly different from zero in 2 of 4 cases for each of the periods 1972-1985. For the period 1986-2000, the slopes of both the MRI and BPI standardized series are not significantly different from zero (4 of 4 cases). Finally, for the long-term period 1972-2000,. the slopes of the MRI and BPI standardized series are not significantly different from zero in 3 of 4 cases, and the remaining case is significantly positive. The slopes of the standardized LMHB standardized series are not significantly different from zero in all cases for any time periods (6 of 6 cases).

The results of the analysis for scup are shown in Figure 6 and summarized in Tables 12a, 12b, and 12c. For both the MRI and BPI standardized series representing UMHB, the slopes are not significantly different from zero for both the periods 1972-1985 and 1986-2000(8 of 8 cases). However for both series over period 1972-2000, the slope is significantly negative in 3 of 4 cases. The slopes of the LMHB standardized series are not significantly different from zero for any of the three time periods (6 of 6 cases).

DISCUSSION, SUMMARY AND CONCLUSIONS

With regard to winter flounder, the standardized long-term series in UMHB have significant negative slopes in 2 of 4 cases, a significant positive slope in 1 of 4 cases, and a slope not significantly different from zero in 1 of 4 cases. Additionally all the short-term series have slopes not significantly different from zero (8 of 8 cases). The results of my analyses of the LMHB series clearly indicate that the abundance of winter flounder in LMHB is following a similar trend to the reference series for NB in 6 of 6 cases. These results clearly refute the conclusion of Gibson (2002a) that winter flounder are declining at a greater rate in the entire MHB system. In fact, it appears that the trends in abundance in LMHB are similar to NB, and that in UMHB the rate of decline is greater than NB in only 2 of 12 cases analyzed. Thus, while there may be some evidence of a greater differential decline in winter flounder in UMHB than in Narragansett Bay in some of the data series, it is neither definitive nor compelling as suggested by Gibson (2002a).

The results of my analyses of our data for windowpane flounder, hogchoker and tautog in UMHB as described by the MRI and BPI standardized series clearly indicate abundance trends for these species are similar to NB (23 of 30 cases). In fact, the analyses suggest that in the remaining 7 of 30 cases, abundance trends for these species are positive relative to NB. In LMHB the analyses indicate that abundance trends for these species are also similar to NB (15 of 15 cases). Again, results of analyses for these species clearly refute the conclusion drawn by Gibson (2002b).

The results of my analyses of our data for scup are also equivocal with respect to UMHB. The shorter terms series indicate that the abundance trend is similar to NB (8 of 8 cases), while the long-term series (1972-2000) indicates that scup have declined at a greater rate than NB in 3 of 4 cases. The analyses of the LMHB standardized series indicate that the abundance trend for scup is not significantly different from NB (6 of 6 cases).

In conclusion, there is conflicting evidence about whether winter flounder in UMHB have declined at a greater rate than in NB. There is no question but that the abundance of winter flounder in LMHB is the same as in NB. Winter flounder have definitely not declined more sharply in LMHB than in NB. As for windowpane flounder, hogchoker, and tautog, the abundance trends in both UMHB and LMHB are similar to NB thus eliminating the Brayton Point Station as a factor in their abundance.

For scup in LMHB, the abundance trend is also similar to NB, but there is limited evidence that scup in UMHB may have declined at .a greater rate than NB. Again, there is definitely no negative effect of the Brayton Point Station on LMHB for the five species investigated and on UMHB for windowpane flounder, hogchoker, and tautog.

[see hard copy for figures]

EPA Response

EPA did not evaluate trends in fish populations in Mt. Hope Bay for its benefits analysis for the final 316b Phase 2 rule. However, EPA has reviewed materials prepared by EPA Region 1 on this issue. The Agency concurs with Region 1's conclusion that the commenter's analysis is incorrect. EPA agrees with Region 1 that the available evidence indicates that the decline in fish populations in Mt. Hope Bay is statistically greater than the decline in Narragansett Bay as a result of the BPS. Additional discussion of this issue is provided in EPA Region 1's 2002 NPDES permit determinations for BPS and the related Responses to Comments document (available at http://www.epa.gov/region1/braytonpoint/index.html)

Subject Matter Code SUP

General statement of support

Numerous aspects of the proposed rule represent welcome changes from previous drafts of 316(b) rules. Instead of imposing specific technology requirements on existing facilities, the rule offers three options for meeting the "best technology available" standard referenced in the Clean Water Act. The first option requires a demonstration that the facility has either reduced intake capacity commensurate with a closed-cycle, recirculating cooling system, or has otherwise already met the applicable performance standards.

EPA Response

EPA notes the comment. Today's rule adopts five compliance alternatives from which facilities may choose how to comply with the Phase II existing facility 316(b) regulation.

Organization Public Service of New Hampshire

Subject Matter Code 11.01

RFC: Proposed use of restoration measures

The second option consists of meeting performance standards measured against a facility-specific baseline with the implementation of selected design, operation, or restoration measures. Restoration measures include enhancing wetlands, operating fish hatcheries or stocking programs, and removing impediments to fish migration. Northeast Utilities has undertaken a number of such restoration efforts, and believes that they can be very effective in mitigating the impacts of intake structures. Northeast Utilities supports the inclusion of restoration as a means of complying with proposed standards, and also urges EPA to provide maximum flexibility in the use of restoration banking and trading. Restoration should not, however, be a mandatory element of 316(b) compliance measures.

EPA Response

In the final rule, EPA allows use of restoration measures to minimize or help to minimize the adverse environmental impacts that derive from the impingement and entrainment of aquatic organisms. Restoration measures must meet the requirements described in the final rule, including those in sections 125.94 and 125.95.

For a discussion of trading programs, see EPA's response to comment 316bEFR.074.020.

For a discussion of the extent to which restoration is voluntary, see EPA's response to comment 316bEFR.060.022.

Option 3--Site-specific determination

Author Name Ross Povenmire

Organization Public Service of New Hampshire

The third option allows for the development of site-specific performance standards to reflect the "significantly greater" costs of implementing the normal performance standards at the facility compared with EPA estimated costs or anticipated benefits. The "significantly greater" test embedded in the third option is much more preferable to the "wholly disproportionate" test that appeared in earlier drafts, and provides essential flexibility for site specific considerations.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

For more information on the use of the term "significantly greater," please refer to the response to comment 316bEFR.006.003.

Permit applications/implementation schedule

Author Name Ross Povenmire

Organization Public Service of New Hampshire

Timetable for Compliance:

The proposed rule states that a facility must comply with the rule when an NPDES permit containing the requirements of the rule “is issued.” Because of a backlog of NPDES applications pending review at EPA, many facilities are currently operating under NPDES “extension letters” that, in essence, extend the effective date of existing NPDES permits. It is impossible to know when the application for a specific facility will be considered, or when compliance will be required. This uncertainty is an impediment to the proper planning for baseline studies, engineering feasibility studies, comprehensive demonstration studies, and other efforts related to compliance with the proposed rule.

For facilities with permit applications pending review, a better approach would be to set the effective date of the performance standards under the proposed rule coincident with the expiration of the NPDES permit currently under application. Because an NPDES permit is typically valid for five years (unless extended), this would provide the necessary time for each facility to conduct the necessary studies required by the proposed rule.

EPA Response

EPA has clarified timing requirements for the submittal of the required studies. See response to comment 316bEFR.034.066 for a discussion. In addition, EPA has decided not to promulgate the regulatory text identified by the commenter because the rule contains a variety of requirements subject to varying timeframes. EPA was concerned that the proposed language would create confusion. EPA therefore eliminated it.

Organization Public Service of New Hampshire

Subject Matter Code 7.01.02

Option 2--Implement performance requirements

Demonstration of Compliance:

Under Option 2, a facility must select design and construction technology, operational measures, or restoration measures to meet the proposed performance standards. The rule requires that data must be "submitted with the NPDES permit application to show that the facility is in compliance with the location, design, construction and capacity requirements" of the rule. It is unclear how this would apply to facilities for which applications have already been submitted but are still pending review, or if this requires the implementation of selected measures prior to receiving a NPDES permit. The implementation of certain measures may require extensive preparatory effort that cannot be accomplished within a permit application period. In addition, although annual monitoring reports are required, there is no indication of when actual compliance with the performance standards must be demonstrated, or what procedure must be followed if the measures prove to be inadequate.

A better approach would be to clarify that under Option 2, measures identified by the applicant as adequate to meet the proposed performance standards will be incorporated into the NPDES permit as requirements for implementation during the permit period. A time-table could be specified in the permit. Timely implementation of the required measures would constitute compliance with the permit and with the requirements of 316(b). The demonstration studies required for the next NPDES application would assess the effectiveness of the implemented measures, and select additional measures, if needed, for implementation during the next permit period.

EPA Response

EPA has clarified timing requirements for the submittal of studies in today's final rule. See § 125.95 and the response to comment 316bEFR.034.066. Please also see the preamble and EPA's responses to comments 316bEFR.063.005 and 316bEFR.017.003 for a discussion of compliance with today's requirements.

RFC: Use of previous demonstration studies

Author Name Ross Povenmire

Organization Public Service of New Hampshire

Consideration of Existing 316(b) Studies:

Since the inception of the NPDES permitting program, NU as worked with EPA's Region 1 offices to ensure compliance with 316(b) requirements at its facilities located in NH and MA. The application materials and studies submitted by NU for these permits reflected the expectations of the EPA office and the prevailing standards for environmental impact assessment and review. Although the proposed rule would allow the use of existing studies, the applicant must demonstrate that the studies represent current conditions and were collected using "appropriate quality assurance and control procedures." Given the evolving and increasingly sophisticated nature of environmental impact assessment and review, strict application of the proposed standard could disqualify many studies upon which previous permits were granted, and upon which current permit applications may be based.

A better approach would be to adopt a rebuttable presumption that existing studies are relevant and scientifically valid for purposes of NPDES permit applications currently under review. This would allow new studies reflecting the requirements of the proposed rule to be developed and completed during the new permit period, typically five years, and submitted as part of the next permit application.

EPA Response

For permits that expire within 4 years, EPA has allowed a facility to submit the required information in accordance with a schedule established by the Director. This information need not be incorporated into the permit application. The facility should discuss the appropriateness of using existing data to meet performance standards with the Director.

See also response to comment 316bEFR.034.066 for a complete discussion of timing requirements.

Option 3--Site-specific determination

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

While our members continue to support a wholly site-specific approach toward the selection of Best Technology Available ("BTA"), the proposed rule can provide a solid initial foundation for rulemaking if certain concerns are addressed. We are encouraged that the proposal recognizes the site-specific nature of the issue, provides several compliance options based on benefit-cost analysis, and, most importantly, rejects any mandate for the retrofit of costly and potentially inefficient closed-cycle cooling towers that affect 40 percent of the nation's total installed electric generating capacity.

Still, EPA must address several critical impediments in its proposal if any new Section 316(b) permitting process is not to undermine the benefits provided by the current program which provides an adaptable, technology-neutral, site-specific approach that yields optimal, cost-effective, and scientifically sound protection of the environment.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

Comment ID 316bEFR.072.002

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 7.01.03

Option 3--Site-specific determination

EEI members and State permitting authorities have 30 years of experience in implementing solutions aimed at reducing averse environmental impacts associated with the operation of cooling water intake structures under Section 316(b). The single most important lesson learned during these 30 years is that the site-specific variations in facility operations and affected ecosystems make& site specific technology selection the most efficient and effective means of minimizing adverse environmental impact from cooling water intake structures. A structured site-specific approach makes it possible to select and install the technology that maximizes the net benefits to society EEI maintains that a rule embodying such a structured site specific approach represents the best approach to addressing any adverse environmental impacts that may result from the operation of cooling water intake structures at their facilities.

Indeed in our view, EPA has not demonstrated in its record for this rulemaking a need to depart fundamentally from the site-specific, case-by-case approach that has worked well in addressing adverse environmental impacts at cooling water intake structures over the past 30 years. At the same time, we recognize that EPA is trying to take a fresh look at operation of the §316(b) program both to ensure that it remains environmentally sound and to seek ways to improve operation of the program through appropriate further guidance to States and permittees. We also recognize that some State permitting authorities have raised concerns over the complexity and transaction costs that could be associated with universal implementation of a site specific approach. especially if that approach required voluminous new analyses under a new EPA final rule.

However, we believe that EPA can address its goals and the State concerns by proper implementation of a more truly site specific approach than the one EPA has proposed in its April 9 Federal Register notice. At a minimum, we encourage EPA to modify the April 9 proposed rule to ensure that any final rule EPA may adopt (a) retains positive attributes of the proposed rule and (b) incorporates further improvements that will allow use of a site specific analysis in appropriate circumstances and streamline operation of the 316(b) program to the benefit of all parties involved, as we will describe in the remainder of these comments.

The rule proposed by EPA represents a legitimate attempt to balance the aced for site-specific flexibility and the desire to reduce implementation costs of the program and as we will discuss below, EPA's proposal contains a number of positive features that clearly should be retained in any final rule EPA may adopt. At the same time, however, the proposed rule raises a number of significant concerns, in particular the potential for unnecessarily requiring new 316(b) analyses and measures that will not increase net benefits to society. We encourage EPA to address these concerns.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA disagrees with the commenter's statement about the historic interpretation of 316(b). Today's rule is the first major regulation for 316(b) for existing facilities; all other § 316(b) determinations for existing facilities to date have used a best professional judgment approach. The final rule does include a site-specific compliance alternative as one of the five alternatives available to facilities, creating a flexible regulatory framework. EPA believes that today's final rule will minimize adverse environmental impact at cooling water intake structures.

RFC: Three-option framework for determining BTA

We appreciate the effort that EPA put into examining a variety of alternative approaches to the regulation. Moreover, we are encouraged that, based on the analysis performed by the Agency, EPA has sought to choose an approach that will provide relatively greater benefit to society than some of the alternatives EPA could have selected. Again, however, we believe that EPA can improve the net benefit to society even further by modifying the proposed rule as we will discuss in the remainder of our comments.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

With respect to selecting the approach with the greatest net benefits, please refer to the response to comment 316bEFR.005.020 for a discussion of the application of the cost-benefit test to assessing the value of alternative CWIS technologies.

Comment ID 316bEFR.072.004

Subject Matter Code 10.1

General: cost tests

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

We are encouraged that EPA's proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that impact the technical practicability of meeting the proposed standards. Specifically, the Agency recognizes that there may be situations where the costs of meeting the proposed standards at a specific facility may be significantly higher than the considered by EPA in establishing these standards. In those instances the proposal provides the facility with the opportunity to justify an alternative technology selection.

EPA Response

The Agency notes that the comment supports inclusion of the cost-cost test in the final rule.

Comment ID 316bEFR.072.005

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

We are further encouraged that EPA's proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that indicate that the costs of meeting the performance standards are not warranted by the projected benefits at that facility. The rule allows facilities to select an alternative level of compliance where the costs of compliance with the EPA's performance levels would be significantly greater than the expected benefits of achieving these levels. This explicitly recognizes the sire-specific variations in the ecology of source water bodies and can help account for controls already in place at many facilities.

EPA Response

The Agency has retained the cost-benefit test for the final rule.

The Agency notes that in developing the costs and benefits of the final rule that it fully considered controls already in place at in-scope facilities. However, should the Agency's assessment of the current performance of these controls prove to be incorrect for certain facilities, then the cost-benefit and cost-cost tests will allow for site-specific adjustments to account for this possibility.

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 7.01

RFC: Three-option framework for determining BTA

We are also encouraged that EPA has chosen a flexible approach to compliance that allows facilities to meet the performance standards through a number of options, including creation or restoration of habitats and trading. This does not freeze compliance in time by relying on today's technologies and allows for continued innovation in addressing the potential adverse environmental impacts associated with impingement and entrainment at power generating facilities. This also leaves significant discretion in determining how best to comply with the standards to State permitting authorities and facility managers who have developed a great deal of expertise on these issues.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

Comment ID 316bEFR.072.007

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 10.02

Benefit Estimation Methodology

EPA's analysis greatly overstates the benefits of all of the options evaluated. For example, EPA reliance on habitat replacement costs as a measure of valuing benefits has no basis in welfare economics and leads to a gross overstatement of benefits, and EPA double counted the value of lost angler days by failing to consider the geographic distribution of power plants.

EPA Response

The habitat-based replacement cost (HRC) method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see response to comment # 316bEFR.005.035. For additional information on the HRC, please see the document entitled "Habitat-based Replacement Cost Method" (Docket #6-1003). EPA now employs a different method for considering geographic effects on angler days; see Phase II Regional Study Document (DCN #6-0003) which addresses concerns about this issue.

RFC: Appropriateness of "significantly greater"

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

The failure to define "significance" for either of its cost tests creates unnecessary uncertainty in the rule.

EPA Response

See responses to 316bEFR.006.003 and 018.009.

Comment ID 316bEFR.072.010

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 10.08

RFC: "Significantly greater" for eval. alt. req.

While we support the consideration of site-specific benefits, the proposed benefit cost test uses incorrect decision criteria. EPA only allows site-specific alternatives to be considered if the cost of achieving the standard is significantly greater than the expected benefits of compliance. This still allows socially suboptimal solutions to be implemented. The correct decision criteria would be to allow facilities to select the control alternative that maximizes net benefits.

EPA Response

See responses to 316bEFR.006.003, 045.012, and 018.009.

Comment ID 316bEFR.072.011

Subject Matter Code 9.06

Burden to facilities (general)

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

We are concerned that the EPA proposal does too little to reduce the costs of implementation for both facilities and State permitting authorities. Much of the information necessary to implement a purely site-specific approach, (e.g., calculation of baseline losses, estimation of technology effectiveness, post compliance monitoring, etc.) must be generated despite not being used to improve the technology selection decision. EPA should provide a much simpler implementation path for facilities that choose to install one of the EPA approved technologies.

EPA Response

The Agency has adopted a simplified implementation path for all facilities, including those that adopt technologies that have been "pre-approved" by EPA in a fast-track alternative. Therefore, the Agency has done much to reduce the costs of implementation for both facilities and permit authorities, as the commenter recommends.

Comment ID 316bEFR.072.012

Subject Matter Code 7.01.03

Option 3--Site-specific determination

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

In summary, taking these points into account, EEI continues to support a wholly site-specific approach as the preferred alternative. At the same time, if EPA's proposed rule is properly modified to retain its positive features and to address our concerns, the proposed rule can provide a solid initial foundation for a final rule that preserves sufficient site specificity while also providing guidance and streamlining the §316(b) process. Again, the final rule must recognize the site-specific nature of the issue, provide several compliance options based on benefit-cost analysis, and, most importantly, reject any mandate for the retrofit of costly and potentially inefficient closed-cycle cooling towers, which would negatively affect 40 percent of the nation's total installed electric generating capacity.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

Comment ID 316bEFR.072.013

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 10.1

General: cost tests

Any final rule EPA may adopt must retain consideration of site-specific variations in cost. This is currently embodied in both the new facility standards and the proposed rule as a test of the cost of compliance against the costs considered by EPA in establishing the standards. For convenience we refer to this as the cost-cost test.

EPA Response

The cost-cost test is retained in the final rule. Therefore, this recommendation from the commenter has been met.

Comment ID 316bEFR.072.014

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

Any such rule must retain consideration of site-specific variations in benefits. This is currently embodied in the proposed rule as a test of the cost of compliance against the expected benefits of compliance. We refer to this as the benefit-cost test.

EPA Response

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020. See also the preamble to the final rule.

Comment ID 316bEFR.072.015

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

The decision criteria for the benefit-cost test should be the maximization of net benefits. To achieve this goal, at a minimum, EPA must delete the “significantly greater than” hurdle so States and permittees can select among all technology with a higher net benefit than EPA’s performance standards would otherwise dictate.

EPA Response

See Sections V and IX of the preamble for a site-specific determination of best technology available for minimizing adverse environmental impact.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

RFC: Use of previous demonstration studies

In order to reduce implementation costs, speed the permitting process, and prevent unnecessary permit backlogs for both facilities and the States, EPA should allow State permitting agencies to rely on existing data and prior analyses and decisions, to the extent those data, analyses, and decisions are sound and demonstrate minimization of adverse environmental impacts or are otherwise relevant to the §316(b) decision. EPA's current proposal could prevent consideration of such information unless directly related to impingement and entrainment. But as studies of sensitive water bodies such as the Chesapeake Bay have demonstrated, entrainment and impingement are not necessarily the correct criteria for ensuring a robust fishery, nor need they be applied when prior studies have already demonstrated a healthy ecosystem. Similarly, EPA should allow the State agencies to waive the requirement for new baseline monitoring, study, and modeling for facilities that (a) install or currently use any of the technologies either referenced by the EPA in establishing the proposed performance standards or that subsequently prove equally effective at producing net benefits or (b) can otherwise demonstrate equal or greater net benefit through the use of alternative technology or approaches. Post-compliance monitoring should be limited to that which is necessary to demonstrate proper operation of the technologies.

EPA Response

EPA has disallowed the use of historical determinations of BTA in today's final rule; however, existing data that is reflective of current conditions may be used to support the required studies. Please see response to comment 316bEFR.040.001 for details.

See also response to comment 316bEFR.034.005 for a discussion of the many streamlining efficiencies added to reduce burden in today's final rule.

Subject Matter Code 7.01.03

Option 3--Site-specific determination

With these and other key improvements, EPA's proposed rule regarding Section 316(b) permitting can result in a consistent decision-making framework that continues to provide flexibility to the States, building on a quarter-century of successful environmental protection. Improving the current permitting scheme would ensure that environmental concerns are addressed using the most cost-effective technologies to preserve and enhance affected waters. At the same time, EPA should preserve positive attributes of the existing Section 316(b) process, including its focus on site-specific analysis, and should allow States to rely on sound past data, analyses, and decisions to the maximum extent possible.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.072.021

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 17.07

Option: Site-specific based 1977 Draft Guidance

EEI's members pride themselves on careful and proactive management of their environmental responsibilities. They use state of the art environmental programs, management systems, and other practices that are directed at both compliance and fostering the implementation of innovative and practical pollution abatement and prevention measures. These efforts yield positive results for the environment, electricity consumers, and shareholders.

Water is critical to the functioning of many electric generation facilities and ancillary operations. EEI is concerned that the actions required in some of the regulatory alternatives considered by EPA in developing this rulemaking would impair the ability of power generation facilities to operate efficiently, from both an environmental and an economic perspective. Moreover, the imposition of costs associated with the installation of controls where they are not warranted can affect both the competitiveness of an individual facility as well as the efficient operation of the entire electricity generating sector.

Because electric utilities are the largest industrial users of cooling water, they have been heavily involved in the implementation of Section 316(b) of the Clean Water Act for the past 30 years. EEI members and the industry as a whole have spent hundreds of millions of dollars on research and development (R&D) related to §316(b) issues and, more importantly, have been applying the knowledge gained from that research to satisfactorily minimize adverse environmental impact at the State level. Many of the difficult issues being addressed in this rulemaking are the subject of ongoing entrainment and impingement research. In comments to EPA, the Utility Water Act Group (UWAG) and the Electric Power Research Institute (EPRI) summarize the latest scientific findings by many of the world's foremost research scientists. The relationships associated with understanding and reducing any potential adverse environmental impact related to cooling water intake structures at electric generation facilities are complex.

EPA Response

Please refer to the preamble for a discussion of the framework of the final rule.

Organization Edison Electric Institute

Subject Matter Code 10.1

General: cost tests

EEI offers in appendices to these comments recommendations on how to improve the Agency's economic impact analysis. While these recommendations by no means address all of the concerns with EPA's analysis, they try to highlight some of the issues that EEI believes will have the greatest impact on EPA's ability to draw reasonable conclusions. EPA has spent considerable time, effort and U.S. taxpayer dollars to develop sound cooling water intake structure regulations. We believe the information contained in industry's comments represents the state-of the-art knowledge about the science and policy surrounding the environmental issues associated with cooling water intake structures, and EPA should fully incorporate this information into its decisions on the proposed rule.

EPA Response

The Agency addresses the specific appendices in subsequent response to comments 316b.EFR.072.201 through 316b.EFR.072.210. This is a general statement and has no bearing on the Agency's final rule requirements or analysis outside of referencing more detailed comments included in the appendices.

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 7.01

RFC: Three-option framework for determining BTA

EEI will begin by discussing our perspectives on Section 316(b) and implementation of that section to date. We will then turn to EPA's proposed rule, including three of the alternative approaches considered by EPA in the preamble to its proposed rule:

1. Fully site specific alternatives, which EEI members strongly support and would prefer EPA to choose.

2. EPA's preferred option, which while not fully site-specific contains some basic elements of site-specificity that clearly should be preserved. In these comments, EEI offers EPA suggestions to make its proposal more meaningful and supportable by the regulated community and the States charged with its effective implementation.

3. The "Waterbody/ Capacity-based" alternative, which we focus on because it is the least stringent option that mandates the retrofit of closed-cycle cooling systems (cooling towers). Our comments will highlight why mandatory retrofit of cooling towers represents bad public policy. EEI members recommend that EPA reject this option and any other option with a broader cooling tower mandate.

The comments and attached supporting documentation also provide a critical analysis of the "Economic and Benefits Assessment for the Proposed Section 316(b) Phase II Existing Facilities Rule" performed by EPA in support of the proposed rule. While we do not present a comprehensive list of all concerns with EPA's analysis, our analysis finds that aspects of the EPA analysis suffer from technical and methodological shortcomings and should be redone to accurately reflect the impacts associated with the proposal.

These comments set forth the crucial concerns of EEI and its members with the provisions of the proposed rule, with particular attention to the preferred alternative, and provide constructive suggestions for addressing these concerns. EEI is also a member of the Utility Water Act Group ("UWAG"). With the assistance of EEI and the rest of the membership, UWAG has brought together some of the most skilled and respected technical, engineering, biological, legal and economic experts to comment on the substantive underpinnings of the rulemaking effort. EEI fully supports the comments submitted by UWAG and together we urge the Agency to consider modifying both its analyses of the rulemaking's proposed options and revising aspects of its preferred alternative to create a framework that is both streamlined and workable at the State level.

EPA Response

Please refer to the preamble for a discussion of the framework of today's rule.

EPA has rejected an entirely site-specific approach to implementing 316(b). Please refer to section VII of the preamble for further information.

EPA elected to not adopt any of the alternative technology-based options discussed in the proposed rule (67 FR 17154-17159). Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

Comment ID 316bEFR.072.024

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 17.07

Option: Site-specific based 1977 Draft Guidance

EEI members strongly believe that a structured site-specific approach is the most prudent method of regulating cooling water intake structures because it both streamlines and focuses the current regulatory programs existing in many States. Our view is reinforced by letters EPA has already received from State offices.

EPA received letters from the Environmental Departments of Illinois, Texas, and Pennsylvania, and a letter from the Governor of North Carolina. In these letters, the States stressed their continued commitment to a site-specific approach based on the reasonable comparison of costs to benefits. The letters also cited a desire not to reopen regulatory decisions that have already been made based on such a comparison, and a desire not to burden their regulated sources with technology requirements that have little environmental benefit. At least one of the States called for a more “holistic” definition of adverse environmental impact, that is, effect on the environment rather than just an accounting of impinged and entrained organisms. All but one of the States objected to a rule that would mandate retrofit of cooling towers in all cases.

In short, implementation of §316(b) by State permitting authorities is working. The need for regulatory guidance is driven by administrative and legal rather than environmental concerns. EPA has failed to develop a convincing demonstration otherwise.

EPA Response

EPA disagrees. Please refer to the preamble for a discussion of the framework of today's rule. Also refer to the preamble to the final rule for information as to why EPA is promulgating today's final rule.

EPA acknowledges receipt of the comments mentioned and has addressed these comments individually.

Comment ID 316bEFR.072.025

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 2.04

EPA's legal authority to:

EPA has not demonstrated that there is a clearly defined and widespread environmental problem resulting from impacts of cooling water intake structures. The case study examples in the rulemaking documentation are examples of those few unusual situations where, because of ongoing controversy, public attention has been focused on the actions taken. Therefore, these facilities have a considerable amount of data on the facility operation and/or waterbody on which it is located. It is for this anomalous reason these "data-rich" were chosen by EPA as case studies. However, these facilities are not representative of the universe of facilities for which thousands of Section 316(b) studies have been conducted and permits issued. EPA acknowledges that it has reviewed these numerous studies, so EPA should be aware of the positive track record States and utilities have in implementing Section 316(b) during the past several decades. In addition, EEI organized tours of facilities around the country for EPA staff and its consultants. During these tours we met with State water pollution authorities and environmental department personnel. Never did any of these officials point to ongoing issues with cooling water intake structures as being a leading cause of water quality impairment. The 1998 EPA report to congress on the status of our nations water resources also never listed cooling water intake structures as a source of impairment.

Even if the case studies were representative, the focus of the case studies is uniformly on the "dramatic" numbers of impinged and entrained organisms. As large as these numbers are, they have little meaning unless evaluated against population and community level impacts. Despite nearly 30 years of research, demonstration of population level impacts has not occurred. In fact, in the case of the Hudson, probably the most studied water body in the U.S. with multiple cooling water intake structures, several key fish populations have increased by an order of magnitude since the 1 980s. Similar increases have been observed in European studies. EPRI's on-going studies on the effects of water withdrawal on reservoirs is demonstrating no relationship between water withdrawal and fish population and aquatic community health.

EPA Response

Impingement and entrainment are primary harmful impacts associated with the use of cooling water intake structures. EPA has discussed the environmental impacts of cooling water intake structures in preambles to this rule and the phase I rule. As discussed in those sections, EPA does not agree that the only measure of adverse environmental impact is population level impacts. Finally, under the final rule, an existing facility that meets the applicable performance standards or restoration requirements (i.e., is applying BTA) does not have to install further technology to meet rule requirements.

Comment ID 316bEFR.072.026

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 18.01

RFC: Definition of "adverse environmental impact"

The EPA proposal says a great deal about the importance of site-specific decision-making but the proposal stops short of truly accommodating such decision making. The issues associated with minimizing adverse environmental impact that can occur as a result of cooling water intake structures are inherently site-specific and need to be dealt with accordingly. The proposal ignores the biological basis for decision making that EEI's members believe is central in Section 316(b) decision making and it does not address the central question of defining adverse environmental impact.

The Clean Water Act Section 316(b) states:

"[a]ny standard established pursuant to section 301 or section 306 of this Act and applicable to a point source shall require that the location, design, construction, and capacity of cooling water intake structures reflect the best technology available ["BTA"] for minimizing adverse environmental impact."

It is difficult to understand how one can minimize what is not defined, but this is exactly what EPA would suggest by proposing performance standards to reduce impingement mortality and entrainment by set percentages without regard to what, if any, adverse impact may be occurring.

In some areas of the country longstanding research has been done to define and measure what, if any, adverse environmental impact has occurred as a result of operation of cooling water intake structures. Studies conducted by both the Federal government and the private sector can provide substantive, scientifically rigorous information that EPA needs to consider prior to promulgation of the § 316 (b) Phase II rule.

To illustrate this point, consider the conclusions of the Maryland Power Plant Research Program (M-PPRP). The M-PPRP is the longest running, most comprehensive power plant research program in the U.S. and the Chesapeake Bay, the largest estuary in the U.S. After 25 years of study, it concludes: "....that while operations of individual power plants impact various ecosystem elements in various ways, those impacts, taken together, have had no identifiable substantive cumulative impact on Maryland's aquatic resources to date" (M-PPRP 1999 and Richkus and McLean 2000 in Dixon et al. 2000).

EPA Response

Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define "adverse environmental impact" in today's final rule. See also preamble to the final rule for a discussion regarding EPA's decision to express impingement and entrainment in terms of percent reduction.

Comment ID 316bEFR.072.027

Subject Matter Code 17.07

Option: Site-specific based 1977 Draft Guidance

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

By departing so radically from the long established practice of site-specific decision making advocated by the Agency in the mid-seventies, the proposed regulation may penalize both the regulated community and States that have acted responsibly to comply with Section 316(b).

Since the 1970s, EPA, State permitting authorities, and industry have worked side-by- side to protect the viability of aquatic communities affected by cooling water intake structures. The current methodology provides an adaptable, technology-neutral, site- specific approach that yields optimal, cost-effective, and scientifically sound results that protect the environment. The outcome of EPA's rulemaking should respect and reflect these hallmarks of the permitting program, while establishing a more streamlined and consistent decision-making process.

We are not advocating that EPA take no action if action is warranted, but rather that EPA take measured and appropriate action based on the scope of the demonstrable concern, the vast amount of science and knowledge that has been generated on §316(b) issues since the seventies, and the needs and limitations of existing State programs. We are also advocating that the EPA give full credit to States for the determinations that they have already made under existing authority.

EPA Response

EPA disagrees. Please refer to the preamble for a discussion of the framework of today's rule. Also refer to the preamble to the final rule for information as to why EPA is promulgating today's final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA elected to not adopt any of the alternative technology-based options discussed in the proposed rule (67 FR 17154-17159) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

With respect to the use of previous studies, a goal of today's rule is to set national minimum performance standards that reflect the best technology available for minimizing adverse environmental impacts. Given that previous determinations of best technology available were not made in reference to the national performance standards, EPA believes that the Director should not rely entirely on historical determinations. EPA believes that these national requirements will promote more effective and consistent implementation of section 316(b) requirements, and ultimately minimize adverse environmental impacts associated with the use of cooling water intake structures by Phase II existing facilities.

Comment ID 316bEFR.072.028

Subject Matter Code 17.06

Option: Site-specific determination of BTA

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Certain tenets about the interaction of cooling water intake structures and the environment have emerged in the more than 30 years it has been intensively studied.

First, the only way to accurately and appropriately select best technology available is on a site-specific basis. Site-specificity maximizes the ability to achieve the most environmentally effective and cost-effective reductions in adverse environmental impact. Moreover, site-specific technology selection is the only regulatory framework that is capable of maximizing net benefits to society. Technology selection should be based on a full examination of site-specific factors.

Second, a sound scientific basis for decision making is critical for making efficient decisions. There is an entire body of science surrounding fisheries management that should be used in any effort to improve the environmental and cost effectiveness of controlling cooling water intake structures. This science suggests that entrainment and impingement are not the sole, or even appropriate, biological endpoints in many cases.

Of course, there are also policy concerns that EEI believes are equally relevant and should be included when EPA takes final action on the proposed rulemaking. These include:

-The use of an appropriate benefit-cost test for selecting BTA. This is consistent with the Administration's goal of cost-effective regulation.

-Recognizing that a variety of protective intake technologies are available, the final rule should take advantage of the entire suite of alternatives and encourage innovation.

-Any final action should encourage the use of readily available data. Tools are available for quickly identifying low-risk sites and facilities, so the rule need not require extensive biological studies in every case. Streamlining decisions wherever possible is desirable.

-Streamlining decision-making is inextricably linked with preserving State authority. Where a State has already made a careful determination of the best technology available for a particular intake, a change in the State's decision is warranted only if there has been a change in circumstance since the decision was made.

-Finally, whatever regime is ultimately selected, the §316(b) rule for existing sources must protect our fisheries without adversely affecting national energy supply.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Please refer to the response to comment 316bEFR.005.020 for a discussion of the application of the cost-benefit test to assessing the value of alternative approaches.

A goal of today's rule is to set national minimum performance standards that reflect the best technology available for minimizing adverse environmental impacts. Given that previous determinations of best technology available were not made in reference to the national performance standards, EPA believes that the Director should not rely entirely on historical determinations. EPA believes that these national requirements will promote more effective and consistent implementation of section 316(b) requirements, and ultimately minimize adverse environmental impacts associated with the use of cooling water intake structures by Phase II existing facilities.

The final rule provides for EPA approval of alternative State program requirements where such State NPDES requirements will result in environmental performance within a watershed that is comparable to the reductions of impingement mortality and entrainment that would otherwise be achieved under § 125.94. (see § 125.90(c)).

Please refer to section XI of the preamble to the final rule and the Economic and Benefit Analysis (DCN 6-0002) for information about the effect of the rule on the national energy supply.

The proposed rule purports to establish national technology-based performance requirements applicable to the location, design, construction, and capacity of cooling water intake structures at existing power producing facilities. The proposal applies to existing electric generating facilities that use one or more cooling water intake structures withdrawing water from waters of the United States have or require a National Pollutant Discharge Elimination System (NPDES) permit, withdraw 50 million gallons per day (MGD) or more and use at least 25 percent of that water for cooling purposes.

EPA outlines a preferred alternative and invites comment on a broad array of other alternatives. These alternatives range from a stringent technology-based requirement for dry cooling at all existing facilities to several decision frameworks that would evaluate adverse environmental impact and determine the best technology available for minimizing such impact on a wholly site-specific basis.

In its preferred alternative, EPA sets forth performance requirements calling for the reduction of impingement mortality by 80-95% and in many cases reduction of entrainment by 60-90% in comparison to a theoretical “baseline.” The reductions required vary based on waterbody type, percentage of the source waterbody withdrawn and facility utilization rate.

Surface waters are grouped into five categories — freshwater rivers and streams, lakes and reservoirs, Great Lakes, estuaries and tidal rivers, and oceans — with different requirements for cooling water intake structures for each distinct waterbody type. According to EPA, the more sensitive or biologically productive the waterbody, the more stringent the proposed requirements.

In discussing its preferred alternative, EPA describes that a facility may choose one of three options for meeting best technology available requirements. These options include:

-Demonstrating the facility currently meets specified performance standards;

-Selecting and implementing design and construction technologies, operational measures, and/or restoration measures that meet specified performance standards; or

-Demonstrating that the facility qualifies for a site-specific determination of best technology available because its costs of compliance are either significantly greater than those considered appropriate by the Agency, or the facility’s costs of compliance would be significantly greater than the environmental benefits of compliance with the proposed performance standards.

This latter “site-specific alternative” is both appropriate and desired public policy. However, this option needs to be modified to ensure the selection of alternatives that maximize net benefits to society. EPA also proposes to allow alternative requirements where the Nuclear Regulatory Commission (NRC) determines that compliance with the rule would conflict with NRC-established safety requirements, an appropriate provision that EEI supports. EPA should provide similar flexibility for other special requirement situations, such as where an endangered species, non-native species, or arid conditions are present.

EPA Response

For a description of the framework of the final rule, please refer to the preamble.

EPA adopted this regulatory scheme because it provides a high degree of flexibility for existing facilities to select the most effective and efficient approach and technologies for minimizing adverse environmental impact associated with their cooling water intake structures. This approach also reflects EPA's judgment that, given the various factors that affect the environmental impact posed by the range of Phase II existing facilities, different technologies or different combinations of technologies can be used and optimized to achieve the best results.

EPA also notes that 125.94(f) allows for a site-specific determination of best technology available if conflict with Nuclear Regulatory Commission safety requirements.

RFC: Three-option framework for determining BTA

The preceding summary of EPA's proposal is consistent with the description of how the rule would work as set out in the preamble. However, the regulatory language itself is insufficiently clear to guarantee that the rule would be applied in this manner. In particular, the language in § 125.94 of the proposed rule is confusing and could lead to an interpretation that is clearly at odds with the Agency's stated intent.

The confusion is created by the inclusion of § 125 .94(b)(1), which says that to demonstrate compliance with the performance standard, one option is for a facility to "reduce [its] intake capacity to a level commensurate with the use of a closed-cycle re-circulating cooling system." This could erroneously be interpreted as the basis for the performance standard.

By way of background, proposed § 125.94(a) specifies that to comply with the proposed rule, facilities must comply with performance standards set in § 125.94(b) or demonstrate that a site-specific determination of BTA is warranted under § 125.94(c). In turn, § 125.94(b) sets out the impingement and entrainment percentage reduction requirements discussed above as well as the cooling water provision just mentioned. Section 125.94(c) allows a facility owner to demonstrate that a less costly alternative than would be mandated by those performance standards is warranted because the costs of meeting the numerical limits are either (a) significantly greater than the costs considered by the Agency in establishing the standards, or (b) significantly greater than the benefits of complying with the numerical standards. Finally, § 125.94(d) allows use of restoration measures that maintain the fish and shellfish within the waterbody at a level comparable to those that would result if the numerical standards were met.

Taken in this context, §125.94(b)(1) could be read to require the installation of closed-cycle cooling if a facility could not demonstrate to the satisfaction of the director that the costs of meeting the numerical limits were too high — relative to costs or benefits — and could not achieve the numerical limits through the installation of some other technology, such as fine mesh traveling screens. This outcome may not be likely given that costs of installing cooling towers are almost certain to be significantly greater than the costs considered by the Agency in establishing the standard — no facility in any of the analysis of EPA's preferred alternative is required to install closed-cycle cooling. Nevertheless, the current language is confusing.

We surmise that EPA included § 125.94(b)(1) to indicate that installation of cooling towers is a prima facia demonstration of compliance with the numerical limits established in § 125.94(b)(2)(3) and (4). But by placing that provision in § 125.94(b), EPA risks driving the §316(b) decision process by reference to cooling towers. Moving this language elsewhere in the regulation would eliminate this source of confusion.

One alternative would be to renumber current §l25.94(b)(2-4) as §125.94(b)(1-3) and replace current § 125.94(b)(1) with a new sentence at the end of 125.94(b) that reads: "If your facility has an intake capacity commensurate with a closed-cycle recirculating cooling system, you meet the performance standards without the need for further analysis." Another alternative would be to include similar language in § 125.94(a)(1) to remove the concept of closed-cycle cooling from the definition of performance standards altogether.

Perhaps the best alternative would be to move the discussion of closed-cycle cooling to §125.91 as follows:

§ 125.9 l(a)(5): Does not have an intake capacity level commensurate with the use of a closed-cycle, recirculating cooling system.

This alternative has the added benefit of relieving facilities and permitting authorities from the burden of preparing and reviewing the additional information required in § 122.21 including: the source Water Baseline Biological Characterization Data at facilities with closed-cycle cooling systems. This information will have no practical utility for these facilities since they already meet the standards.

EPA Response

EPA believes that the perceived confusion noted by the commenter has been resolved. The final rule contains five compliance alternatives from which a permittee may choose, one of which specifically addresses facilities with cooling towers. EPA agrees that facilities with intake flows commensurate with a closed-cycle cooling system meet the requirements for 125.94(a)(1)(i) and will be subject to fewer reporting requirements. Please refer to the preamble for a discussion of the framework of the final rule.

Examination of a wide variety of alternatives

We appreciate the effort that EPA put into examining a wide variety of alternative approaches to the regulation. Moreover, we are encouraged that, based on the analysis performed by the Agency, EPA sought to choose the approach among those considered that provided the greatest net benefit to society, a correct goal.

EPA outlines a preferred alternative and invites comment on a broad array of other alternatives. These alternatives range from a stringent technology-based requirement for dry cooling at all existing facilities to several decision frameworks that would evaluate adverse environmental impact and determine the best technology available for minimizing such impact on a wholly site-specific basis.

The "Economic and Benefits Analysis" produced by the Agency in support of the rule provides benefit and cost estimates for five alternative approaches to the regulation. The net benefit estimates for these alternatives range from a negative $2.3 billion for the alternative requiring universal retrofit of wet cooling towers to a positive $452 million for the proposed rule. EPA correctly chose its preferred option as the basis of the proposal from among these options even though that option has the lowest absolute benefit estimate, because the incremental costs associated with the achieving each additional level of benefits were greater than the additional benefits achieved.

For example, moving from the preferred alternative to the next most stringent alternative —universal application of I&E controls — would increase the estimated benefits of the rule by $14 million. Unfortunately, it would cost $17 million to achieve that additional $14 million in benefits, and society would be made worse off by three million dollars. As a result, moving from the preferred option to the next most stringent alternative would not represent sound environmental policy. The negative incremental benefits become even greater as the stringency of the alternative chosen increases EPA recognizes that the correct decision criterion is not whether the total net benefits of the rule are greater than zero, but whether the estimated incremental benefits between alternatives can be justified.

As will be discussed later, the total net benefit associated with any of the cooling tower options is negative if a more realistic estimate of cooling tower costs is used.

We will also discuss the fact that EPA's proposed benefit-cost test for site-specific determinations is not consistent with the good principles EPA used in selecting between regulatory options.

It should be noted that although EPA selected the correct regulatory alternative from among those it examined, a wholly site-specific alternative would have even higher net benefits. There are undoubtedly situations where the performance standards established by the Agency will be inappropriate at a given facility. A site-specific approach would allow the permittee to work with the permit writer to select the alternative that provides the greatest net benefit at each individual facility. EPA makes some attempt to address the most egregious deviations from site-specific benefits maximization by including two cost tests that can be used by a facility to justify a site-specific alternative. As currently proposed, however, these tests do not sufficiently support the maximization of net benefits, and the tests need to be improved in ways we will recommend.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

Comments regarding the net benefits of a cooling tower option or the benefit-cost test for site-specific determinations will be addressed individually in other comments.

EPA did not select an entirely site-specific option for a variety of reasons. Please refer to the preamble for more information. However, a facility may still opt to seek a site-specific determination of best technology available under the fifth compliance alternative. In addition, use of a TIOP, with the approval of the Director, can help address site-specific conditions.

General: cost tests

Inclusion of a cost-cost test

We are encouraged that EPA's proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that impact the technical practicability of meeting the proposed standards. Specifically, the Agency recognizes that there may be situations where the costs of meeting the proposed standards at a specific facility may be significantly higher than the costs considered by the Agency in establishing these standards. In those instances, the proposal provides the facility with the opportunity to justify an alternative technology selection.

Facilities can demonstrate that a site-specific alternative is warranted if the costs of achieving the standards at a given facility are significantly greater than the costs considered by the Agency in establishing the standards. While this falls short of site-specific technology selection in all instances, it does provide an important safety valve. It should be noted, however, that this provision, by itse1f, does not avoid all situations where achieving the standards reduces net benefits to society, because it does not consider the benefits associated with achieving the standards at a given facility. So EPA needs to retain both the cost-cost and benefit-cost tests.

EEI recommends that this provision of the proposal be retained in the final rule.

EPA Response

The Agency includes the cost-cost and cost-benefit tests in the final rule. Therefore, the commenter's concerns and recommendations have been met.

RFC: Cost: benefit ratio for site-specific BTA?

Inclusion of a benefit-cost test

We are further encouraged that EPA’s proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that indicate that the costs of meeting the performance standards are not warranted by the projected benefits at that facility. The rule allows facilities to select an alternative level of compliance where the costs of compliance with the EPA’s performance levels would be significantly greater than the expected benefits of achieving these levels. This explicitly recognizes the site specific variations in the ecology of source water bodies and can help account for controls already in place at many facilities.

A site-specific evaluation of benefits and costs is the only means of guaranteeing that the benefits of §316(b) are maximized at every facility. The benefit-cost provision in EPA’s proposed rule will help avoid extreme cases where the application of technology will make society worse off in absolute terms, but it will not allow States and facilities to maximize the net benefits of the standards.

Therefore, while we strongly support the inclusion of a benefit-cost provision in the rule, we believe that the “significantly greater than" test should be replaced with a provision that allows facilities to select a site-specific alternative if they can demonstrate that it will lead to a greater net benefit than would meeting the performance standards set forward in the rule. This alternative is discussed in greater detail later in these comments.

EPA Response

See the preamble for a discussion of the site-specific compliance alternative.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

For EPA's response to comments on application of the "significantly greater then" test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.006.003.

RFC: Three-option framework for determining BTA

Allowance for flexibility in compliance

We are also encouraged that the Agency has chosen a flexible approach to compliance that allows facilities to meet the performance standards through a number of options, including creation or restoration of habitats and other non-traditional approaches. This does not freeze compliance in time by relying on today’s technologies and allows for continued innovation in addressing the potential adverse environmental impacts associated with impingement and entrainment at power generating facilities. This also leaves significant discretion in determining how best to comply with the standards to State permitting authorities and facilities managers who have developed a great deal of expertise on these issues over the past 30 years.

The proposal goes a long way in recognizing that many technologies, including those specifically identified in the proposal (wedge wire screens, fine mesh screens, fish returns, and aquatic fabric filter barriers) can be effective in reducing impingement mortality and entrainment but that no single technology will be the “best available."

The proposal goes even further to allow the use of methods other than the installation of end-of-pipe controls to meet the requirements of the rule.

EEI recommends that the EPA retain the flexibility of the proposal in the final rule. Later in these comments, we will discuss an alternative approach that would streamline the permitting process for facilities that choose to install those technologies that the EPA has determined will met the standards. This alternative is not intended to reduce the flexibility of the approach taken by EPA in the rule, but as a means of reducing transaction costs for the States and permittees at those facilities that do not need the flexibility provided by the proposal.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA does not specify any single technology as best available, but also recognizes that many technologies can be highly effective in reducing impingement mortality and entrainment.

AREAS OF CONCERN

Still, there are a number of areas of the proposed rule and the supporting analysis that cause us concern. These fall into two categories: concerns with the design of the regulation and concerns with the methodology used to support it. The balance of this document discusses our regulatory design and methodological concerns with an expanded discussion provided in Appendix 1-4. The concerns discussed below are not meant to be an exhaustive list of all of the concerns with EPA's analytical methodology, instead we try to highlight some of the concerns that we believe have the largest potential impact on EPA's ability to draw a reasoned regulatory conclusion.

EPA Response

Please refer to the preamble for a discussion of the framework of today's rule. No further response is required, as the concerns referred to in this comment will be addressed individually in other comments.

Option: Site-specific based 1977 Draft Guidance

EPA fails to demonstrate a compelling need to overturn the existing system.

EPA suggests that there is a demonstrable environmental problem that needs to be solved by citing 8 case studies or examples of facilities where ongoing work is being pursued to minimize adverse environmental impact resulting from cooling water intake structures. In fact, the case studies used by EPA in its technical and economic support documents are appropriate as case studies not because they represent the norm but because of the very fact that they represent the small number of facilities where there remains some ongoing concern or continuing research to measure the extent of the impact caused by cooling water intake structures. EPA itself points out that it has a large number of Section 316(b) demonstration studies and permits showing little if any evidence of adverse environmental impacts occurring at these facilities.

In addition, ample studies exist that cast doubt upon the need for such a sweeping change in the existing system. The M-PPRP examines the largest estuary in the U.S., one that has historically yielded large harvests of a wide variety of fish and shellfish. Thirteen power plants, withdrawing and discharging 8 billion gallons per day of the Bay's waters for cooling purposes, are located on the main stem of the Bay.

Even though EPA has identified estuaries as being particularly sensitive to the effects of cooling water intake structure operations; it failed to note the conclusions of the M-PPRP: "...that while operations of individual power plants impact various ecosystem elements in various ways, those impacts taken together, have had no identifiable substantive cumulative impact on Maryland's aquatic resources to date" (M-PPRP 1999 and Richkus and McLean 2000 in Dixon et al. 2000).

Moreover, in 1996, in preparation for the impending relicensing of nuclear power plants in the U.S., the U.S. Nuclear Regulatory Commission (NRC) published the results of a multi-year study of the generic environmental impacts resulting from the operation of nuclear generating stations. (NRC 1996). The NRC study explicitly examined the impacts of impingement and entrainment at nuclear plants with once-through cooling water operations. NRC did not reference any specific population level impact with regard to plants where impingement and entrainment remains an issue or a concern. In fact, where issues or concerns remain, they were based solely on the subjective opinions of State regulators and resource agencies. The NRC concluded due to unresolved impingement and entrainment issues at some plants that this issue should be dealt with on a site-specific basis during plant relicensing.

EPA, in its own biannual report to Congress on the quality of our nation's water, never identified cooling water intake structures as a source of water quality impairment. In searches of the 1998 Report to Congress, specifically the Executive Summary, Chapter 3 (Streams and Rivers), Chapter 4 (Lakes and Reservoirs), Chapter 5 (Coastal Resources including Estuaries and Coastal Oceans), and Chapter 8 (Aquatic Life Concerns), the key words cooling water intake structure, impingement, entrainment and water withdrawals are not found. This is fully consistent with the fact that, when EEI hosted EPA on various power plant tours throughout the nation, no State employee or natural resource manger noted that cooling water intake structures were a priority concern in the management of the State's water resources.

On the Connecticut River, from 1965-1972, a comprehensive study on the effects of Connecticut Yankee was performed. The study concluded that impacts were not expected to be significant. (AFS monograph #1 (Merriman, D., and L. M. Thorpe. 1976. The Connecticut River Ecological Study: Impact of a Nuclear Power Plant. American Fisheries Society Number 1, Bethesda, MD.).

In the Fall of 2001, EPRI brought the original scientists and State personnel back together to re-visit the original studies conclusions. ALL persons involved — including State regulatory personnel — concluded that the plant had "benign" impacts on the River. (EPRI. 2002. Proceedings of Workshop — Connecticut River Ecological Study: Revisiting the Impacts of a Nuclear Power Plant. EPRI Workshop held at University of Connecticut Marine Laboratory, Avery Point, CT, November 15-16, 2001. EPRI CD 1006900, April 2002. Palo Alto, CA.)

EPA seems to be applying the precautionary principle, and has structured a proposal that mandates that every facility must "do something" to reduce environmental impact even if there is no evidence that adverse impact is occurring.

EPA Response

EPA disagrees. Please refer to the response preamble for a discussion of the framework of today's rule. Also refer to the preamble to the final rule for information as to why EPA is promulgating today's final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Subject Matter Code 17.06

Option: Site-specific determination of BTA

EPA's proposed rule is insufficiently site-specific

The EPA proposal says a great deal about the importance of site-specific decision-making but stops short of truly accommodating it. The issues associated with minimizing adverse environmental impact that can occur as a result of cooling water intake structures are inherently site-specific and need to be dealt with accordingly. Site-specific determination of the "best technology" is the only way of ensuring that net benefits to society are maximized.

Since the 1970s, FPA, State permitting authorities, and industry have worked side-by-side to protect the viability of aquatic communities affected by cooling water intake structures. The current regulatory system provides an adaptable, technology-neutral, site-specific approach that yields optimal, cost-effective, and scientifically sound results that protect the environment. The outcome of s rulemaking should respect and reflect these hallmarks of the permitting program, while establishing a more streamlined and consistent decision- making process.

EPA is proposing to abandon the current site-specific decision making framework in favor of a uniform national performance standard that only allows consideration of site-specific factors as a basis for exception from the standards. This proposed change would allow suboptimal technology determinations to stand except in extreme circumstances, significantly reducing the ability to maximize net benefits.

EPA Response

EPA disagrees. While EPA rejected a purely site-specific approach, EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

Comment ID 316bEFR.072.038

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 9.06

Burden to facilities (general)

EPA has expressed concern that a site-specific approach may be too burdensome for State permit writers to easily administer. There are several reasons why this is not the case. First, this approach has been implemented for 30 years and the science and understanding of cooling water intake structure effects are better understood and approaches to study the issue better refined than in the seventies. Second, for the past 30 years, site-specific implementation has been done (successfully) without the aid of a formal rule and companion guidance. Presumably, once an approach is clearly communicated to the States, implementation will be easier to implement and reasonably consistent. Moreover, under a risk assessment/site-specific approach, permittees bear the burden of collecting and analyzing information with which the Director will make a determination. This would ease the workload of State permit writers.

By departing so radically from the long established practice of site-specific decision making advocated by the Agency in the mid-seventies, the proposed regulation would penalize both the regulated community and States that have acted responsibly to comply with Section 316(b). Furthermore, this approach to Section 316(b) ensures that more societal resources will be spent complying with the section than warranted.

EPA Response

The final rule includes site-specific regulatory provisions. See § 125.94(a)(5). Therefore, the commenter’s concern in that matter has been met.

The commenter’s premise that because site-specific implementation has been the status quo method of implementation for 30 years means that it is the least burdensome approach is faulty logic, in the Agency's opinion. The Agency believes that historical implementation of 316(b) has in cases been sufficiently burdensome to permit writers over the past 30 years to warrant a new approach. As such, the Agency has included a combination of national standards, a flexible implementation pathway, alternative regulatory options for site-specific cases, pre-approved technology fast-track pathways, and substantial guidance in implementing the final regulation. The ultimate approach will serve to reduce the extreme cases of burden that have plagued the industry and permit writing community over the past 30 years and provide a steady but manageable workload to permit writers.

Subject Matter Code 17.06

Option: Site-specific determination of BTA

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Under the proposed rule, site-specific factors would be considered only in exceptional circumstances, not as the basis for technology determinations. Both of the proposal's cost tests include a "significantly greater than" requirement that is incompatible with the goal of maximizing net benefits to society. While these tests may prevent some truly egregious technology applications, it is not clear that they are designed to lead to significantly better technology determinations.

RECOMMENDATION: EPA should promulgate a rule that is based on a site-specific determination of the best technology. The site-specific alternative regulatory plan submitted by PSEG and included in the preamble is a good model for such a program. If EPA persists with promulgation of a rule based on the "preferred alternative" as proposed, the Agency must broaden consideration of site-specific factors through modification of both the cost-cost test and the benefit-cost test.

EPA Response

EPA disagrees. While EPA rejected a purely site-specific approach, EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Please refer to the responses to comments 316bEFR.005.020 and 316bEFR.410.001 for a discussion of the application of the cost-benefit and cost-cost tests.

EPA elected to not adopt any of the alternative technology-based options discussed in the proposed rule (67 FR 17154-17159) in today's final rule, including the approach proposed by PSEG. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

Subject Matter Code 18.01

RFC: Definition of "adverse environmental impact"

EPA's proposal is not based on the correct biological endpoint.

The proposal ignores the biological basis for decision making that EEI's members believe is central in Section 316(b) decision making and it does not address the central question of defining adverse environmental impact.

The Clean Water Act Section 316(b) states:

[a]ny standard established pursuant to section 301 or section 306 of this Act and applicable to a point source shall require that the location, design, construction, and capacity of cooling water intake structures reflect the best technology available ["BTA"] for minimizing adverse environmental impact.

It is difficult to understand how one can minimize what is not defined, but this is exactly what EPA would suggest by proposing performance standards to reduce impingement mortality and entrainment by set percentages without regard to what, if any, adverse impact may be occurring. EEI makes the following two recommendations aimed at rectifying this issue.

Define Adverse Environmental Impact

The proposal lacks a definition of the statutory term "adverse environmental impact" (AEI). EEI believes that defining AEI will lead to better, more streamlined decision making, focusing resources where they will have the greatest impact. In fact, we believe it is a necessary precondition to the application of any best technology available determination.

The lack of a definition for AEI in the proposed rule leads one to conclude that any impingement mortality and any entrainment is adverse. This is not consistent with fisheries management science — which focuses on management of populations and communities of species rather than individuals — or with current practice and past precedent as expressed by EPA.

In EPA's draft 1977 guidance for §316(b) the Agency states "[t]he exact point at which adverse aquatic impact occurs at any given plant site or waterbody segment is highly speculative and can only be estimated on a case-by-case basis by considering the species involved, magnitude of the losses, years of intake operation remaining, ability to reduce losses, etc." U.S. EPA, Office of Water Enforcement, Guidance for Evaluating the Adverse Impact of Cooling Water Intake Structures on the Aquatic Environment: Section 316(b) P.L. 92-500 at 11 (Draft May 1, 1977). If magnitude of losses and reductions of losses were to be considered it stands to reason that adverse environmental impact must be more than the loss of one individual.

RECOMMENDATION: EPA Should Define "Adverse Environmental Impact." In doing so the Agency should remain consistent with accepted biological management models that stress the maintenance and protection of populations not simply the protection of individuals. Essentially, the definition should embody the notion that the structure and function of the aquatic community be preserved. The utility industry has recommended an appropriate definition <FN 1> of AEI in prior comments filed with the Agency on different phases of this rulemaking.

Footnotes

1 UWAG and EEI recommend the following definition:
Adverse environmental impact is a reduction in one or more representative indicator species that (1) creates an unacceptable risk to the population's ability to sustain itself, to support reasonably anticipated commercial or recreational harvests, or to perform its normal ecological function and (2) is attributable to the operation of the cooling water intake structure.

EPA Response

Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define "adverse environmental impact" in today's final rule.

UWAG definition of "adverse environmental impact"

Allow Ecological Risk Assessment to Provide Basis for AEI Determinations

As described in the decision principles presented by UWAG (see UWAG Comments, Appendix 2), the use of ecological risk assessments provide an Agency-endorsed approach that can be used to demonstrate whether there is any risk of AEI occurring, how much risk may be occurring, and what technology is "best" for a site under §316(b). The Agency has been reluctant to embrace a definition of AEI, asserting that it is a difficult and often variable target to assess. However, assessing risk using a structured AEI decision making process consistent with EPA's 1998 Ecological Risk Assessment Guidelines would provide both the process and the consistent decision making framework that EPA suggests would be lacking if a site-specific approach were to be implemented. Furthermore, EPRI's recent report Evaluating the Effects of Power Plant Operations on Aquatic Communities (EPRI Report 100758 July 2002) offers an "ecological risk assessment framework" for §316(b) demonstrations.

EPA Response

Please see the response to comment 316bEFR.002.019 for the discussion on the definitions EPA rejected for adverse environmental impact in this rulemaking. For these same reasons, EPA has rejected an ecological risk assessment framework for section 316(b) demonstrations in the NPDES permitting program.

Cooling system costs (e.g., dry, wet, recirculating)

The estimated cost of a cooling tower retrofit was grossly understated.

EPA's estimate of the cost of a cooling tower retrofit was based largely on the extrapolation of a single datapoint representing a "rule of thumb" guess by a vendor for a non-representative size of cooling tower. The resultant cost "equation" was significantly at odds with any estimate from any other study that has been done on this subject. The costs of a cooling tower retrofit are likely to be at least twice what EPA states they will be.

As a result, any regulatory alternative that would require the retrofit of cooling towers is even more undesirable than would appear to be the case based on EPA's analysis. Based on our recalculation of the Waterbody/Capacity-based alternative, this — and all other cooling tower alternatives — would have negative net benefits. These net costs become even greater when our concerns over EPA's benefits estimates are considered.

Applying EPA's retrofit equation for redwood cooling tower installation yields a rough average cost estimate of $80 per gpm for redwood towers. Other analyses performed by DOE, the industry, and elsewhere in the literature all find that the costs of tower retrofits are between $140 and $225 per gpm:

[see hard copy for table]

EPA's estimate is half or less than the costs estimated by other sources.

As a result, the costs associated with any option involving cooling towers will increase significantly if more realistic numbers are used. For example, the costs of the 'Waterbody/capacity based option" — the option with the fewest additional cooling towers —increase from $970 million to $1.7 billion.

RFC: Appropriateness of "significantly greater"

EPA's failure to define "significance" for either of its cost tests creates unnecessary uncertainty in the rule.

The EPA proposal contains both a cost-cost test and a benefit-cost test to account for site specific variations in costs and benefits that may affect whether meeting the EPA's proposed performance standards is appropriate at any given facility. As discussed above, EEI members support these tests as providing a necessary option to avoid the application of technologies to plants where such application clearly does not make sense.

However, both of these cost tests rely on facilities demonstrating that the costs faced at that facility are "significantly greater" than either the costs considered by EPA in establishing the standards or the expected benefits of applying the standards at that specific facility. Unfortunately, the term "significantly greater" is never defined. This limits our ability to judge how useful these necessary provisions will be. In addition, the "significantly greater" decision criterion is inappropriate for making determinations based on a weighing of benefits and costs — this will be discussed in greater detail below.

By choosing the term "significantly greater," EPA is abandoning an earlier standard of "wholly disproportionate." We assume EPA intended that facilities could demonstrate that costs were significantly greater before they reached the level of wholly disproportionate. Common sense would suggest that two cost estimates are proportionate if they are roughly the same. If one estimate were twice as high as the other, they would clearly be out of proportion. Therefore, significantly greater would need to be some difference less than two times the cost considered by the EPA in establishing the standard or two times the estimated benefits of compliance with the performance standards.

Another interpretation of significance would be that used in statistics. The difference between two numbers is determined to be statistically significant if the two numbers can be demonstrated, to a given level of certainty, to be different. To make this demonstration with respect to cost estimates, one requires information on the variance in cost estimates that the Agency considered. Unfortunately, the EPA did not provide this information.

RECCOMMENDATION: EPA should either delete the "significantly greater than" requirement for purposes of the cost tests that it includes in the rule or define the term. If the term is retained, EEI suggests that it should be defined as a multiplier between zero and one.

EPA Response

RFC: Appropriateness of "significantly greater"

"Significantly greater than" is an inappropriate decision criterion for weighing costs against benefits.

While we support the consideration of site-specific benefits, the benefit-cost test proposed in the rule uses the incorrect decision criteria. EPA only allows site-specific alternatives to be considered if the cost of achieving the standard is significantly greater than the expected benefits of compliance. Moreover, EPA only allows deviation from the standard to the extent justified by the significantly greater costs. This could be read to imply that a facility must install a technology that has no net costs or net benefits. As explained below, this allows socially suboptimal solutions to be implemented. The correct decision criterion would be to allow facilities to select the control alternative that maximizes net benefits.

EPA considers four possible alternative criteria for identifying the "best technology" in the proposed rule:

(1) the wholly disproportionate cost test, whereby the alternative which exhibits the greatest environmental gain without bringing about costs which are "wholly disproportionate" to the benefits (of the environmental gains) is preferred (p. 17165);

(2) a modified wholly disproportionate cost test proposed by Public Service Electricity and Gas Company (PSEG), whereby the alternative which exhibits the greatest net benefits (difference between benefits an costs) without bringing about costs which are "wholly disproportionate" to the benefits is preferred (p. 17166);

(3) a significantly greater cost to benefit test, whereby the alternative which exhibits the greatest environmental gain without bringing about costs which are significantly greater than the benefits is preferred (p. 17166); and

(4) a benefits should justify the costs test, proposed by the Utility Water Act Group (UWAG), whereby the alternative which exhibits the greatest net benefits without bringing about negative net benefits is preferred (p. 17165). The Proposed Rule's description of the UWAG recommendation incorrectly refers to the ranking as one characterized by "cost-effectiveness," whereas the ranking is actually according to efficiency (page 17165).

The latter is the preferred alternative. Economic thinking looks toward the test that will lead consistently to decisions that are in the general social interest. When comparing different options, economics dictates that the option with the greatest difference between benefits and costs is the best option. This is the universally accepted "Kaldor-Hicks test," which is the basis of benefit-cost analysis and which is the prescribed method in EPA's own "Guidelines for Preparing Economic Analyses."

In the §316(b) context, the technology adopted by a company is in society's interest if the present discounted value of net benefits is greater the net benefits of the alternative options - including the status quo. EPA incorrectly interprets this approach as meaning the best choice is that alternative which exhibits the greatest environmental gain so long as it does not create costs which are significantly greater than the benefits of other options.

The basis for including a benefit-cost test is to avoid the implementation of controls where those controls are not be warranted by sound public policy principles. One such instance may be where a facility is drawing water from a waterbody that does not support life. In this instance installing screens to protect organisms that do not exist would not be a wise use of society's resources. Another instance could be where a facility already has controls in place that achieve a level of control that is less than the EPA's proposed standards. In this case, the marginal improvement associated with replacing the existing controls may not warrant the level of expenditure required to make those improvements.

To put this in more concrete terms, we would provide the following hypothetical example. For the purposes of this discussion we will assume that there is a facility that faces the following four alternative technology scenarios:

Alternative Approach	Cost	Expected Benefits
Alternative 1: Controls already in place	"$0"	$300
Alternative 2: First order control (e.g. move intake)	$283	$735
Alternative 3: EPA proposed standards	$610	$890
Alternative 4: Greater control (e.g. cooling towers)	$3,507	$1,223

In this example, Alternative 2 would be the economically preferred alternative because it would provide the maximum benefit in excess of cost — net benefit — ($735 - $283) of any of the alternatives. Yet under EPA's current proposed rule, a facility could not make a case for Alternative 2 because the costs of Alternative 3 do not exceed its benefits. As a result, the facility would have no basis for arguing for a site-specific approach that would allow selection of Alternative 2. However, this would lead to a socially suboptimal outcome, since the net benefit of Alternative 3 is only $280 whereas the net benefit of Alternative 2 is $452. Put another way, the incremental cost of moving from Alternative 2 to Alternative 3 is $327 while the incremental benefit is only $155. Society is made worse off by $172, and the benefit-cost provision in EPA's rule does nothing to avoid this outcome. This situation would arise any time existing controls generate benefits in excess of the net benefits of achieving EPA's proposed new standards at a given facility.

As part of the maximum net benefits analysis, EPA also must allow consideration of past actions taken by States and permittees in determining the benefits of new technologies if it is to reach the correct decision. In addition, this consideration of past expenditures is consistent with the concept of fairness as well as efficiency. EPA should avoid doing anything in this rulemaking that would punish those facilities, relative to their competitors, for past actions taken in good faith that were consistent with the environmental goal of reducing adverse environmental impacts from the operation of cooling water intake structures.

Thus, EPA needs to ensure that the cost-benefit test also compares incremental costs and benefits between existing technology at a facility and any additional technology being considered at the facility. Again in this example, if the benefits already being generated by the existing controls are considered, a much different conclusion is reached. In this instance, we would be incurring $610 in costs to generate $590 in benefits, for a negative net benefit of $20. Even so, the “significantly greater than” standard means that the permittee might be required to adopt changes that would produce a negative benefit to society. Instead, the maximum net benefits test should be used.

The numbers used in the example above are not used by coincidence. They are one millionth of the costs used by EPA to justify the rule nationally. Alternative 2 represents the benefit and cost estimates of the proposed rule. As discussed previously, EPA correctly chose the alternative that maximized net benefits from among the alternatives examined. However, the proposal forbids facilities from doing the same at individual sites. This reduces the net benefits of the rule unnecessarily.

RECOMMENDATION: EPA should allow facilities to demonstrate that a site-specific alternative approach is warranted based on a demonstration that the net benefits of the alternative are greater than the expected net benefit associated with meeting the performance standards proposed in the rule.

RFC: Three-option framework for determining BTA

EPA Should Streamline BTA Decision making to Reduce Implementation Costs

EPA and some States have expressed concern that the flexibility afforded in the preferred alternative could either:

1) create a situation where permittees may immediately take advantage of the site specific determination compliance option and attempt to demonstrate that no action is required at a particular facility; or

2) produce an undue administrative burden to State permitting authorities as a result of site- specific demonstration information requirements. EEI believes that scientific facts and understanding of the adverse environmental impact at a particular situation are indeed what should predominate in a BTA decision making. If the demonstration from the permittee leads the State to making a no action decision, then so be it. As explained elsewhere in these comments, if EPA added certain streamlining provisions to the preferred alternative, combined with experience from past years, maturing science, and the fact that the burden of demonstration falls to the permittee, EEI does not believe tint the burden on State permitting authorities will be excessive or unmanageable.

Having said that, EPA could modify the proposal to add a “technology-specific” option based on the same technologies as EPA’s proposal while still allowing permittees to demonstrate that the technology does not meet the cost-cost or cost-benefit tests at their particular facility. This would afford a much simpler implementation path for facilities that choose to install one of the specific technologies that EPA has reviewed for this rulemaking. This addition would save time and money, deploy technologies in suitable circumstances quicker than otherwise would be done, and considerably reduce the administrative burden to State permit authorities and reduce transaction time associated with permit negotiations.

The EPA performance standards are based on the performance of technologies that the Agency is confident can meet the standards. However, the proposal requires significant resources be devoted to demonstrating that installation of these technologies will meet these performance levels at each individual facility. A significant portion of the burden on State permitting authorities associated with this rule is a direct result of these studies and demonstrations. These studies and demonstrations, while adding to burden (and delaying implementation) do not provide any additional information concerning the performance or implementation of the technologies discussed in the proposal.

The NPDES permit would not need to specify a numerical limit on the number or mass of fish entrained or impinged or on the percent reduction, but the commitment to install, operate, and maintain an approved technology would be enforceable. Once the permittee had installed the approved technology, his or her continuing obligation would be to verify periodically that he or she was properly maintaining and operating the technology.

There are two reasons why such an addition should not be viewed as inhibiting technology advancement. First, the approved technologies cannot be deployed cost effectively in all cases — EPA implicitly acknowledges this fact by including a site-specific alternative to account for those instances where unique situations occur that affect the practical deployment or cost associated with installation of these technologies. Second, with the site-specific alternative still in place, regulated entities would have built in incentives to find cost-effective and environmentally protective technologies that meet the performance standards.

In fact, this alternative may present a unique means for EPA to promote innovation and combine that with a means for institutionalizing those technologies that, through innovation, show themselves to be effective in many situations. Take for example the following illustration. Through the application of the site-specific alternative, an innovative application of a conventional technology or the application of an "new" technology could be found to be effective in several different waterbody types and different plant configurations, it conceivably could be added to the "approved" list of technologies needing only proper installation, operation and maintenance for purposes of demonstrating compliance. Innovation can flourish, reduced administrative burden to State permit agencies can result and the environment can be adequately protected.

The greater level of demonstration would still be required for facilities choosing to make a site-specific demonstration based on one of the cost tests included in the rule and for facilities that wish to demonstrate that an alternative compliance regime is capable of meeting the standards proposed by the EPA.

RECOMMENDATION: Facilities that choose to install one of the technologies that EPA expects to meet the standards need only demonstrate proper installation and operation of the technology to be deemed in compliance.

EPA Response

EPA recognizes the advantages of providing a simpler, expedited permitting process and has added an approved technology alternative to the final rule. Under this provision, a Phase II existing facility may demonstrate to the Director that it has installed and is properly operating and maintaining a rule-specified design and construction technology in accordance with § 125.99(a). Submerged cylindrical wedge-wire screen technology is a rule-specified design and construction technology that may be used in instances in which a facility's cooling water intake structure is located in a freshwater river or stream and meets other criteria specified at § 125.99(a). In addition, under this compliance alternative, a facility or other interested person may submit a request to the Director for approval of a different technology.

Facilities demonstrating compliance under the approved technology alternative have fewer information collection requirements, as noted in § 125.95.

In addition, EPA has authorized the use of a Technology Installation and Operation Plan, with the approval of the Director, as a means of demonstrating compliance with today's rule.

Subject Matter Code 21.05

Role of States and Tribes (alt./equiv. programs)

In addition, EPA's proposal does not sufficiently recognize the work already done by the States in implementing this section of the Clean Water Act. The preferred alternative would be fortified if adapted to encourage States to maintain and promote comparable programs proven to work effectively in environmental protection and to take advantage of knowledge already collected about certain facilities.

EPA correctly has discussed the ability to allow a State to show that its program is "functionally equivalent" to the details of the proposal. Consideration of such an approach is appropriate and should be encouraged since, in the case of §316(b), it is not a new regulatory program but one in effect since 1972. There are many States that have elements in place providing adequate oversight and reasonable BTA decision making. It is unnecessary, bureaucratic and costly to all involved, especially the States, to require these decisions to be re-evaluated and permits re-issued.

Unfortunately, it appears that the proposal would require a showing that a State's program meets or exceeds the numerical performance standards if it were ever to be deemed an equivalent program. This is an inflexible and too conservative approach. Since the endpoint of concern is a healthy environment, such a rigid approach disallows the use of different and possibly more effective or innovative approaches for determining the adequacy of environmental protection.

Where a facility already has performed a successful §316(b) demonstration and no significant aspect of facility operations or the biota has changed, or where local regulatory authorities have at their disposal sufficient credible data about a waterbody to be confident that entrainment and impingement will not be a concern, EPA should allow and even encourage States to rely on this knowledge.

EPA Response

See response to 316bEFR.025.017 for details on State program approval. Please also see response to 316bEFR.040.001 for a discussion on the use of historical BTA determinations.

Char. of Industries Potentially Subject to Prop. Rule

The selection criteria used by the Agency to identify the universe of in-scope facilities may have excluded, either randomly or systematically, facilities that must comply with the rule.

If facilities have been excluded, the benefit-cost analysis cannot assess the full impact of the rule. This may not present a substantial problem since the facilities would theoretically be excluded from both the cost and the benefit analyses. In the case of the alternative options, however, some of them have negative net benefits. In these instances, the exclusion of a facility would result in an underestimation of the net costs of the options.

RECOMMENDATION: EPA should check the STQ responses from the facilities excluded based on a lack of EIA data against the assumption that these facilities will not be covered by the rule. The exclusion of facilities can significantly alter both the costs and the benefits of the rule, particularly in those cases where the missing facilities are from a subpopulation that is particularly sensitive to the costs of compliance. The Agency should also check the extrapolated maximum design flow values against the information reported to the EIA.

EPA Response

EPA believes that it has correctly characterized the universe of in-scope facilities. As discussed in section III of the preamble in the proposed rule [67 FR 17131 - 17135], EPA conducted an extensive data collection effort, including the use of existing data sources and administering an industry questionnaire.

For a discussion of EPA's use of design intake flows, please refer to the response to comment 316bEFR.072.202.

Facility & firm-level costs/Econ. Practicability

None of the three methodologies used to assess economic impact — the Cost-to-Revenue Test, the Average Household Impact, and an analysis of the IPM-based Electricity Market Indicators — can predict economic impacts with any accuracy.

a. The Cost-To-Revenue Test (CRT). The CRT is a method that has no basis in economic or financial analysis. It compares both average and maximum annual costs per facility against the facility's and firm's gross revenue. This method completely ignores the fact that gross revenue is a meaningless measure of economic viability or lack thereof — a facility might have gross revenues of $15 million but still have negative net revenue after costs/debt are subtracted.

Recommendation: The Agency should instead evaluate the effect of the regulation by calculating the ratio of the net present value (NPV) of the marginal cost of compliance to the NPV of expected net revenues. This is the method used by financial markets, the ultimate arbiters of the viability of a given investment.

b. Average Household Impact. Average cost per household also is not a meaningful statistic — the denominator is so large that it masks the true effects of the rule. This approach is only warranted in those instances where the entire population is homogenous with respect to the percentage of cost shouldered —that is, in those cases where each household can reasonably be expected to see identical increases in costs as a result of rule. This is clearly not the case.

Recommendation EPA should eliminate this analysis altogether. It cannot provide a meaningful measure of the impacts of the regulation, and in fact leads to erroneous impressions.

c. The IPM. There are three categories of issues associated with IPM modeling analysis: 1) General assumptions used in the model, 2) scope issues regarding the set up and operation of the model, and 3) technical and economic assumptions specific to the §316(b) rule options. Overall, there is a systematic bias in the assumptions and operation of the model that lead to an underestimation of market impacts.

EPA Response

Please refer to the following comment responses:

--The Cost-To-Revenue Test (CRT): 316bEFR.072.206 (subject matter code 9.01).
--Average Household Impact: 316bEFR.072.207 (subject matter code 9.02).
--The IPM: 316bEFR.072.209 (subject matter code 9.03).

Methods to Evaluate I&E

The EPA analysis greatly overstates the benefits of all of the options evaluated.

EPA vastly overestimates the extent of the entrainment and impingement losses caused by cooling water intakes nationwide, the implications of such losses for consumers and society at large, and the economic benefits of reducing losses. Appendices 13, 14, and 17 to the UWAG comments, prepared by nationally recognized fisheries biologists and resource economists, provide a detailed critique of the data and methods EPA used to assess the losses associated with once-through cooling, as well as the likely benefits of requiring cooling towers and various intake structure technologies. The following represent a subset of the methodological issues associated with EPA's estimation and extrapolation of benefits. These issues are addressed in the appendices to the UWAG comments as well as in Appendix 2 of these comments.

Besides these appendices, recent EPRI studies support the conclusion that EPA's benefits estimates are too high. As a report by Dr. Charles Coutant commissioned by EPRI shows, a linear relationship does not exist between flow on the one hand and entrainment and impingement (on which EPA' s benefits estimate for cooling towers principally rests) on the other. Nor is there a meaningful correlation between flow and impingement/entrainment effects at higher levels of biological organization. (EPRI, Impacts of Intake Flow Rate on Fish Populations and Communities (Principal Investigators M.S. Bevelhimer & C.C. Coutant) (EPRJ 1005178) (Final Report June 2002)).

EPA Response

EPA reviewed the study document cited by the commenter. The study focused on effects of reservoir withdrawal rates on fish populations, not I&E rates. EPA notes that because a statistically significant relationship was not found doesn't mean that one does not exist. As the authors note, many factors affect fish populations in the reservoirs examined, including stocking and natural environmental perturbations, which may have impaired the authors' ability to detect a relationship between withdrawal and fish abundance. See also response to Comment 316bEFR.041.037 concerning EPA's assumption that I&E are proportional to flow.

Fish Population Modeling

EPA ignores sound science in favor of a baseless “precautionary approach.” The appropriate method of valuing losses associated with the operation of cooling water intake structures is based on the changes in fisheries stocks and related catch levels. This has long been recognized as the correct approach by both biologists and economists. A large body of peer-reviewed research supports this approach through the use of bioeconomic models such as “stock recruitment” models.

EPA chooses to replace this large body of peer reviewed science with a normative approach thinly disguised as scientific. EPA labels this “a precautionary approach.” This approach appears to serve no purpose other than to inflate the benefits estimates through the application of a number of questionable to clearly invalid methodologies.

EPA Response

EPA's analysis is based on sound science throughout. Please see responses to Comment 316bEFR.005.009 on fish population modeling, Comment 316bEFR.025.015 on compensation and Comment 316bEFR.074.201 on the term "precautionary approach."

Use of Replacement Costs (HRC and hatchery-based)

Habitat Replacement Cost (HRC) has no basis in economic theory or practice, and is incorrectly applied in the 316(b) Phase II rule. HRC is a measurement of the costs of an alternative means of compliance. It tells us nothing about the value of the lost resource. It measures what we can spend on a resource, not what we should. Since there is no information on the demand for the resource, this methodology is incapable of providing any information on value. The fact that avoided-cost methodologies of assessing benefits are invalid is well-accepted among economists. Moreover, EPA asserts that replacement of habitat is superior to more direct (and generally cheaper) forms of replacement because habitat creation generates additional benefits such as groundwater filtration and flood control. While it is likely that these benefits exist, they haw nothing to do with the resource that is lost through impingement and entrainment.

EPA Response

EPA does not use the Habitat-based Replacement Cost (HRC) method in the cost benefit analysis for the final Section 316(b) Phase II rule.

Please see the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003) for additional discussion of the HRC method. Please also see EPA's response to comment #316bEFR.005.035.

Use of Replacement Costs (HRC and hatchery-based)

Societal Revealed Preference is an inappropriate measure of value. In its two San Francisco Bay studies EPA uses an "innovative" approach they term societal revealed preference. In this instance the innovation appears to be ignoring principles of sound economics and invalidating the basis of benefit-cost analysis. Like habitat replacement cost, this method does nothing more than look at costs and deem them to be benefits. Under this approach all governmentally imposed costs are assumed to be at least as great as the benefits. There is no basis for this assumption in economic theory or empirical observation. If this assumption were true, there would be no need to do benefit-cost analysis of government regulation. Any conclusions drawn from application of this methodology are completely invalid.

EPA Response

EPA does not use the Societal Revealed Preference (SRP) method in the cost benefit analysis for the final Section 316(b) Phase II rule.

For EPA's response to comments on the SRP, please see the response to comment #316bEFR.005.006

Valuing Forage Species (incl non-use and non-landed)

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

EPA's use of a "rule of thumb" to estimate non-use values is completely arbitrary. EPA uses a unique rule of thumb that assumes that non-use values associated with a good, in this case recreational fishing, is equal to 50 percent of the use value. There is absolutely no basis for this assumption and its use in these studies inflates the benefits artificially.

EPA Response

In the cost-benefit analyses for the NODA and for the final Section 316(b) Phase II rule, EPA did not use the 50% rule-of-thumb to estimate non-use benefits. For EPA's response to comments on the use of the 50% rule-of-thumb to estimate non-use benefits, please refer to EPA's response to comment #316bEFR.005.034.

Please also refer to EPA's response to comments on the HRC methods (316bEFR.005.035) and the SRP methods (316bEFR.005.006); the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003); and to EPA's Guidelines for Preparing Economic Analyses (EPA 240-R-00-003).

Revealed preference

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Angler days are double counted. EPA estimates benefits for recreational fisheries using the number of angler days within 120 miles of each facility. This will lead to an overestimation of benefits when facilities are located within 120 miles of one another. EEI mapped the facilities covered by the proposed rule to see how prevalent this overlap of these areas of influence might be. This mapping exercise demonstrated that 100% of the areas in the eastern half of the United States fall within the area of influence of at least two facilities. EPA needs to adjust its benefit estimates to account for this overlap. (See Appendix 4 for map of in-scope facilities, explanation of analysis, and summary statistics regarding percent of overlap.)

EPA Response

In the cost-benefit analysis of the benefits for the final Section 316(b) Phase II rule, EPA no longer uses the angling index to extrapolate benefits. Rather, all benefits are now extrapolated based on average annual operational flow. Because the angling-related approach is no longer used, the issue of potential double counting is now moot.

Extrapolation of Case Study Ben. to National Level

The choice of case study facilities does not constitute a representative sample that can be used as the basis for extrapolation to national estimates of benefits. The benefit estimates are based upon an extrapolation from five of case studies, supplemented with information from six other studies. This process has two serious problems: (a) the case studies are not representative, and (b) the small sample of case study facilities magnifies any biases.

1. The choice of case study facilities does not constitute a representative sample that can be used as the basis for extrapolation to national estimates of benefits: EPA chose case studies based on those facilities that had the greatest amount of available data. As a result, the sample facilities are not a random (or representative) sample of the affected population. Moreover, the facilities that have the most data are likely to be the facilities that have come under the most scrutiny under the existing program. These facilities are more likely to be representative of facilities where concern with I&E impacts may have existed, not of the general population of facilities. Any extrapolation from these facilities, therefore, will overstate the impacts of I&E losses, and consequently, overstate the benefits of I&E controls.

2. A small sample size magnifies the bias associated with individual studies: The concern over the bias on the sample facilities exacerbates the bias that is created by extrapolating from a very small sample, in many cases a single facility, to the entire population. This magnifies the upward bias in the estimate at individual facilities. For example, the Salem case study is the basis for 55 of the total baseline loss estimates.

EPA Response

(1) Representativeness: EPA did not select case study facilities only on the basis of the quantity of I&E data available, nor did EPA examine only facilities with high I&E losses. To the extent possible, EPA sought facilities with several years of I&E data that were also relatively complete in terms of details such as life-stage specific I&E numbers and growth and mortality rates, within-year monitoring, and the number of impacted species that were evaluated. Nonetheless, EPA's selection of facilities to evaluate was constrained by the lack of I&E studies for most of the over 500 facilities in scope of the Phase II rule, making it impossible to develop a statistically-based sampling design.

(2) Sample size: EPA understands the desire for more case studies than were presented at proposal. Therefore, for its final analysis for the Phase II rule, EPA examined many more facilities (a total of 46), substantially increasing sample size.
Extrapolation in the final analysis was conducted within seven regions, rather than nationwide.

Overview of I & E effects on organisms

Estimates of I&E impacts and benefits are not proportional to cooling water flows. EPA assumes that I&E impacts are directly correlated with flow at a facility. However, EPA's own data in the one instance where it composed multiple facilities in the same pool indicates that this proportionality assumption is incorrect (see Appendix 13 of the UWAG comments on this proposal for a more detailed discussion of this issue). The direction of the bias introduced by this is unclear. However, when combined with the fact that the sample facility is likely to have an uncharacteristically high impact per unit of flow, the effect of the assumption will be to overstate the benefits.

EPA Response

EPA agrees that there is no clear directional bias. For a discussion of EPA's assumptions regarding the relationship between intake flow and I&E rates, please see response to Comment 316bEFR.041.037.

EPA disagrees that the facilities used in the case study or regional analysis are likely to have an uncharacteristically high impact per unit of flow. While one facility may be above average in its level of I&E per unit of flow, other facilities may be below average. For its final regional analysis, EPA based regional estimates on multiple facilities.

Commercial Fishing Benefits

EPA inflates the benefits estimate by valuing losses further up the value chain than is appropriate. EPA develops a series of multipliers to translate dockside market value into larger numbers to reflect secondary economic benefits. These multipliers are not based on any significant empirical data. Moreover, they ignore the additional value added at each step of the market chain, leading to an upward bias in the perceived contribution of losses to social cost. Lastly, they lead to an unfair comparison of costs and benefits, since the costs associated with reducing impingement and entrainment are measured at the equivalent of the dockside and are not adjusted by similar multipliers to account for their movement through the value chain. (Comments submitted to EPA by Robert N. Stavins, Ph.D).

EPA Response

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits, please see the response to comment 316bEFR.005.029.

Benefit Estimation Methodology

EPA application of otherwise valid approaches was flawed. Some of the approaches used by the EPA, such as random utility models, do have a sound foundation in economic theory. However, application of these models to individual case study facilities was uneven.

EPA Response

For EPA's response to comments on the benefits transfer approach used at proposal, see response to comment #316bEFR.075.504.

The Agency disagrees that its RUM approach suffers from methodological problems. For EPA's response to comments on the RUM method, please see responses to comments 316bEFR.041.452, 316bEFR306.320, and 316bEFR337.010.

EPA further notes that it has revised its RUM analyses for the final Phase II 316b analysis to be consistent across all regions. Each coastal region's RUM model uses data from the National Marine Fisheries Service (NMFS) Marine Recreational Fishing Statistics Survey, which have been collected for a number of years using a thoroughly tested survey methodology. EPA's coastal RUM models are built upon models estimated for NMFS by highly respected Resource Economists (e.g., Ted McConnell). EPA has improved on NMFS' models by modeling individual fishing sites rather than aggregating sites by county, and by estimating distances traveled using a state of the art GIS-based program developed specifically for this analysis. Although for the Great Lakes region EPA used a different data set (i.e., the Michigan Recreational Anglers Survey conducted by Michigan Department of Natural Resources), the modeling technique used in the Great Lakes recreational fishing benefits analysis was consistent with the techniques used for the coastal regions. Therefore, EPA's application of RUM models cannot be considered to be "uneven," as consistent modeling techniques were used across all regions.

General/Benefit Transfer

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

EPA relied on questionable “benefits transfer” and other approaches to draw conclusions that may not be applicable to the actual facility being studied.

EPA Response

The comment refers to EPA’s benefit transfer approach from the proposed rule analysis. For EPA’s response to comments on the benefits transfer approach used to value recreational fishing benefits at proposal, see comment #316bEFR.075.504.

For the final Phase II 316b analysis, EPA has reduced its reliance on benefit transfer to estimate recreational fishing benefits. In addition, EPA no longer uses case studies of individual facilities. Instead, EPA has estimated regional models. For the recreational fishing analysis, benefit transfer is used for the Inland region, and benefit function transfer is used for the North Atlantic region. EPA has estimated RUM models for all other coastal regions (Mid-Atlantic, South Atlantic, Gulf of Mexico, and California), and for the Great Lakes region. Where the benefits transfer approach was applied (including proposed rule analysis), EPA generally followed its Guidelines for Preparing Economic Analyses for benefits transfer (BT) and has carefully applied benefit transfer methods. The following steps were followed as recommended in the Guidelines when using BT:

1. describe the policy case;
2. identify existing, relevant studies;
3. review available studies for quality and applicability;
4. transfer the benefit estimates; and
5. address uncertainty.

All of these steps were followed in the Phase II benefits analysis for the final rule.

For EPA’s responses to specific comments on commercial fishing methods please see comment # 316bEFR.323.016.

The HRC method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see comment # 316bEFR.005.035."

In the analyses for the NODA and the final rule, EPA no longer uses hatchery costs to estimate impacts on forage species. Instead EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule (DCN #6-0003). See Chapter A5: Methods Used to Evaluate I&E.

Cooling system costs (e.g., dry, wet, recirculating)

EPA overestimates the benefit of cooling towers. EPA appears to have calculated the benefits of cooling towers based upon a reduction from the maximum design flow at existing facilities. The reduction in flow relative to actual operating flows is likely to be much less. Therefore, the benefits estimates associated with closed-cycle cooling will be biased upwards.

EPA Response

The Agency has based its calculation of benefits for the final rule on the reported actual operating flows of the facilities within the scope of the rule.

The Agency disagrees that the benefits estimates with closed-cycle cooling presented at proposal were biased upwards. For EPA's responses to specific concerns regarding the benefits assessment methods used at proposal and NODA, see Section 10.02 of the 316 (b) Comment Response document. For the final Section 316(b) rule the Agency did not re-estimate benefits associated with closed-cycle cooling.

Comment ID 316bEFR.072.061

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 9.04

Cooling system costs (e.g., dry, wet, recirculating)

The EPA analysis greatly understates the cost of retrofitting cooling towers.

EPA based its recirculating cooling estimates on the cooling tower costs developed for the final new facility §316(b) standards. The basic capital cost was derived from a "rule of thumb" cost per gallon per minute ("gpm") obtained from vendors. This rule of thumb figure was modified to attempt to account for installation costs, construction material, and splash fill. The Agency then translated this determination information into a scientific looking equation from which one can calculate cooling tower cost based on flow in gpm.

However, EPA's cost estimates for cooling towers retrofits are substantially underestimated. Applying EPA's retrofit equation for redwood cooling tower installation yields a rough average cost estimate of $80 per gpm for the redwood towers. Other analyses performed by DOE, the industry, and elsewhere in the literature all find that the costs of tower retrofits are between $140 and $225 per gpm. EPA's estimate is at least 50 percent lower than any other cost estimated by other sources.

Retrofitting cooling towers at existing facilities presents highly complex technical challenges. These engineering issues are at once time consuming and costly, as EPA acknowledges throughout the preamble and the Technical Development Document. EPA has only limited data that it has collected concerning the outage period associated with retrofitting cooling towers and these data show that outage periods are likely to be highly variable and, in some cases, quite long (i.e., ranging from 83 hours for the Jeffries Plant (a relatively small two-unit fossil- fueled plant) to 10 months for the Palisades Nuclear Generating Plant (EPA TDD Chapter 4, pp. 4-6). EPA subsequently dismisses this 10-month time frame.

From personal communications EEI has had with utility engineering experts familiar with cooling towers and cooling water intake structure design and operation, we believe such a long time frame may be more representative of the likely time required to retrofit a cooling tower on an existing facility. In fact, when queried about what would be the "typical" start-to-finish time to convert a once-through cooling system for a 400-MW fossil unit to a recirculated system, experts suggested a one year time would be optimistic scenario. (This estimate includes design, bidding, procurement, delivery, construction and testing). Assuming the very best circumstances, it was estimated that the "typical" unit downtime for the cooling system retrofit would ranges from a possible eight weeks (2 months) to a more realistic estimate of 13 weeks (3 months). (Personal communication with Wayne Micheletti, January 2002).

Moreover, redwood cooling towers may not be used as widely as EPA assumes. At some facilities, site-specific conditions may prevent the use of redwood towers, causing those facilities to turn to more costly options. EPA's total cost estimate, therefore, may substantially underestimate the true cost of regulatory compliance for non-nuclear generating facilities. In addition, EPA has not considered the environmental effects of widespread use of redwood lumber.

EPA Response

See response to comment 316b.EFR.208.002.

The Agency notes that it revised downtime estimates from proposal to NODA for its cooling tower analysis. The Agency also points out that the cost basis of redwood cooling towers is the median cost material, which just happens to be made of redwood. The Agency stresses, in the off-chance that the commenter's unusual line of reasoning is carried out elsewhere (i.e., that because the Agency utilized a median cost material for estimating costs that it has somehow mandated that this material be used) that the material of construction for any technology is chosen to best represent what the Agency deems the likely cost incurred and in no way instructs, recommends, or mandates a material selection when many others are available. This is a decision, regardless of the technology involved, that the Agency strongly believes is made by the complying facility based on its site conditions.

RFC: Regulating limited capacity facilities

EPA should expand the definition of capacity utilization to incorporate legal or practical restrictions

The performance standards pertaining to entrainment are different for facilities with capacity utilization rates of 15% or less. This distinction recognizes the differences between “peaking” units and other facilities. This is an appropriate distinction and one that should be maintained. Moreover, there are other circumstances where a facility’s capacity utilization rate is limited as a practical matter. In these situations the facility should be deemed to have a capacity utilization rate no greater than the practical limit dictates. Also, if the permittee agrees to limit its capacity utilization to below the threshold (15% in EPA’s proposal) -- either by agreement with the permitting authority or by permit condition --then the facility should be deemed to be below the threshold.

EPA Response

The final rule includes the capacity utilization threshold. The final rule definition allows for any case in which the capacity utilization of a facility is historically below 15 percent (based on a single permit cycle). As such, if a facility’s capacity utilization rate is limited by a “practical matter,” this will be accounted for in the final definition.

The Agency has included in the final rule a flexible definition of capacity utilization that allows the permittee to agree to limit its capacity utilization, in the future, to below the threshold by permit condition. Therefore, the comment has been met.

RFC: Application to "unique" facilities

EPA may not apply §316(b) to facilities subject only to permits for storm water discharges

EPA proposes to apply §316(b) to existing facilities covered by NPDES permits (whether general or individual) applicable solely to storm water. EEI and UWAG believe that EPA lacks authority to do this, because such facilities are not subject to effluent limitations under §301 and 306, which is a threshold requirement for applying §316(b). Also, EPA's proposal to cover these facilities vastly increases the number of permits covered and raises numerous administrative issues that will serve only to increase burdens on State and federal permit writers — the opposite of EPA's avowed mission.

EPA's proposal also raises complex and troubling legal issues — for instance, does EPA have authority, as it claims, to issue to a general permittee a separate permit containing only intake limits? Section 402 of the CWA suggests it does not. If EPA were to take the position that it could force storm water permittees to obtain individual storm water/cooling water intake structure permits, would it not have to amend the storm water rules and the storm water general permits, estimate and justify the additional reporting and recordkeeping burden, and obtain OMB approval? If EPA were to attempt to include cooling water intake structure conditions in general permits, would it not need to prepare burden estimates, obtain OMB approval, and develop special mechanisms to ensure that such conditions apply only to relevant facilities?

All of these factors weigh against EPA's proposal to apply the §316(b) rule to storm-water-only permittees with cooling water intake structures.

EPA Response

See responses to 316bEFR.035.001 and 041.127.

RFC: Three-option framework for determining BTA

EPA's operational performance standards penalize certain geographical regions

EPA is proposing to establish performance standards in Section 125.94(b) that would offer facility owners several options for compliance including the option to reduce "intake capacity to a level commensurate with the use of closed-cycle, recirculating cooling system;..."

EEI is concerned that the existing performance standard does not offer sufficient latitude to accommodate all closed-cycle, recirculating facilities in all geographical regions. Some facilities that are located in more arid regions have on-site cooling ponds and pumping facilities that are designed to appropriate large amounts of water from waters of the U.S. over a limited time period during, for example, spring run-off. Such facilities have a higher pumping capacity, but the pumps would operate for only a portion of any calendar year. States have considered and mitigated possible impacts by limiting pumping based on site-specific permit conditions.

It is unreasonable for EPA to establish performance standards based strictly on an intake capacity comparison with closed-cycle, recirculating cooling systems while ignoring the annual amount of water pumped.

EPA Response

EPA disagrees. To begin, please refer to the response to comment 316bEFR.006.001 for more information about the case-by-case nature of determinations of the status of cooling ponds as closed-cycle cooling systems. If a facility is considered to employ closed-cycle recirculating cooling, then the facility is considered to be in compliance with the rule. While the timing and volume of the intake flows might be considered in assessing the appropriateness of being designated as using closed-cycle cooling, these flow characteristics would not be important for a facility that has been determined to be in compliance with the rule.

On the other hand, a facility with a cooling pond may not be determined to employ closed cycle cooling. In such a situation, EPA does not wish to speculate on the compliance alternative that the facility may pursue. However, EPA believes that the final rule offers sufficient flexibility for such a facility to meet the requirements of today's rule.

Subject Matter Code 21.09

Permit applications/implementation schedule

EPA should implement the BTA requirements using a permitting condition that sets out a process for choosing BTA

There is insufficient time built into the regulation as proposed to allow the permitting agency (the Director) to review and approve the key steps. For example, the Director will need to approve the data collection program and also, later, the permittee's choice of technology. This holds particularly true for facilities that are very near their date of permit reapplication when the final rule is promulgated. The §316(b) rule should make clear that time for agency review must be built into any schedule either prescribed by the rule itself or required by an NPDES permit condition. At the very least, permittees who have applied already for a permit renewal when the §316(b) rule becomes final should not have to redo their application. In such a case, the succeeding five-year permit term should be the time in which the permittee complies with the new rule. Similarly, if the new rule becomes final when a permittee is very near the time when his or her renewal application is due (for example, 365 days before his permit expires), it would be almost as unreasonable to require him or her to adjust his or her application process to the new rule.

EPA Response

EPA has added many efficiencies to today's final rule since the proposal and NODA to provide options for streamlining application requirements and speeding permitting. See response to comment 316bEFR.034.005 for details.

Additionally, EPA has clarified timing requirements for the submittal of the required studies. See response to comment 316bEFR.034.066 for a discussion.

Comment ID 316bEFR.072.066

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

Subject Matter Code 3.03

Definition: Waters of the U.S.

EPA should clarify that ponds and lakes created specifically for cooling are not "Waters of the U.S." for the purposes of this rule.

Waste treatment systems, including ponds and lagoons designed to meet CWA requirements, which cooling ponds clearly are, are specifically exempted from the NPDES permit requirement. EPA's proposed definition of "once-through cooling water system" mistakenly says that such systems sometimes use "ponds." This could result in the incorrect interpretation that cooling ponds are "Waters of the U.S." rather than waste water treatment systems.

EPA has long asserted broad authority to define waters of the U.S., and to include and exclude waters from the definition where necessary to achieve the purposes of the CWA. EPA should treat "cooling lakes," or those built in whole or in part to supply cooling water by damming rivers that are waters of the U.S., as closed-cycle cooling systems that already achieve the §316(b) requirements. Cooling lakes do not require additional intake technology, both because AEI was considered when the impoundment was constructed and because experience shows that AEI typically does not occur in cooling lakes.

EPA Response

See responses to 316bEFR.006.001 and 316bEFR.035.015.

Subject Matter Code 18.01

RFC: Definition of "adverse environmental impact"

EPA should clarify what is "Entrainable"

EPA appropriately acknowledges, through the concept of the calculation baseline, that many existing plants have already reduced their potential impact and, therefore, should get credit for their actions to reduce impact.

However, EPA should provide clarity in its proposal on how to measure the baseline level of impingement mortality and entrainment. The Agency needs to clarify the difference between impingement and entrainment organisms, which depends on screen mesh size. A larger mesh means, other things being equal, that there are more "entrainable" organisms and fewer impingeable ones. Reducing the mesh size means that some organisms that would have been entrained now may be impinged. Thus, a fine mesh screen might be installed to reduce entrainment, with the result that formerly entrainable fish or larvae are now impinged against the screen.

Recommendation: In its description of a baseline intake, the Agency can resolve this uncertainty by explicitly defining an "entrainable" organism as one that will fit through a standard 3/8-inch intake screen. This will lend certainty and consistency to the rule.

EPA Response

EPA has clarified its definition of calculation baseline in today's final rule (see 125.93).

Option: UWAG's recommended approach

ATERNATIVE PROPOSAL

The only way accurately and appropriately to select best technology available is on a site-specific basis. The mandate of Section 316(b) is distinct from the classic environmental protection paradigm where there is a source discharging some level of an identified pollutant. In the more traditional discharge cases, the concerns at issue are often technical capability (is there a technology of controlling the emission), economic practicability (is it practical or cost-effective to control the pollutant), and scientific (is there evidence that the. pollutant presents an unacceptable risk to society or some portion of society). In the case of Section 316(b), those same concerns are present. However, the situation is complicated by the fact that there is a not a "source" discharging anything. Rather there is the inherently variable and complex juxtaposition between individuals of aquatic populations of many species and human engineering. The interaction between the two is highly variable and site-specific for a myriad of factors such as the shape of the shoreline, the flow of the river, site design, the time of year, and especially the species present. Regardless of the engineering designs in place, the nature and variability of aquatic populations are such that some impact may occur despite well-intentioned planning. The question becomes one of degree, efficiency, and flexibility to deal with peculiar issues when they arise. No one solution will be best or even practical in every situation.

It is for these reasons that regulations implementing Section 316(b) of the CWA need to be sensitive to the inherent variability associated with measuring and minimizing adverse environmental impacts associated with cooling water intake strictures and flexible enough to account for unusual situations. In other words, Section 316(b) implementing regulations should allow for site-specific decision making and should calibrate its success by a measure of whether the environment and society are being served. Put another way, the statute calls for the minimization of adverse environmental impact. It is appropriate to interpret this to mean that it should be viewed as broad (greater than simply aquatic), relative ("adverse "and "minimize" are measures of relative risk), and flexible to adjust to unknowns.

Some have argued that the administrative costs associated with the site-specific approach have been too high. There are always some higher costs to pay when a new issue is confronted and a great deal has to be learned about the issue. But now, 30 years after Congress enacted the Clean Water Act, a great deal has already been learned about the key issues to examine and how best to study them. In addition, past administrative costs were, in part, a result of implementation with a rule and with only minimal draft guidance.

RECOMMENDATION: SITE SPECIFIC OPTION: EEI advocates that EPA select a purely site-specific regulatory scheme such as those advocated by UWAG and PSEG. Such approaches not only would build on a record of successful past precedent but also allow new methods to be developed to advance our understanding and measurement of biological integrity and ecosystem level impacts concepts that the Agency acknowledges in the preamble, and proposed regulatory language as important and central to this rulemaking.

EPA does not need to re-invent the wheel and develop new unproven and complex approaches when arguably all that may be needed is a federal regulatory structure codifying what is already in place with simple, easy to understand guidance to assure consistent decisionmaking. We strongly urge the Agency to consider the wisdom in promoting and refining existing decisionmaking approaches by promoting site-specific decisionmaking rather than fundamentally reordering a program that for many States has a 30-year history of successful implementation.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.072.069

Organization Edison Electric Institute

Subject Matter Code 17.06

Option: Site-specific determination of BTA

EEI members support a fully site-specific approach to determining the best technology available for minimizing adverse environmental impacts associated with the operation of cooling water intake structures. EPA should develop a reasonable definition of adverse environmental impact and allow facilities to demonstrate that their chosen technological solution minimizes these impacts in a way that maximizes net benefits. This can be done with no significant increase in transaction costs over EPA's proposed rule.

EPA's proposed rule falls short of this ideal, but it does include some provisions that allow for consideration of site-specific factors under certain conditions.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA has chosen to not define the term "adverse environmental impact" for the final rule. Please refer to the preamble to the final rule for more information.

Please refer to the response to comment 316bEFR.005.020 for a discussion of the application of the cost-benefit test to assessing the value of alternative approaches.

RFC: Three-option framework for determining BTA

If the EPA insists on pursuing a version of its preferred option, the following changes are necessary for that approach to be minimally supportable by the industry.

1. Modify the regulatory language of its proposal to remove any reference to closed-cycle recirculating cooling systems from the "performance standards" section of the regulation.

2. Maintain a cost-cost and a cost-benefit test in the final rule. These tests should be modified to allow facilities to choose any alternative that results in greater net benefits than would result from achieving EPA's numerical impingement and entrainment reduction targets, deleting the "significantly greater than" constraint.

3. Retain the flexibility to select from among all available technology and non-technology solutions in choosing a compliance strategy for an individual facility.

4. Include a streamlined permitting approach for facilities that choose to install the technologies considered by the Agency in establishing the standards and others that prove protective of fisheries at reasonable cost. This will reduce transaction costs for both facilities and permitting authorities.

5. Correct all of the major methodological issues with its economic and benefits analysis. This new analysis should be provided to the public prior to promulgation of the final rule.

6. Allow States to select alternative criteria for minimizing AEI than impingement and entrainment, including reference to the overall health of the fishery; encourage use of readily available data; preserve State authority including sound prior State analyses and decisions; and reexamine /use of the NPDES permitting process as the means of implementing Section 316(b) given that process's repeated reviews every 5 years, which we are concerned do not fit well with the § 316(b) issue

EPA Response

Please refer to the preamble for a discussion of the framework of today's rule. EPA notes that the final rule uses a similar approach.

With respect to item #1 in the above comment, EPA has revised the rule language. Please refer to § 125.94(b) for a description of the performance standards.

With respect to item #2 in the above comment, the cost-benefit and cost-cost tests have been retained as part of the site-specific compliance alternative. Please refer to the response to comment 316bEFR.005.020 for a discussion of the application of the cost-benefit test to assessing the value of alternative CWIS technologies.

With respect to item #3 in the above comment, EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose, which include restoration technologies.

With respect to item #4 in the above comment, EPA recognizes the advantages of providing a simpler, expedited permitting process and has added an approved technology alternative to the final rule. Please refer to the response to comment 316bEFR.072.045 for a discussion of this compliance alternative.

With respect to item #5 in the above comment, EPA revised its economic and benefits analysis in the NODA [68 FR 13522-13587].

With respect to item #6 in the above comment, please refer to the response to comment 023.001 for a discussion of alternative regulatory requirements.

ON LOCATION, INC. ELECTRICITY MARKET MODELING ANALYSIS

Analysis of EPA's Proposed 316(b) Rule

Prepared for the Edison Electric Institute

by

OnLocation, Inc.	EOP Group, Inc
Energy Systems Consulting	819th Street, NW
501 Church Street	Washington, DC 20001
Vienna, VA 22180	

August 2002

Executive Summary

This report summarizes the results of an electricity modeling analysis conducted by OnLocation, Inc, Energy Systems Consulting, for the Edison Electric Institute on the Environmental Protection Agency Proposed § 316(b) Rule for Phase II Existing Facilities (67 Fed Reg 17,121-225). The analysis used the POEMS electricity market model to compare and contrast key assumptions with the modeling analysis conducted by EPA using the IPM model.

The modeling analysis was performed for two of the EPA regulatory options: the preferred option (consisting of national performance standards for reduction of impingement and entrainment), and the waterbody/capacity-based option (consisting of installation of cooling towers at about 50 selected facilities). Due to constraints on the availability of data, the modeling analysis was not a comprehensive re-analysis of the EPA IPM modeling work, but instead focused on several key assumptions in order to highlight issues for further review and discussion with EPA.

The principal analytical objective of the POEMS analysis was to test several key assumptions used in the EPA IPM modeling in order to better understand the sensitivity of EPA's estimates of electricity market impacts. This was done by varying the input of several key assumptions, such as cooling tower retrofit costs and energy penalties, as well as using updated reference economic conditions. Not all of the issues regarding EPA assumptions raised in Appendix 2 were addressed in the POEMS modeling. The result illustrates the sensitivity that modifying a few of the variables with more appropriate data can have on the model output (impacts on electricity markets). If all the potential shortcomings of the original EPA study were rectified, an even more accurate (and presumable larger) impact on electricity markets would result. This is a critical finding that at least one of the proposed regulatory options (Option 1- waterbody/ capacity-based option), if analyzed more accurately, would likely lead to more significant impacts on electric markets than those identified in the EPA study

For the EPA preferred option, the POEMS modeling analysis showed that electricity market prices in general were not significantly affected by changes in assumptions regarding the costs of I&E controls. Price effects tended to be within the "noise level" of the model, resulting in little or no increased costs to consumers. The compliance costs of roughly $800 million (in 2002$) were absorbed by generators as a reduction in net income. The impacts to consumers would be greater if generators were allowed to pass through costs (in regulated markets) or if generators incurred additional costs due to site specific factors not addressed in the modeling analysis.

For the EPA waterbody/capacity-based option, the POEMS modeling analysis showed that the consumers would incur total costs of $2 billion (2002$) through 2015 resulting from the application of cooling tower costs derived from industry facility-level estimates, and from consideration of seasonal energy penalties resulting from the combination of outages, increased plant auxiliary power requirements and seasonal derating of steam turbines Producers incur increased costs totaling $9 billion over a 10 year period. Market prices for electricity would be higher in all of the NERC regions in some years, and system reliability would be reduced in 6 regions in the years in which cooling towers are installed. A total of 18 GW of existing generating capacity would be prematurely retired — of which 5.3 GW are directly attributable to the proposed 316(b) requirements. Further analysis of the EPA schedule assumptions, along with the possibility of higher levels of pass-through costs in regulated markets, likely would yield higher estimates.

Finally, to be consistent with the EPA IPM modeling analysis, the POEMS analysis considered the impacts of the 316(b) options separate from the Administration's Clear Skies proposal. Many of the facilities significantly impacted by the Clear Skies initiative also will be affected by the proposed new 316(b) guidelines in a manner that may not be identified through a modeling analysis of 316(b) alone.

Introduction

The proposed rule establishes national technology-based performance requirements applicable to the location, design, construction, and capacity of cooling water intake structures at existing power producing facilities. The proposal applies to existing electric generating facilities that use one or more cooling water intake structures withdrawing water from waters of the U.S., have or require a National Pollutant Discharge Elimination System (NPDES) permit, withdraw 50 million gallons per day (MGD) or more and use at least 25 percent of that water for cooling purposes.

EPA outlines a preferred alternative and invites comment on a broad array of other alternatives. These alternatives range from a stringent technology-based requirement for dry cooling at all existing facilities, required cooling tower retrofits based on waterbody type, to several decision frameworks that would evaluate adverse environmental impact and determine the best technology available for minimizing such impact on a wholly site-specific basis. This requirement has implications not only for the economic viability of these facilities but also has broader impacts for regional electricity markets. The POEMS modeling system was used to assess these impacts in a consistent economic framework.

The Policy Office Electricity Modeling System (POEMS) integrates the Energy Information Administration's (EIA) National Energy Modeling System (NEMS) with a detailed electricity market model Tradelec TM , developed by OnLocation, Inc. The model was designed specifically to analyze competitive electricity markets and the transition from regulated markets. The core of the Tradelec TM model is market-driven electricity dispatch and trade among 69 power centers representing the country's power control areas.

POEMS has been used by the Department of Energy for several studies. Most recently it was used to analyze wholesale trade and congestion in the National Transmission Grid Study, and was also used to support DOE's analysis of the Comprehensive Electricity Competition Act proposed by the Clinton Administration. For various participants in electricity markets, POEMS has been used to assess regional markets, forecasting electricity prices, supply, and demand under alternative economic and fuel price scenarios. The model has also been used to assess the impact of alternative environmental policies on utility industry capital turnover and inter-fuel substitution.

Analytical Objectives

The review and assessment of the EPA modeling analysis, conducted for the Edison Electric Institute by the EOP Group, Inc., identified many issues with the assumptions used in the setup and operation of the IPM model used by EPA. A complete reanalysis of the IPM modeling was beyond the scope of this study, in part because much of the data used in its analysis was classified as confidential business information and the fact that the IPM is a proprietary model that EEI would need to purchase to use. The principal analytical objective of the POEMS analysis was to test several key assumptions used in the EPA IPM modeling analysis in order to better understand the sensitivity of EPA's estimates of electricity market impacts the scope of this effort was limited — it is not intended to be a complete market reassessment.

The POEMS analysis was based upon three modeling scenarios the description and principal analytical objectives for each scenario is summarized as follows

1. A Reference Case absent the EPA rule, that incorporated more recent electricity market information and projections than were used in the EPA IPM base case,

2. An Impingement and Entrainment (I&E) Case that represents the EPA's preferred option for establishing performance standards for the reduction of impingement mortality. This modeling scenario examined the general sensitivity of EPA cost estimates for I&E controls, using the updated reference case market assumptions. This scenario did not examine the market impacts resulting from site specific compliance issues,

3. A Limited Cooling Towers Case that represents EPA's waterbody/capacity-based option one where roughly 50 plants are required to install wet recirculating cooling towers. This scenario examined the market impacts of different assumptions for the cost of cooling towers and the seasonal energy penalties, using the updated reference case market assumptions. This scenario did not attempt to examine the different compliance patterns based on site specific factors. In addition, it was not feasible in this scenario to explore all of the factors that would affect compliance costs, such as different compliance schedules and additional site specific variances in cooling tower retrofit costs.

All three POEMS modeling scenarios assumed that the wholesale electricity markets were fully deregulated. In addition, all scenarios incorporated the estimated impacts of the EPA NOx SIP call, but not the impacts of the Administration's proposed Clear Skies Initiative. These assumptions were chosen in order to provide comparability to the EPA IPM modeling analysis which were based on similar assumptions. These two factors could significantly affect the modeling results and should be examined further in any follow-up analysis.

-In a fully competitive market, the ability of generators to pass through costs to consumers is affected by market forces rather than cost-of-service pricing rules. To the extent that markets are cost-of-service regulated, subject to price caps, or allow for the exercise of market power, the impact of costs incurred for cooling water compliance would affect consumer prices differently.

-The combined cost of compliance with air and water quality requirements could be the critical factor in determining whether certain facilities will be prematurely retired in the future. Many of the facilities significantly impacted by the Clear Skies initiative also will be affected by the proposed new 316(b) guidelines in a manner that may not be identified though a modeling analysis of 316(b) alone.

A detailed description of each modeling scenario, including key assumptions, is appended to this report. Also appended are charts that compare the POEMS assumptions with the EPA IPM assumptions, showing which assumptions were retained and which were modified in the POEMS modeling analysis.

In summary, the principal analytical objective of the POEMS analysis was to test several key assumptions used in the EPA IPM modeling in order to better understand the sensitivity of EPA's estimates of electricity market impacts. This was done by varying the input of several key assumptions, as well as using updated reference economic conditions. The most significant differences were more appropriate data for cooling tower retrofit costs and energy penalty data more accurately reflect real world seasonal variability. However, not all of the issues regarding EPA assumptions raised in Appendix 2 were addressed in the POEMS modeling. The result illustrates the sensitivity that modifying a few of the variables with more appropriate data can have on the model output (impacts on electricity markets). If all the potential shortcomings of the original EPA study were rectified, an even more accurate (and presumable larger) impact on electricity markets would result. This is a critical finding that at least one of the proposed regulatory options (Option 1-waterbody/ capacity-based option), if analyzed more accurately, would likely lead to more significant impacts on electric markets than those identified in the EPA study.

Results from the I&E Modeling Scenario

The modeling results from the I&E Scenario showed that the combination of sensitivities in the costs of I&E controls with updated electricity market projections did have any significant adverse impacts on wholesale electricity market consumers relative to the updated reference case. Producers incur significant compliance costs but these are not passed through to consumers in a competitive market. Instead the compliance costs were borne largely by producers as a reduction in net income. In summary:

-The costs of the I&E technologies, as estimated by EPA, were not large enough to cause additional plant retirements above the Reference Case due to the adoption of the EPA preferred option.

-The changes in wholesale electricity prices were very small (less than 0.1%) and within the "noise level" of the model.

-The total additional costs to producers was estimated at $833 million of equipment investments plus increased O&M costs of $62 million per year, while the net additional cost to consumers was estimated to be negligible. The producer costs are less than the original input costs because of the plant retirements occurring in the Reference Case.

However, as described earlier, the results did not consider possible additional costs due to site specific factors, such as failure of the EPA assumed compliance technologies to meet the proposed performance standards.

An additional sensitivity case was run where it was assumed that all facilities incur costs for installation of I&E equipment near the high end of the range assumed by EPA. The sensitivity analysis showed that some NERC regions would experience a price increase of $0.1/mwh (or 0.2% increase) relative to the reference case. In the sensitivity case, the total cost to consumers would increase by less than $100 million per year.

Further sensitivity analysis could show larger impacts from three possible factors: (1) higher variable O&M cost assumptions would lead to higher wholesale prices, (2) continuation of cost-of-service regulations in certain regions would likely result in higher pass-throughs of costs to consumers, and (3) consideration of the combined impact of 316(b) requirements and new clean air compliance costs likely would result in some premature facility retirements.

Table 5 shows a comparison of the major assumptions used in the EPA IPM modeling analysis of the EPA preferred option relative to the assumptions used in the POEMS analysis. The comparison shows that there are several additional EPA assumptions that were unchanged in the POEMS model that could be subject to further analysis.

Results of the Limited Cooling Towers Modeling Scenario

The modeling results showed that changes in the assumptions of cooling towers costs and consideration of a seasonal energy penalty, combined with updated market projections, resulted in adverse effects on generation capacity, wholesale electricity prices and reserve margins. Both electricity generators and electricity consumers experienced significant additional costs. These impacts are discussed individually in the following parts:

Facility Closures: The model results showed that 18 GW of capacity (of the 64 GW subject to cooling tower requirements) would retire prior to the assumed compliance date for installation of cooling towers. Of the 18 GW, 13.1 GW were marginal facilities that close even in the absence of new 316(b) requirements. The capacity reductions from closures are mitigated by increased additions of new capacity, and by 2015 the industry will need to build roughly 2 percent more capacity than in the Base Case. Table 1 shows the breakdown of plant closures by region and by fuel type. This result is somewhat different from the EPA modeling analysis, which showed 3010 MW of primarily nuclear facility closures due to the installation of cooling towers. Table 2 provides context of capacity projections for the U S as a whole.

Table 1. Facility Retiremments
[see hard copy for table]

Table 2. Total U.S. Summer Rated Capacity (GW)

[see hard copy for table]

Energy Penalties: The modeling analysis incorporated seasonally-adjusted energy penalty estimates, with peak summer penalties ranging from 2.08% to 3.53% depending upon region and fuel type. The model analyzed the combined effect of the energy penalties, facility closures, facility outages for the cooling tower installations, and additional capacity construction in projecting available generation capacity. As an example, Chart 1 shows graphically the net change in available generating capacity in the New England region. For this region, 2010 is the year of the most cooling tower installations when 3405 MW of nameplate capacity is converted. The loss of this capacity in April and May (the assumed outage months) leads to a rescheduling of maintenance for other plants, but available capacity is still reduced by 760 MW for the two months. Peak demand is highest in the winter months, so the maintenance rescheduling primarily affects the summer and fall seasons. The post-retrofit capacity deration is roughly 100 MW.

Available Capacity - New England
[see hard copy for figure]

System Reliability: The reductions in net available generation capacity directly reduce reserve margins, adversely affecting system reliability. The reductions in reserve margins vary by region, by year and by season of the year. Reserve margins are reduced by up to 5.9 percentage points (12.5 versus 18.4), which could have an adverse impact on reliability. The greatest reductions occur in April/May (the assumed outage months) in the years when the towers are installed. Table 3 shows the complete result of estimated changes in reserve margins by region, by year, and by season. The shaded numbers are those with greater than a 1 percentage point drop in reserve margins.

Table 3. Percent Point Change in Reserve Margin (After Maintenance)
[see hard copy for table]

Wholesale Electric Prices: The modeling results show higher wholesale electricity prices, with significant variation by region and by season of the year. The seasons and the years in which the cooling tower retrofits occur show larger price increases because there is less capacity available. Wholesale price increases are up to $1.4 per MWh, mainly in the Western regions of NWP, RA and CNV regions. Table 4 shows a complete breakdown of estimated wholesale prices by region and by season, for three years – 2008, 2010 and 2013. The shaded prices are those that increased in the Towers Case. The modeling results show that prices also are increased in regions that do not have cooling tower retrofits due to electricity trading. In addition, the modeling results show that wholesale electricity prices decline in certain areas, due to the replacement of higher cost steam units with more efficient combined cycle plants.

Total Costs to Consumers and Producers: Consumers will incur roughly $2 billion dollars of higher electricity costs due to higher wholesale electricity prices for the period 2005 to 2015 (in constant 2002$). Electricity generators will incur higher net costs resulting from compliance costs that are not fully reflected in higher prices. These costs include $5.4 billion to install the cooling towers, and $26 billion in additional O&M costs plus $1.2 billion in additional fuel costs over the 10 year period. In addition, the industry will spend $62 billion more to build new generation facilities to replace retired and the derated units.

Table 4: Wholesale Electricity Prices by Region and Season in 2002 Dollars per Megawatt-hour
[see hard copy for table]

Sensitivity Analysis: There are 5 factors that could result in higher estimates than were obtained through the modeling analysis: (1) higher variable O&M cost assumptions would lead to higher wholesale prices; (2) longer down times for equipment installation would reduce net generation capacity and increase princes; (3) a more compressed schedule for installation of cooling towers would increase price effects; (4) continuation of cost-of-service regulation in certain regions would likely result in higher pass-throughs of costs to consumer; and, (5) consideration of the combined impact of 316(b) requirements and new clean air compliance costs likely would result in additional plant retirements.

Table 6 shows a comparison of the principal assumptions used in both the EPA IPM and POEMS modeling analysis of the waterbody/capacity-based option. The comparison highlights the areas where different assumptions were used in the POEMS analysis. The comparison also indicates where certain EPA assumptions were used without change in the POEMS modeling analysis. Additional modeling work could be addressed to some of the other issues in the EPA assumptions that were beyond the scope of the initial POEMS analysis.

Appendix: Description of the Modeling Scenarios

POEMS Reference Case

The POEMS Reference Case for this analysis is based largely on the current Annual Energy Outlook (AEO2002) projections prepared by the Energy Information Administration. The greatest differences between assumptions in this case and the IPM EPA Base Case 2000 are in fuel prices and electricity demands. In general, the AEO2002 fuel prices are higher than those used in the EPA Base Case that was developed a year or more ago. All else equal, higher fuel prices will lead to higher projected electricity prices and higher penalty costs associated with the 316(b) rulemaking, e.g., heat rate penalties.

Electricity demand, expressed in terms of generation, in the POEMS Reference Case is significantly higher than in EPA's (IPM does not include retail sales, so a comparison of sales cannot be made). EPA derived their projections by taking AEO2001 generation levels and subtracting their estimates of the energy efficiency savings expected from the Climate Change Action Plan programs. The POEMS demand and generation are essentially the same as those in the AEO2002. Note that the POEMS generation in the tables below include large non-utilities and cogenerators as well as utilities.

Input fuel prices and electricity demands were held fixed between the POEMS scenarios, so that focus would remain on impact of the cooling water policies rather than small perturbations caused by energy sector price feedback.

The POEMS Reference Case is initialized with capacity additions that are currently under construction and expected to be on-line by the end of 2002. The May 2001 RDI NEWGen database was used to identify these planned additions between 2000 and 2002. The model then forecasts additional new capacity as necessary. The EPA Base Case is older and therefore does not contain the full wave of new additions that has occurred in the last few years. The addition of significant amounts of new capacity in some regions will increase the propensity for retirements of existing plants.

Wholesale electricity markets are assumed to be fully competitive, with marginal costs determining the generation price. This was also assumed in EPA's analysis. To the extent that markets are cost-of-service regulated,. subject to price caps, or allow for the exercise of market. power, the impact of costs incurred for cooling water compliance would affect consumer prices differently.

Comparison of Baseline Assumptions
[see hard copy for table]

I&E Case

Capital Costs for I&E Technologies

The data provided by EPA for the compliance CWIS technology modification costs varies considerably by plant. The capital costs range from $0 where no modification is necessary (roughly one third of the facilities) to $22 million, with one outlier at $45 million. Because these plants are not identified in the EPA file, and matching these to the EIA-767 data is virtually impossible, an average cost for all steam plants was used. In computing the average, the plants with zero costs were excluded.

The EPA total capital cost for all 539 plants equals $963 million. These 539 represent the 550 facilities, totaling 416 GW of capacity, that are potentially subject to the Phase II rule, with an average plant size of 756 MW (416/550). Assuming that the plants with compliance costs are on average the same size as the rest of the plants, the capacity with non-zero costs represents 260 GW. Spreading the $963 million cost over 260 GW yields an average cost of $3.7/kW or $2.8 million per plant. The capital cost was converted to an annuity, using a capital charge rate of 0.20. The amortized value of $0.75/kW-year is added to the capital addition cost for each steam plant within POEMS.

Averaging the costs leads to an overstatement of cost for plants that would not have to comply, while understating the cost for plants that would have to install the most expensive I&E measures. A sensitivity case was performed to test the impact of the most expensive possibility. If the cost of $22 million for compliance was at a plant of 1000 MW, then the cost would be $22/kW or $4.4/kW-year.

Additional O&M costs

The O&M costs provided by EPA total $27.7 million. These costs are assumed to be incurred by 260 GW of capacity for an average cost of $0.106/kW-year. In POEMS it was assumed that half of these costs would be considered variable and would be added to the marginal costs for determining unit bids and market prices. In addition, each facility is assumed to have a monitoring cost of $75,000 or $90,000, with the total across all facilities of $42.4 million. These costs of $0.104/kW-year are assumed to be fixed and have no direct influence on market prices A parallel worst-case scenario for O&M costs would be $580,000 per year for a 1000 MW plant, or $0.58IkW-year.

Compliance Schedule

All I&E retrofits were installed in 2008.

Limited Cooling Towers Case

All plants except those that must install cooling towers have the same I&E costs as in the I&E Case.

Selection of plants subject to cooling towers

The EIA-767 year 2000 data was used to determine plants using once through saltwater cooling and with design intakes greater than 500 million gallons per day (MGD). Then a second criteria was applied that the plants (sum of all units) have a greater than 15 percent average capacity factor for the years 1995 to 2000. This yields a total of 50 plants with a capacity equal to 62.9 GW. In aggregate this is very similar to EPA's 54 total and 62.5 GW of capacity that they coasted with cooling towers. However, as shown in the tables below, the two sets of plants are not identical. The 767 extract contains less coal capacity, more oil/gas/other steam, and the geographic distribution of nuclear plants is not the same. An inspection of the nuclear plants suggests that in some cases the 767 data lists a plant as using fresh water, whereas it may have an estuary water source. A few additional plants were identified.

Another likely difference is how capacity is aggregated by plant type. In our tabulation each unit of capacity is listed under its fuel type. The EPA table appears to have been prepared with all of the plant capacity listed under one fuel type. This makes some difference although not very significant because only a subset of the selected plants have multiple fuels at one site. Finally, our simplified criteria of design flow greater than 500 MGD may contribute to the difference from EPA.

Capital costs for cooling towers

The cooling tower capital costs for the individual units at the 51 plants were taken directly from Shaw/Stone & Webster. <FN 1> A few units did not have costs in the Shaw list and were identified in the EIA 767 as using once-through cooling. Excluding any combustion turbine units, the same cost per kW was assigned to the missing unit as a similar size unit for the plant that included.

The Shaw costs were provided in a spreadsheet in millions of 2002 dollars. Each of the capital costs was converted to an annuity, using a capital charge rate of 0.15. This was divided by the plant capacity to create a POEMS model input of additional annual capital additions in $/kW, resulting in a range of $8/kW to $45/kW per year.

Candidates for Cooling Tower Retrofits Under the Water-body/Capacity-based Option
[see hard copy for table]

Additional O&M costs

The Shaw/Stone & Webster report estimates O&M costs to be $12 million for mechanical draft towers. Excluding the cost associated with the plant deration, because this is directly represented in POEMS as heat rate and capacity penalties, the net cost is roughly $6.6 million per year. This cost was for a 1100 MW plant, and Shaw advised that the costs could be scaled linearly. A cost of $6.0/kW-year was applied to the O&M of each unit. As with the O&M costs for the I&E equipment, half of this cost was assumed to be treated as variable and half as fixed.

Energy penalties

The EPA data and equations <FN 2> were used to create monthly energy penalties associated with the turbine backpressure penalty due to cooling towers relative to once through cooling. The auxiliary power losses computed by the Shaw report were added, and the totals were combined for the POEMS 2-month seasons. The POEMS seasonal heat rates and net output capacities were adjusted with the seasonal factors shown in the table below, with the exception that the capacity for summer season of July and August was adjusted by the maximum turbine penalties reported by EPA plus the Shaw auxiliary power penalty. The maximum penalties were used for the summer capacity derations, because the peak demand is likely to occur at the time of greatest deration because both are temperature related.

Energy Penalties (Percent Loss of Capacity)

	Nuclear				Fossil			
	Northeast	South	Midwest	West	Northeast	South	Midwest	West
Jan, Feb	1.43%	2.49%	1.39%	1.53%	1.63%	2.39%	1.59%	1.62%
Dec, Mar	1 60%	2 58%	1.60%	1 56%	1.76%	2.44%	1.78%	1.64%
April, May	2.10%	2.46%	2.60%	1.84%	2.10%	2.28%	2.76%	1.89%
June, Sep	2 70%	2 06%	2 78%	2 06%	2.52%	1.94%	2.65%	2.04%
July, Aug	2.75%	2.01%	3.23%	2.19%	2.55%	1.89%	2.99%	2.14%
Oct, Nov	1.91%	2.47%	1.73%	1.67%	1.90%	2.29%	1.72%	1.69%
Reported Max	3.32%	2.22%	3.53%	2.60%	3.04%	2.08%	3.23%	2.50%

Compliance Schedule

The compliance schedule used in the POEMS modeling follows that used by EPA as much as possible. The first installations are assumed to occur in the second year of the first permit cycle, even though facilities will have until the end of the cycle to comply Each plant/unit that was assumed to have a cooling tower added was also assumed to be out-of-service in the retrofit year for an additional two months (i.e., two months in addition to their normal annual maintenance). April and May were selected as the likely months for the outages because demand is generally low during this period.

Tower Candidate Plants by Compliance Year (Nameplate MW)

EOP GROUP ASSESSMENT OF EPA'S ECONOMIC & BENEFITS ANALYSIS

A CRITICAL ASSESSMENT OF THE EPA ECONOMIC AND BENEFITS ANALYSIS FOR THE § 316(b) PHASE II PROPOSED RULE

Prepared for: Edison Electric Institute

Prepared by: The EOP Group, Inc. Washington, D.C.

August 2002

EXECUTIVE SUMMARY

This paper presents the results of a comprehensive assessment performed by the EOP Group for the Edison Electric Institute of EPA's Economic and Benefits Analysis supporting the Proposed 316(b) Rule for Phase II Existing Facilities (67 Fed Reg. 17, 121-225). This assessment:

-Summarizes and critiques the EPA estimates of costs and benefits for both the EPA preferred option and the Waterbody/Capacity-Based Option;
-Analyzes both methodological issues and specific technical and economic assumptions used in the EPA analysis; and,
-Discusses specific recommendations for modifying the analysis.

The conclusion of this assessment is that the EPA analysis overestimated the benefits of reducing impingement mortality and entrainment and underestimated many of the costs of compliance with the proposed requirements In addition, the EPA analysis did not adequately address the impacts to electricity generators and electricity consumers A summary of the major issues identified by the EOP Group with, the EPA analysis is presented in Tables 1, 2 and 3. If EPA fully responds to the issues and recommendations in this paper, a re-analysis will show that the waterbody/capacity-based option will have net negative benefits, and that the preferred option will have near zero net benefits.

[see hard copy for table]
Table 3. Summary Assessment of Impact Analysis

Footnotes

1 EPA used information obtained through EIA form 860A (Annual Electric Generator Report-Utilities) and EIA form 860B (Annual Electric Generator Report-Non-utilities). EPA used the data from 1999, as more recent data was not available as of March 2002.

2 It should be noted that only the estimates for the Gulf Coast and Great Lakes facilities can be recreated using EPA's stated methodology based on the information contained in Part C of the EBA.

3 For some facilities multiple estimates were generated based on different methodologies. This column identifies the study type that is primarily responsible for the baseline loss estimate. The study types are Random Utility Model ("RUM"), Habitat Replacement Cost ("HRC"), and Societal Revealed Preference ("SRP").

4 For the Brayton Point and Monroe studies, HRC was used to define the upper bound loss estimate. The "best" estimate was calculated by averaging the upper and lower bounds. In each of these case studies the upper bound exceeded the lower bound by at least two orders of magnitude heavily influencing the "best" estimate.

5 The "best" estimates for JR Whiting, Pilgrim, and Seabrook are based exclusively on the HRC methodology.

ASSESSMENT OF THE EPA COST ESTIMATES

I. THE NUMBER OF IN-SCOPE FACILITIES MAY BE UNDERESTIMATED

A. Description of EPA Methodology

EPA's economic analysis relies upon correctly identifying the universe of in-scope facilities that would be affected by the rule. EPA's analytical approach may not have captured all of the covered facilities. If the universe of in-scope facilities is larger than EPA's estimate, then the total cost of the rule is commensurately larger than projected by the current economic analysis.

EPA used information collected by the Energy Information Agency ("EIA") to determine which plants (both utility and non-utility) had non-retired units using steam as a prime driver <FN 1>. EPA then obtained additional information on these plants through a two-tier questionnaire.

-The Detailed Industry Questionnaire (DQ) — gathered detailed information from a sample of the in-scope populations; and,

-The Short Technical Industry Questionnaire (STQ) — gathered less-specific information from a larger number of facilities.

The DQs and STQs provided to the utilities differed from those provided to the non-utilities in order to capture as. much facility-specific information as possible. The sampling designs differ between the utilities and non-utilities.

Initial Screening of Potential In-Scope Facilities: Working from a national inventory of electric generating facilities, EPA determined the subset of facilities that would receive the DQ.
-EPA estimated that 934 traditional generating facilities existed nationwide, based upon the 1999 Form EIA-767 database.
-56 of the 934 facilities were non-industrial non-utility power producers that had been misclassified – these were added to the non-utility sampling frame instead.
-241 were eliminated from the group of potential facilities eligible to receive the DQ because EPA believed that those facilities were unlikely to be in-scope due to either:
--The cooling water intake flow data was missing or zero; or
--The designation of cooling water source was either municipal or well water (which are not subject to 316(b) requirements) or missing.

The total sampling frame (total population from which the sample for the DQ survey could be drawn) consisted of 637 potentially in-scope facilities. A stratified sample of 282 received the DQ survey. The sample frame was first stratified using publicly available data based upon:
-Size (large and small)
-Receiving waterbody type (river, lake, marine/estuarine)

-Cooling-type system (closed cycle, once through, other)

This resulted in ten primary strata. The number of facilities sampled for each of the primary stratum is equal to the percent of the sampling frame in each stratum (except for the smallest stratum, which was over-sampled to prevent misrepresentation). The sampling frame was then further stratified based upon cooling water flow estimates to achieve a representative sample, yielding 26 strata. Each stratum was systematically sampled to represent NERC regions using a random sample.. Facilities in the sampling frame not selected for the detailed questionnaire received the STQ. EPA sent out a total of 282 DQs and 590 STQ5 to utility-owned generating facilities.

Sample Weights: The purpose of the surveys is to create estimates for the entire population of facilities nationwide. To achieve this goal, the sample must be weighted to account for sample size within each stratum and the non-response rate for each survey.

The DQ survey may be used alone to create nationwide estimates, or the DQ and STQ surveys may be combined to construct national estimates. Each type of estimate requires a separate weight for accuracy. Survey estimates produced from the combined DQ and STQ survey responses would be more efficient (same mean, smaller variance due to the larger sample).

Use of the Survey Information: The information obtained in the DQ and STQ was used to determine which plants would be covered by the rule, what compliance responses would be required at each facility, and what the costs of compliance would be for any regulatory option.

Discussion of Issues

1. The Small Sample Size may not have yielded Statistically Significant National Estimates

The relatively small number of facilities (282), divided into 26 strata in the DQ process, raises statistical issues regarding the Agency’s ability to generalize from this information. This could call into question the Agency’s ability to generalize from this information. However, it appears that the only information that was extrapolated from the 282 DQ facilities to those facilities covered by the STQ was design intake flow. As a result, the estimate of the engineering compliance costs for STQ facilities, which are based on design flow, may be biased. It may be appropriate to rely on the extrapolated values only if these biases are not systematic. However, this is not known.

2. The Initial Exclusion of Facilities Not Reporting CWIS information to EIA from the Surveys may have biased the Final National Estimates and Underestimated Costs

EPA excluded 241 facilities from the population from which it drew its stratified random sample. Based on information from EIA databases, EPA excluded facilities for which cooling water intake flow information was missing or zero and facilities for which the source water was missing or reported as municipal or well water. Exclusion of these facilities from further consideration in the EPA survey process leads potentially to an underestimate of the number of in-scope facilities.

There is no basis for assuming that facilities with a reported intake flow of zero, or no reported intake flow, are not subject to the rule. Facilities that did not report this data to EIA may still be covered by the requirements of the rule. However, since these facilities did receive STQs, it is possible that some of these omissions were corrected in the final EPA database. Even if these facilities were identified in the STQ response, they could still bias the final database if they were systemically different from facilities included in the DQ sample frame.

3. EPA did not use the best available data on cooling intake design flows.

Finally, EPA may have introduced errors in the design flow values in its database by not using the best available data. Rather than using the reported values for design flow in the EIA database, EPA estimated design flow based on the relationship between design flow and actual flow contained in the responses to the DQ survey. Since the design flow estimates are used as the basis for estimating compliance costs, these EPA cost estimates would be affected. It is not known whether the EPA approach would have underestimated or overestimated the cooling water design flows.

C. Recommendations for Re-Analysis

1. EPA should check the STQ responses from the facilities excluded based on a lack of EIA data against the assumption that these facilities will not be covered by the rule. The exclusion of facilities could have led to underestimates of costs, particularly in those cases where the missing facilities are from a subpopulation that is particularly sensitive to the costs of compliance.

2. EPA should compare the results of its approach to estimating cooling intake design flows to the actual design flows reported in the EIA 767 database.

EPA Response

The Agency has considered the points raised in the comment and has met the conclusory recommendations of the commenter regarding re-analysis of flow data.

Regarding Discussion of issues, #1:
The Agency notes that 282 is not a small sample size, and division into 26 strata is expected to increase rather than decrease precision. The commenter suggests that bias may arise but provides no evidence, reasoning or data to support the claim.

Regarding "excluded" under Discussion of Issues, #1 & #2, and Recommendations for Re-Analysis, #1

EPA did not exclude any facilities from its final database. All facilities were surveyed with either a detailed questionnaire or a short technical questionnaire. All facilities either reported a design intake flow or the design flow was estimated as described in the record. All reported design flows, and all estimated design flows, were reviewed for consistency with other relevant data. Costs were estimated for all facilities responding to questionnaires (i.e. for those responding to either form of questionnaire, detailed and short technical). The commenter presents no reasoning or data to support the notion of a bias.

Regarding Recommendations for Re-Analysis, 2:
All reported design flows, and all estimated design flows, were reviewed for consistency with other

relevant data. Design flows reported in the survey were certified as correct by the respondent.

The Agency compared the results of its approach to estimating design intake flows for short-technical questionnaire facilities to the design intake flows in the EIA 767 data base. The Agency found that its design intake flows generally exceed those found in the EIA 767 data base (at a facility level) by a median of 25 percent. For short-technical questionnaire facilities within the scope of the final rule, the median ratio of EPA design flow to EIA design flow is 1.35. These facts contradict the commenter's assertion that the methodology used by the Agency for estimating design intake flows for short-technical questionnaire facilities would potentially underestimate design flows (and therefore costs). In addition, the Agency notes that the EIA database lacks flow data on 33 facilities that EPA found had reported a median actual annual intake flow of 48 MGD in the short-technical questionnaire (i.e., their design intake flows would be appreciably above 50 MGD, and therefore within the scope of the rule). This brings into question the validity of the commenter's assertion that the Agency has potentially overlooked in-scope facilities in its short-technical questionnaire.

The Agency compared the design intakes reported through the Detailed Questionnaire to EIA 767 data. This comparison shows that the flows reported to EPA for design intake flow generally exceed those reported to EIA 767 by 2 percent. The median ratio of facility-level EPA design flow to EIA design flow for detailed questionnaire facilities is 1.02. In addition, the Agency notes that the EIA database lacks flow data on 30 facilities that reported to EPA a median design intake flow of 96 MGD (and a median actual annual intake flow of 46 MGD) in the detailed questionnaire. This further brings into question the validity of the commenter's assertion that the Agency has potentially overlooked in-scope facilities in its data collection.

The Agency also compared the EPA and EIA design intake flows for all facilities within the scope of the rule. This comparison shows that the flows used by EPA for design intake flow generally exceed those reported to EIA 767 by 10 percent. The median ratio of facility-level EPA design flow to EIA design flow for detailed questionnaire facilities is 1.12.

The Agency notes that of the facilities that it determined are within the scope of the rule due to the flow threshold (i.e., their design intake flows were above 50 MGD in the EPA database), the EIA data predicts 18 facilities to have design intakes below the threshold. Therefore, had the Agency relied on the incomplete EIA 767 flow data, it would also have under-predicted the number of facilities within the scope of the rule by 18. Therefore, the concerns of the commenter that the Agency would be underestimating the number of facilities within the scope of the rule are again not supported, since the Agency's reliance on data reported in the 316(b) survey has both identified 18 facilities not above the threshold according to EIA 767, but further identified 63 facilities for the in-scope database missing flow data in EIA 767.

Costs

THE ESTIMATED ENGINEERING COMPLIANCE COSTS FOR THE PREFERRED OPTION ARE UNDERESTIMATED

A. Description of EPA Methodology

EPA developed costs for three compliance technologies:
1. Traveling screens with fish handling systems.
2. Traveling screens without fish handling systems.
3. Fine mesh screens.

Costs for each facility were estimated based on the installation of one or more of the technologies above depending upon the regulatory option being evaluated and the technologies already in place at the facility.

EPA used vendor estimates of capital costs for new facilities (the same estimates found in The Technical Development Document for the Final Regulations addressing Cooling Water Intake Structures for New Facilities) as the base capital costs of each control technology. The Agency then accounted for the costs of construction, retrofitting, and location (by State, but not by waterbody). EPA's estimate of a utility's total capital/construction cost, therefore, is the result of the following equation:

Total Capital/Construction Cost = (Estimated Total Capital Costs) x (Construction Factor) x (Retrofit Inflator) x (State Specific Capital Cost Factor)

Where:
-Estimated Total Capital Cost = (Vendor Estimate) x (Contingency Factor), and is based on vendor information reflecting the cost of the specified technology at a new facility.
-Construction Factor represents the increases in cost necessary to modify an existing CWIS to accept the specified technology.
-Retrofit Inflation Factor represents the additional cost associated with a retrofit to an existing facility.
-State Specific Capital Cost Factor adjusts for regional differences in construction costs.

Facility-level cost estimates for each compliance option: EPA assumes that any facility selecting the appropriate compliance suite will fall into the compliance ranges required by the proposed rule. The cost analysis, therefore, is based upon a series of compliance option tables that provide the input for the "Estimated Total Capital Costs" variable for the cost equation shown earlier. A facility owner should be able to calculate the total capital and construction costs by taking the appropriate value from one of the tables and inserting it into the above equation. For example, a facility projected to install or upgrade impingement control or survival technologies by including a fish handling and return system would use the applicable value from Table 2-11 in the Technical Development Document:

[see hard copy for table]

Generalized average compliance costs: EPA reviewed the list of in-scope facilities and made certain assumptions regarding the applications of a compliance technology at each facility. EPA then developed an estimate of compliance costs, by facility, in three cost categories: capital costs, annual O&M costs and annual monitoring costs.

B. Discussion of Issues

1. The EPA compliance cost estimates make no allowance for site specific factors.

The EPA lists of facilities and estimated compliance costs does not provide specific information on geographical location, so it is not possible to determine how the assumed compliance technologies are related to specific locations. In addition, the data do not provide any information to determine how differences in fuel sources and site specific factors such as geometry of the intake, were considered in estimating costs.

The EPA cost data were analyzed by performing a statistical regression analysis on the 344 facilities (out of 550 total in-scope facilities) for which EPA provided facility-level cost data. The regression analysis showed that costs were almost entirely correlated to design flow, which would further confirm that site-specific factors were not considered in the cost estimates. The results of the regression analysis are summarized in the following cost curves.

Impingement Controls Only (fish handling and return system)
Capital Cost = 84191 + 1.78678 (design intake flow)
Sample Size = 155 plants
R^2 = 0.97124695

Entrainment Controls Only (Fine mesh traveling screens)
Capital Cost =0.331142 + 7.403304 (design intake flow)
Sample Size = 58 plants
R2 =0 96216887

Impingement and Entrainment Controls
Capital Cost = 8974905 + 8.203129 (design intake flow)
Sample Size = 131 plants
R2=0.9825143

The review of the EPA facility level cost data raises an additional issue, namely the number of facilities that were included in the EPA cost estimate. The EPA discussion of cost and benefits stated that 470 facilities would be required to install either impingement controls only or combined impingement and entrainment controls. However, the facility level cost data only includes 344 facilities, raising a question as to whether all impacted facilities were included in the national cost estimate. The comparison of facilities is discussed in more detail in the discussion of the integrated planning model later in this report.

2. The assumed compliance technologies may not meet the proposed performance standards, thereby

underestimating compliance costs.

EPA assumes that if a given facility adopts the suite of compliance options modeled by the Agency then that facility will achieve the performance levels specified in the proposed rule. There may be site-specific cases where the compliance technologies assumed by EPA may not achieve the proposed performance standards. These facilities, therefore, may not be in compliance with the regulation even if they install one of the technologies considered by the Agency in the proposal. The problem will be exacerbated if the Agency mandates that facilities achieve the maximum values within the required compliance ranges (i.e., 95% reductions in impingement mortality, 90% reductions in entrainment). Other provisions of the proposed rules, such as the cost-cost and cost-benefit tests, and other measures such as trading and environmental enhancements, could help to mitigate the potential for higher costs, but the impact of these measures is uncertain.

C. Recommendations for Re-Analysis

1. EPA should review the database of the compliance cost estimates for each facility to ensure that the cost estimates include all 470 facilities that are assumed to have retrofit requirements.
2. EPA should review and compare the cost and benefit estimates to ensure that both sets of estimates are based on the same number of facility-level retrofits.
3. EPA should review and revise its cost estimation methodology to address site specific factors in addition to only design flow. In addition, EPA should retain and expand the language in the proposed rule regarding:

a) Site Specificity: At a minimum, EPA should retain the cost-cost test, the cost benefit test, and other flexible approaches such as trading and environmental enhancements, and clarify that these provisions may be used in site specific cases where the application of one of the technologies considered by the Agency in the proposal is not technically feasible at a site or will not meet the specified performance levels; and,

b) Presumptive remedy: The language in the proposed rule should provide for a presumption of compliance with the regulatory requirements in the event that a facility either:

-Installs one of the technology suites evaluated by EPA; or
-Installs alternative technologies, engages in habitat restoration, or undertakes a combination of both that produce reductions in impingement and entrainment commensurate with the approved technologies.

In either case, facilities would have the responsibility to demonstrate that they have both installed and operated the compliance technologies correctly. This change, combined with the existing options found at 125.94(a) (3) of the proposed rule, will significantly reduce uncertainty, transaction costs, and costs of the rule without reducing the benefits estimated by EPA.

EPA Response

First the Agency notes that it revised and expanded the set of technologies upon which the costs of the preferred option were based for the NODA (68 FR 13526). The overall national technology upgrade costs of the preferred option increased appreciably for the NODA. In addition, the Agency incorporated construction downtime outages into the assessment of national costs for the technologies forming the basis of the preferred option. As a result, the primary basis of the comparison in the comment is no longer relevant to the costs of the final rule. Also, the commenter's "Description of EPA Methodology" is no longer relevant.

Regarding the assertion that the Agency's compliance costs estimates do not take into account site-specific factors, the Agency points out that it revised the majority of the bases for assessing technology upgrade costs so as to incorporate more site-specificity into its analysis for the final rule. The Agency believes that the methodology utilizing all available site-specific data and the wide range of technologies applied to model facilities has incorporated and accounted for site-specificity in the final rule cost estimates.

Regarding the assertion that the assumed compliance technologies may not meet the proposed performance standards, thereby underestimating compliance costs, the Agency again reiterates that it revised the majority of the basis of its cost estimates for the final rule. Also see response to comment 316b.EFR.306.039.

Regarding the recommendations for reanalysis, the Agency notes that it has adopted these recommendations for the final rule.

Regarding the recommendation of a "presumptive remedy," the Agency notes that the final rule has adopted a set of presumptive technologies and has allowed for Directors to expand the list of presumptive technologies. The final rule meets the recommendations under this category from the comment.

Costs

THE COSTS FOR COOLING TOWERS FOR THE WATERBODY/CAPACITY BASED OPTION ARE SIGNIFICANTLY UNDERESTIMATED

A. Description of EPA Methodology

The cost estimates for the waterbody / capacity based alternative were evaluated because EPA stated that this alternative is under consideration for the final rule in section B7- 1 of the Economic and Benefits Analysis: "While EPA is not proposing this option, EPA is considering it for the final rule."

The EPA based its cost estimates on the cooling tower costs developed for the final new facility 316(b) standards. The basic capital cost was derived from a "rule of thumb" cost per gpm obtained from vendors. This rule of thumb figure was modified to attempt to account for installation costs, construction material and splash fill. The Agency then translated this information into a cost equation from which one can calculate cooling tower cost based on flow. To account for the fact that the costs of retrofitting a cooling tower to an existing facility is likely to be greater than the cost of constructing a cooling tower at greenfield facility, the Agency applied a 20 percent adjustment factor to its cost estimates. For purposes of this analysis, the Agency assumed the use of mechanical draft redwood cooling towers with a ten degree Fahrenheit approach for non-nuclear facilities and a mechanical draft concrete cooling tower with a ten degree approach for nuclear facilities.

Capital Costs: For the non-nuclear facilities, the equation for an installed ("greenfield") redwood mechanical draft cooling tower with a 10 degree F design approach and splash fill is:

[see hard copy for equation]

For a nuclear facility needing a mechanical-draft concrete cooling tower system with splash fill:

Y=-6E-5 x^2+87.845 x 31674 (in1999 $)
where x = flow in gallons per minute valid up to 225,000 gpm

These equations represent the starting point for assessing the conversion project costs. The costs are then adjusted by:
-The regional cost factor (same as for the proposed option)
-A 20 percent retrofit factor
-Additional adjustments for makeup and discharge piping.

EPA reported that it tested the conclusions of its estimation equation against actual cooling tower construction projects. However, the details of the comparison were not included in the documentation.

Operation and Maintenance Costs: The O&M cost equation for an installed ("greenfield") redwood mechanical-draft cooling tower with a 10 degree F design approach and splash fill is:

y = -4E-6 x ^2 ÷ 11.617 +2055.2 (in l999 $ for with Splash Fill)
where x = flow in gallons per minute valid up to 225,000 gpm

For a nuclear facility with a mechanical-draft concrete cooling tower system and splash fill, O&M costs are calculated with the following:

y -3E-6 x^2 + 10.305 x + 1837.2 (in 1999 $ for Concrete with Splash Fill)
where x = flow in gallons per minute, valid up to 225,000 gpm.

The O&M cost estimates subtract out the reductions in pumping cost associated with operation of the existing once-through system, but do not include a retrofit factor. The Agency also accounted for the costs of refurbishing condenser tubing where necessary to avoid failures that can be associated with cooling tower retrofit. For this purpose, the Agency assumed that all facilities using brackish water will convert to copper-nickel alloy tubing or better (more corrosion resistant), and all facilities using salt water will convert to stainless steel or better.

Energy Penalty: The energy penalty has two components, the long-term reduction in available capacity for sale and the cost of the connection outage that occurs during the downtime required for the retrofit. The long-term reduction in available capacity resulting from recirculating cooling towers is expressed as a percentage of generating capacity:

Annual Revenue Loss = (Annual Loss of Electricity Sales) x (Electricity Price)

Where:
Annual Loss of Electricity Sales = (Annual Electricity Sales) x (Energy Penalty)

The loss of electricity sales is the result of:
-A reduction in unit efficiency due to increased turbine back-pressure; and,
-Increased auxiliary power requirements to operate the new system.

EPA developed the following table of energy penalties, by region and by fuel type, expressed as a percentage of plant capacity.

Table B1-1: Annual Energy Penalty (% of Plant Capacity) by Facility Type and Geographic Region.
[see hard copy for table]

EPA assumed that the connection outage would add one month to the normal planned outage schedule. EPA monetized the cost of the one month downtime by taking the lost revenue and subtracting the foregone fuel expense:

[see hard copy for equations]

A. Discussion of Issues

1. Redwood Cooling Towers may not be used as widely as EPA assumes, underestimating costs

EPA assumes that all 41 non-nuclear facilities required to install cooling towers will select redwood towers. At some facilities, however, the site-specific conditions may prevent the use of redwood towers, causing those facilities to turn to more costly options. EPA's cost estimate, therefore, may substantially underestimate the true cost of regulatory compliance for non-nuclear generating facilities. For example, EPA's own cost data show that concrete towers using concrete are 25% more expensive than redwood towers. In addition, EPA has not considered the environmental effects of widespread use of redwood lumber.

2. The methodology for calculating the cost of the energy penalty is flawed, and the costs are underestimated.

The EPA estimate was developed by applying an annual average energy penalty factor to annual average revenues. This methodology is flawed and is misleading.

-This methodology implies that the energy penalty leads to a net reduction in electricity sales and consumption. Consumption does not change. Instead, the loss of supply due to the energy penalty is likely to be made up from other sources with higher marginal cost. The increased cost to the consumer is based, not on average price, but rather on the difference in price between the foregone supply and the replacement supply. In addition, if the replacement supply has the effect of increasing the market price of electricity within a regional market, then all consumers will incur higher costs for their entire supply, not merely the replacement supply. The impact on generators is more difficult to estimate, because of potential shifts in generation among facilities and among firms.

-The EPA methodology also fails to account for seasonal impacts. The energy penalty is most pronounced in the summer season, when demand is highest, and when market prices are at their peak. The analysis of the cost of the energy penalty should be estimated seasonally, and not merely on an annual average basis.

3. EPA's cost estimates for cooling towers are substantially underestimated.

Applying EPA's retrofit equation for redwood cooling tower installation yields a rough average cost estimate of $80 per gpm for the redwood towers. Other analyses performed by DOE, the industry, and elsewhere in the literature all find that the costs of tower retrofits are between $140 and $225 per gpm. EPA's estimate is half or less than the costs estimated by other sources. The documentation for these estimates is shown in the table below:

COMPARISON OF COOLING TOWER COSTS
[see hard copy for table]

There are several easily identifiable factors that account for the differences between EPA and industry estimates.

-The EPA estimates exclude the construction cost of modifications to the intake system and costs for "blowdown" systems (i.e., processing of deposits that build-up on cooling tower surfaces). Based on a detailed analysis of costs at two retrofit installations – Salem and Millstone – the costs for intake modifications and blowdown are estimated to add about 5 percent to EPA's estimates.
-The EPA retrofit cost factor is too low. EPA included a cost adjustment factor of 20 percent to account for the higher cost of a retrofit installation compared to the cost of a new installation. Other

industry information suggests that the retrofit factor is more like 50-100 percent.

C. Recommendations for Re-Analysis

1. EPA should revise its cost estimates for cooling towers to reflect the industry cost data In addition, the considerable uncertainty surrounding the EPA assumptions makes it appropriate to use a sensitivity analysis to determine the robustness of the cost estimates.

2. The EPA methodology for estimating energy penalties should be dropped entirely, in favor of a modeling approach that can capture the net effect of a variety of market changes. The IPM model could potentially be used, but there are flaws with the IPM methodology as well (discussed later in the paper).

3. EPA should revise its estimates of the costs of the energy penalty to address seasonal variation The use of annual averages underestimates the effects in the summer season, when both the energy penalty and the reduction in revenues are greatest.

EPA Response

The Agency determined that retrofitting cooling towers was not an acceptable basis for the final regulatory requirements, in part, based on the costs and uncertainties of the technology.

The Agency notes that the following comment is incorrect: "EPA reported that it tested the conclusions of its estimation equation against actual cooling tower construction projects. However, the details of the comparison were not included in the documentation." The Agency did include the documentation of the comparison of its cooling tower construction project estimation in the proposal record. See DCNs 4-2526 and 4-2522.

Nonetheless, the Agency notes the commenter is misled in his interpretation of the Agency's choice of redwood for cooling tower material costs. As documented in the Technical Development Document for the proposal, the Agency selected redwood for cooling tower material because it is the median cost material. The Agency then went on to point out that fiberglass is becoming industry standard for cooling towers (and documented so), which roughly corresponds to the median cost material of redwood. By basing a national cost estimate on a particular material (redwood) that happens to be the median cost item and well correlated to the industry standard (fiberglass), the Agency's actions would in no way ever require facilities to use said material. This point is important for the case of other technologies, and, hence the Agency addresses it here, despite the fact that the cooling tower technology does not form a basis for the final rule.

EPA also notes that the commenter apparently misunderstands how the Agency determined the cost of construction downtimes (and the resultant electricity generation foregone). As the commenter recommends as a solution to fix an perceived error, the Agency indeed did utilize the IPM model to market specific costs of electricity losses.

Facility & firm-level costs/Econ. Practicability

THE METHODOLOGIES USED BY EPA TO ASSESS THE ECONOMIC AND MARKET IMPACTS OF COMPLIANCE COSTS ARE FLAWED

The estimated compliance costs provide a measure of the total cost to society. The impacts of these costs are then further evaluated, to determine the effect on electricity generators and the effect on electricity consumers. In concept the effect on electricity generators is determined by the change in profits from operations, which is the net effect of increased compliance costs that are not recovered through increased revenues. The effect on consumer would be determined by the change in electricity prices. EPA employed four different approaches to assess these effects:

-Cost-to-Revenue Test (CRT) – a test of effects on generators at both the facility level and the firm level.
-Average Household Impact – a test of effects on consumers.
-Average Electricity Price analysis – a test of effects on consumers.
-Electricity Market Impacts Based Upon an Analysis Using the Integrated Planning Model (IPM) – test of the net effects on both generators and consumers.

As applied, none of the four tests employed by EPA yielded meaningful results. The first three tests have serious methodological flaws, and the IPM modeling analysis is based upon problematic assumptions

EPA Response

Please refer to the following comment responses:

--Cost-to-Revenue Test (CRT): 316bEFR.072.206 (subject matter code 9.01).
--Average Household Impact: 316bEFR.072.207 (subject matter code 9.02).
--Average Electricity Price analysis: 316bEFR.072.208 (subject matter code 9.02).
--Electricity Market Impacts (IPM): 316bEFR.072.209 (subject matter code 9.03).

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

The Cost-to-Revenue Test (CRT) Is Not a Valid Measure of Economic Impact

A. Description of EPA methodology

The CRT compares both average and maximum annual costs per facility against the facility's (and firm's) gross revenue. EPA estimated the CRT at both the individual facility level and the firm level. The CRT for the preferred option was in the range of 0.02% to 32.3%. A detailed breakdown of the EPA estimates is shown in the two tables on the following pages.

B. Discussion of Issues

The CRT methodology completely ignores the fact that gross revenue is a meaningless measure of economic viability (or lack thereof). Commodity industries (including the electric power industry) are generally characterized by low profit margins earned on high volumes of transactions. This means that while gross revenues can be quite large, the net revenues are frequently a small percentage of gross revenues. In electric power, these margins are generally predicted to shrink even further in the wake of expanding deregulation. Thus, a facility or firm with a low estimated CRT may actually have negative net revenues after application of the 316(b) requirements, resulting in facility closure.

By using the CRT, therefore, EPA failed to evaluate the actual economic impact to firms and facilities. A more appropriate measure would be to analyze the impact on the firm's net revenues, with consideration of the portion (if any) of increases costs that can be recovered through higher revenues.

[see hard copy for tables]

C. Recommendation for Re-Analysis

1. EPA should evaluate the effect of the proposed rule by calculating the ratio of the net present value (NPV) of the marginal cost of compliance to the NPV of expected net revenues. This is the method used by financial markets, the ultimate arbiters of the viability of a given investment.

2. The guidelines for economic analysis for E.O. 12866 specifically direct the Agency to consider the relative impacts of a regulation on different segments of the industry. EPA should therefore compare the net present value ratios of discrete groupings of facilities to assess the possibility of competitive harm. These groups should be delineated by factors such as:

-Size
-Location.
-Customer Base

Only by determining the reductions in net present values (as a result of compliance) of the facilities in each group can the Agency determine the actual economic impact on firms and facilities resulting from the rule.

EPA Response

EPA notes that the cost-to-revenue measure is only one of several measures used in the economic analysis of the Phase II regulation. As stated in Chapter B2 of the EBA in support of the proposed rule, and as described elsewhere in these responses to comments (see 316bEFR.005.021), EPA used the cost-to-revenue analysis as a measure of the magnitude of likely compliance costs. Footnote 1 of Chapter B2 of the EBA explicitly states that the measures presented in Chapter B2 are not intended to predict plant closures or other types of economic impacts.

Economic impacts as a result of the proposed rule and the final rule were estimated using an energy market model (the IPM). For each facility subject to the final Phase II rule, this model calculates the Net Present Value (NPV) of future operations. This calculation is done both in the absence of the Phase rule (the baseline) and with the estimated Phase II compliance costs (the policy case). If the NPV of future operations becomes negative as a result of Phase II regulation, the model will predict the facility to close. As such, EPA's analysis explicitly takes into account the impacts of reductions in net present values on economic viability.

In answer to the commenter's request that the impact analysis should be reported by segments within the industry, EPA notes that the IPM analysis is organized and reported according to the most important industry segment framework, the regional electricity markets as defined by the North American Electric Reliability Council regions. EPA also conducted and reported extensive analyses according to entity size classification as required for the Regulatory Flexibility Act assessment of regulatory impacts. EPA would also like to point out that in addition to reporting economic information by NERC regions, many other analyses are reported on a regional basis.

Subject Matter Code 9.02
Economic impacts on consumers/households

Estimates of Average Household Cost Impacts Are Not Meaningful, and in Fact Misleading.

A. Description of EPA Methodology

EPA estimated the average price increase in energy per household resulting from compliance with the proposed regulatory requirements as another method of assessing the economic impact of the rule. The calculated annual cost per residential consumer ranges from $0.33 in NERC region ASCC to $2.55 in NERC region HI.

EPA evaluated the annual cost per household by multiplying the average annual compliance cost per MWh of sales by the average annual electricity sales per household. Both input variables were calculated by NERC region according to the following methods:
-Average Annual Compliance Cost per MWh of Sales = Total electricity sales divided by total pre-tax compliance costs. EPA compiled the total electricity sales from the 2000 Form EIA-861 database and used utility-level sales aggregated by region.
-Average Annual Electricity Sales per Household = MWh of residential sales divided by the number of households. The raw data came from EIA-861.

B. Discussion of Issues

Average cost per household is not a meaningful statistic – the denominator is so large that it masks the true effects of the rule. This approach is only warranted in those instances where the entire population is homogenous with respect to the percentage of cost shouldered — that is, in those cases where each household can reasonably be expected to see identical increases in costs as a result of rule This is clearly not the case

-EPA states that only 13 percent of existing facilities (representing 50 percent of electricity generation) are in-scope facilities under the proposed rule. However, the average cost calculation is weighted across the entire industry base.

-The impact of the rule is not uniform across regions, or even within regions. Specific localities and/or regions of concern may contain populations dependent upon in-scope facilities. For example, rural populations or those served by government-owned facilities might face a significant increase in the cost of electricity, but that effect would be masked by dividing the total cost to the nation by the number of households. The demand for electricity is ubiquitous across populations, but the elasticities of demand, the constraints on supply, and the expected cost increases are not.

The Agency's presentation of the cost impact assessments masks the true impacts on sensitive subpopulations. Both UMRA and E.O. 12866 specifically direct the Agency to consider the effects of the regulation on sensitive subpopulations. This is impossible when the costs are only calculated as a function of a population-wide average.

C. Recommendation for Re-Analysis

EPA should eliminate this analysis altogether. It cannot provide a meaningful measure of the impacts of the regulation, and in fact leads to erroneous impressions.

EPA Response

The commenter suggests that EPA's analysis of costs per household is not meaningful and misleading and should therefore be eliminated. Specifically, the commenter asserts that because only 13 percent of existing facilities (representing 50 percent of electricity generation) are in-scope facilities under the proposed rule, it is not reasonable to spread the cost across the entire industry base.

EPA disagrees with this comment. EPA notes that its analysis is conservative because it rests on the assumption that affected facilities can pass 100% of their compliance costs on to customers. In fully or even partially deregulated markets, this is unlikely. If any portion of the costs could not be passed on to customers, the estimated cost per MWh of sales, and the resulting cost per household would be lower than presented in EPA's analysis. EPA understands that, if costs were passed on to customers, there is considerable uncertainty over how costs would be distributed among electricity customer classes – residential, commercial, and industrial – and costs could be passed more heavily to the residential customer class than to the industrial or commercial classes. EPA therefore conducted a sensitivity analysis assuming that all compliance costs are passed-through to residential customers – that is, neither the complying facilities nor other customer classes bear a share of these costs.

This analysis showed that in nine of the ten NERC regions, the estimated annual cost per household would be less than $5 per household, ranging from $1.44 to $4.87. Only Hawaii is estimated to bear higher costs of $28.74 per household (see DCN 6-4037 for more detail). The results of this conservative sensitivity analysis do not differ materially enough from the basic analysis to affect EPA's decision with respect to this final rule.

The commenter further states that "The impact of the rule is not uniform across regions, or even within regions. Specific localities and/or regions of concern may contain populations dependent upon in-scope facilities. For example, rural populations or those served by government-owned facilities might face a significant increase in the cost of electricity, but that effect would be masked by dividing the total cost to the nation by the number of households."

EPA disagrees with this comment. EPA notes that rural populations, or those served by governments, do not exist in isolation of the rest of the electricity market. It is difficult to envision a scenario where some customers in a region enjoy the benefits of deregulation while others don't.

EPA further notes that this analysis is only one of several measures used by EPA in support of this final rule. Results from the other analyses support EPA's findings of low likely impacts on electricity markets and electricity consumers.

Comment ID 316bEFR.072.208

Subject Matter Code 9.02

Economic impacts on consumers/households

Author Name Thomas R. Kuhn

Organization Edison Electric Institute

3. The Electricity Price Analysis Test is Not Meaningful and is in Fact Misleading

In order to assess the potential effects of the regulation on electricity prices, EPA compared the average compliance cost per KWh of sales against baseline electricity prices. EPA used the total electricity sales and the consumer prices from the Annual Energy Outlook (AEO) 2002. The analysis assumes that industry passes the full cost of compliance through to consumers. In addition, the Agency assumes that all sectors -- residential, commercial, industrial, and transportation -- bear an equal share of the increase per MWh of purchased electricity.

EPA estimates that the additional costs of compliance resulting from the preferred option will raise the price of electricity:
-0.09% for Residential
-0.10% for Commercial
-0.17% for Industrial
-0.10% for Transportation

Several problems exist with this analysis. First, the estimates do not provide an accurate picture of the compliance impact since the costs of compliance are averaged against total sales. Total sales include the purchase of MWh supplied by facilities that are not in-scope, and therefore exempt from complying with the regulation.

Second, by averaging across entire NERC regions, the EPA analytical approach makes it impossible to assess the impacts on sensitive subpopulations Both UMRA and E.O. 12866 specifically direct the Agency to consider these vulnerable groups.

Finally, it is unrealistic to assume that cost is allocated uniformly across customer groups. In a relatively competitive power market, different types of consumers have different power requirements. This can lead to vastly different elasticities of demand, resulting in some groups paying a proportionately larger share of the rate increases than others.

EPA Response

EPA notes the following:

1. This analysis is only one of several measures used by EPA in support of this final rule. In particular, EPA refers the commenter to its analysis of potential price effects using the IPM. This analysis showed very low expected impacts on energy prices, which supports the findings of this analysis.

2. The purpose of this analysis is not to identify potential impacts to sensitive subpopulations. For more information on potential impacts on small entities see Chapter B4 of the final EBA (DCN 6-

0002). See also response to comment 316bEFR.028.008 for a discussion of potential impacts on small governments.

3. EPA understands that, if costs were passed on to customers, there is considerable uncertainty over how costs would be distributed among electricity customer classes – residential, commercial, and industrial – and costs could be passed more heavily to residential customers than to industrial or commercial ones. EPA therefore conducted a sensitivity analysis assuming that all compliance costs are passed-through to residential customers – that is, neither the complying facilities nor other customer classes bear any of the compliance costs. This analysis showed an estimated increase in prices to residential customers ranging from 0.1% to 0.8% (see DCN 6-4038 for more detail). The results of this conservative sensitivity analysis do not differ materially enough from the basic analysis to affect EPA's decision with respect to this final rule.

The EPA Market Impact Analysis, Using the Integrated Planning Model (IPM), is Flawed.

A. Description of EPA Methodology

The IPM is an engineering-economic optimization model of the electric power industry. It calculates the optimal solution to an objective function equal to the present value of the sum of all capital costs, fixed and variable O&M costs, and fuel costs. The model generates least-cost resource dispatch decisions based upon user specified constraints including:

-Demand Side
---Reserve margin constraints
---Minimum system-wide load requirements
-Supply Side
---Capacity constraints
---Availability of generation resources
---Plant minimum operating constraints
---Transmission constraints
---Environmental constraints

The model is capable of evaluating new resource investment options (capacity expansion/repowering of existing plants and investment in new plants) in addition to existing capacity during the optimization calculations.

Electricity Generating Plant Database: The IPM uses a database of all existing utility-owned, independent, and cogeneration generation units that contribute capacity to the electric transmission grid. Individual generators are aggregated into model plants with similar O&M costs and specific operating characteristics. The EPA Base Case 2000 contains 1,390 model plants. However, the Base Case 2000 was originally created to support air policy analyses, so the facilities subject to the Phase II rule were disaggregated from the IPM model plants and “run” as individual units along with other model plants. This change increased the number of model plants from 1,390 to 1,777.

IPM Regions: The IPM divides the contiguous U.S. power market into 26 regions. For the purposes of evaluating the Phase II rule, the IPM regions were aggregated into NERC regions.

Regulatory Options Modeled: EPA did not ever run the IPM model for the preferred option, as described in the proposed rule. The two runs of the model actually conducted by the Agency were for two other options:
-The waterbody/capacity-based option; and
-The all cooling towers option.

EPA stated that time constraints made it impossible to fully evaluate the preferred option The Agency determined that since the two options evaluated were both more stringent than the preferred option, the results placed an upper bound on the probable costs of the proposed rule EPA made two critical assumptions to adjust the two completed runs of the IPM (for the Waterbody/Capacity-Based Option and for the All Cooling Towers Option) to better reflect the impacts of the preferred option:

-EPA determined that the following NERC regions — ECAR, MAIN, MAPP SPP — did not have any facilities costed with a closed-cycle recirculating cooling water system. The Agency assumed that the modeling results for the waterbody/capacity option could be used to represent the impacts of the preferred option for those four regions.

-EPA then compared the modeled differences between those four NERC regions and the other six NERC regions — ERCOT, FRCC, MAAC, NPCC, SERC, and WSCC. EPA determined that the IPM model overstated the costs for these regions (e.g., some facilities were required to use wet cooling towers that were not assumed compliance measures in the preferred option). The Agency then compared the two regional groups using three characteristics and found no substantive difference. EPA therefore concluded that the results from the four regions that were modeled would be representative of the other NERC regions (that were not modeled). The characteristics were:

---The percentage of total base case capacity subject to the proposed rule;
---The average annualized compliance costs of the proposed rule per MWh of generation;
---The distribution of compliance requirements of the proposed rule.

Model Run Years: EPA only ran the model to generate data for several discrete years:
-2008 – selected based upon the assumption that 2008 represents the industry conditions upon full implementation of the preferred option.
-2010 – identified as a representative year during which facilities that retrofit cooling tower (under the waterbody/capacity-based option) may experience a temporary outage during installation;
-2013 – represents the first full, post-compliance year for regulatory options requiring cooling towers; and,
-2020 & 2026 – these years were run in order to ensure that the model was in balance, although the outputs from these years were not used in the analysis.

EPA primarily relied upon the 2008 model run to analyze the impacts of the preferred option, and the 2013 model run for the analyses of the regulatory options involving cooling towers.

The model assumes that capital investment decisions are only implemented during the run years. EPA used the results of various model run years as representative of particular period. Table B3-2 specifies the results of this “mapping” process.

Table B3-2: Model Run Year Mapping

Run Year	Mapped Year
2008	2005-2009
2010	2010-2012
2013	2013-2015
2020	2016-2022
2026	2023-2030

Source: IPM Model specification for the Section 316(b) Base Case

Model Inputs: The IPM Modeling Analysis used the following impacts.

-Capital Costs
---Costs of construction, equipment, and capital necessary to install compliance technology, with a discount rate of 5.34 percent and a capital charge rate of 12 percent for either the assumed duration of the 30-year book life of the investment or the years remaining on the modeling horizon, whichever is shorter.

-Fixed O&M Costs

-Variable O&M Costs

-Capacity Reductions (Only for facilities with flow reduction technologies)
---Energy penalty.
---Generator down-time.

Model Outputs: The IPM model reported the following outputs.
-Capacity (net summer dependable capacity)
-Generation
-Capacity Revenues
-Energy Revenues
-Energy Prices (annual average)
-Facility Retirements
---Closures of nuclear plants as a result of license expiration.
---Closures due to the estimated negative net present values for future operations.

B. Discussion of Issues

There are a myriad of issues with IPM modeling analysis which lead to a systematic underestimate of market impacts. This assessment identifies a number of the most significant issues, based upon the information made available by EPA. It is likely that there are additional issues in the remaining detailed information on the modeling analysis that EPA did not make available for review.

For discussion purposes, these issues can be grouped into three categories.
1) General assumptions used in the model
2) Scope issues regarding the set up and operation of the model.
3) Technical and economic assumptions specific to the 316(b) rule options.

Each of the three categories of issues is described in more detail below.

1. The General Model Assumptions are Outdated or Biased or Both: The IPM modeling analysis was based on the "IPM Base Case 2000". This base case incorporates market assumptions that have significantly changed over the past two years. Also, some of these assumptions are not consistent with the Administration's Energy Policy Task Force report. As a result, the IPM Base Case 2000 underestimates the key parameters of electricity markets relative to current projections. Underrepresenting these electricity market parameters, in turn, leads to underestimated impacts of the 316(b) regulatory options. The key areas of differences are:

-Electricity demand growth: IPM assumes 1.07% per year load growth between 2005-2015. This estimate also is artificially low because it assumes full implementation of the Clinton Administration's Climate Change Action Program (CCAP). By comparison the current 2002 Annual Energy Outlook (AEO) projection is 1.56% per year, which was the basis for the Report of the Vice President's Energy Task Force.

-Electricity Generation: The IPM model does not account for all new electricity generation projects currently underway. The IPM model projects total electricity generation of 4,366 billion kwh by 2015, 10% lower than 4,841 billion kwh projected in the AEO.

-Prices: The key assumption is the price of natural gas, which is expected to account for an increasing share of electricity generation. The IPM analysis assumes natural gas prices of $2.80 per mmbtu in 2010, declining even further to $2.70 by 2015. The current AEO projection of $3.40 in 2010 is 20% higher, and the 2015 projection of $3.60 is 33% higher than the comparable IPM assumptions.

The net effect of these assumptions is to underestimate impacts. Market impacts of the 316(b) proposed rule are likely to be more significant in a market environment characterized by higher electricity demand and higher fuel costs.

2. The Operation of the Model was Flawed: There are three aspects of the set-up and operation of the IPM model that lead to problems with the results.

-The model was never run for the preferred option; instead, the model results for the preferred option were extrapolated from other model runs: EPA conducted an IPM model run for the waterbody/capacity-based option, but did not conduct a separate model run for the preferred option. EPA assumed that portions of the results of the waterbody/capacity-based model would be representative of the preferred option and then extrapolated the results. Specifically, EPA used the waterbody/capacity-based option results for four NERC regions which were assumed to have no retrofit of cooling towers (the remaining 6 NERC regions did assume some retrofits under the waterbody/capacity-based option). EPA then extrapolated the results of the 4 NERC regions (with no cooling tower retrofits) to the remaining 6 regions in order to approximate a model run supporting the preferred option. This methodological approach assumed that the modeling results for the four NERC regions were unaffected by the cooling water compliance actions in the remaining 6 regions. Furthermore, the extrapolation assumed that the market impacts in the 6 NERC regions (unmodeled for purposes of the preferred option), would be proportional to the impacts in the 4 regions modeled under a different option. There are a number of market characteristics that vary significantly across NERC regions, such as fuel mix, average prices, reserve margins, transmission constraints and others. EPA failed to take these other factors into account in its extrapolation. This combination of analyses has the potential to compound any errors in the original modeling analysis.

-The IPM model modeled the energy penalty associated with retrofit of cooling towers as an annual average penalty, ignoring seasonal impacts that can vary by a factor of at least 2-3 times (or even higher outside the South): The retrofit of cooling towers to existing generating plants reduces the plant's electricity generation for the same amount of fuel use. There are two components of this "energy penalty": (1) increased use of auxiliary power on site to operate the cooling tower equipment; and (2) reduced turbine efficiency due to increased back pressure from less efficient cooling. The latter impact varies by season. In summer months, the recycled cooling water from cooling towers is less efficient in its cooling capability (due to both temperature and humidity). As a result, turbine efficiency is more adversely affected. However, it is in the summer months that most generating plants experience peak level demand, and when electricity market prices are most sensitive to small changes in supply. The IPM model runs did not account for seasonal impacts. As a result, electricity market impacts in the summer season were not adequately assessed. The IPM model has the capability to model some seasonality. It divides, the year into 2 seasons — a 5 month "summer" season and a 7 month non-summer season. However, it appears that, for modeling convenience, the IPM modeling analysis did not assume different energy penalties in the two seasonal periods.

-The IPM model did not address the potential impacts on reliability of electricity supplies. The 316(b) requirements can impact electricity reliability in two ways: (1) permanent derating of facilities due to the energy penalty could reduce reserve margins; and (2) temporary outages of facilities during the installation of 316(b) retrofit measures could result in short term price spikes or supply shortfalls if the outage occurred during a period when the market was very tight. These problems are more likely to occur if several facilities within a region are implementing 316(b) retrofit measures at the same time. The IPM model adjusts to any permanent derating of capacity by assuming that more new capacity is constructed. Thus, on a longer term basis, the model results do not allow for any reduction in reserve margins. However, the IPM modeling analysis was not conducted in a manner that would address the potential for short-term, or transient problems that could occur during the implementation phase of the 316(b) requirements. For example, the model was run only for years beyond 2008, a period when most, if not all, retrofits were already in place. Thus, the model did not attempt to analyze near-term market impacts, including reliability, during the implementation phase when outages would occur due to installation of cooling towers. In addition, the modeling analysis did not adequately address the seasonal effects on reliability due to outages during the retrofit process. The one month average outage for retrofit installation was averaged over the 7 month non-summer season, with no assumed impact on the peak summer season. This underestimates impacts in two ways: (1) the one month outage period is too short, and (2) the outage is most likely to occur during the spring season, especially if the outage is scheduled to occur in conjunction with planned maintenance activities.

3. There are detailed technical and economic assumptions specific to the 316(b) options that lead to underestimates of market impacts. There are a number of specific assumptions regarding the number of facilities impacted by the 316(b) requirements and the cost of compliance that contribute to underestimates of the market impacts. These include:

-Number of In-Scope Facilities: As described earlier in this assessment paper, the number of in-scope facilities may be underestimated due to the bias in excluding from the analysis those plants for which certain data were unavailable.

-Number of Facilities subject to retrofit: There appears to be a significant discrepancy between the number of facilities that EPA assumed to have retrofit requirements and the number of facilities modeled by IPM. This discrepancy lead to a significant underestimate of costs in the EPA estimates for the preferred option in the IPM modeling analysis. The discrepancy in the number of facilities is shown in the table below:

[see hard copy for table]

The table shows that the cost estimate assumed that an additional 126 facilities (195 less 69) have no compliance costs, even though these facilities are assumed elsewhere in the analysis to have retrofit requirements. In addition, the cost estimate has 88 fewer facilities (229 less 131) with costs for combined entrainment and impingement retrofit requirements. Because the Agency has not provided specific designations for these facilities, it is extremely difficult to determine the amount of the underestimate.

-Cost of Screens: As described earlier in this assessment paper, the costs for installation of screens is underestimated in instances where site specific screen performance falls short of the performance standards in the proposed rule.

-Cost of Cooling Towers: The cost of retrofitting cooling towers is underestimated for two major reasons (1) EPA assumes that 41 of the 51 facilities retrofitted with cooling towers can deploy the mechanical draft redwood towers, which cost 25% less than other towers; and (2) EPA cost estimates are significantly below estimates from other sources (as described earlier in the paper).

-Amortization Period: The IPM model appears to use an algorithm for amortizing all capital costs over a 30-year period. When applied to 316(b) compliance costs, this assumption is inconsistent with the 316(b) engineering cost assumptions and results in underestimates of the annual cost impacts of retrofits at those facilities, such as nuclear plants, that have remaining lives of less than 30 years. For example, in the engineering cost analysis of I&E controls, EPA assumed that screens would have a useful life of only 10 years. A number of nuclear facilities has remaining permit lives of less than 30 years, so it would not be appropriate to assume that the capital costs of a retrofit measures could be amortized over a 30 year period.

-Transaction Costs: EPA's estimate of transaction costs (e g, studies in support of permitting actions) is low because of the manner in which the model run for the preferred option was extrapolated from other model runs. The earlier model runs did not account for the higher permitting costs associated with the requirements for the preferred option. The EPA analysis indicated that permitting costs would be 30% higher under the preferred option relative to the other regulatory options that were actually modeled.

-Plant Closures: Although the IPM model has the capability to estimate plant closures, the modeling runs identified no potential additional closures attributable to 316(b) requirements. Modification of the various assumptions discussed above likely would have a compounding effect on market impacts, leading to possible plant closures.

-Temporary Plant Shutdowns & Reliability Impacts: The IPM modeling analysis assumed no additional plant outages due to the installation of screens in cooling water intake structures (i.e., the screen could be installed during periods of scheduled maintenance outages, which usually occur in the Spring or Fall). In addition, the IPM analysis assumes that the installation of cooling towers adds only one month to scheduled outages. These assumptions represent "best case" rather than "average case" situations. For example, the actual downtime for 316(b) modifications to the Calvert Cliffs Nuclear Plant was 5 months per unit with an overlap where both units were down simultaneously for a 2 month period. In addition, the assumptions fail to recognize the industry trend, especially for nuclear power plant refueling, to compress scheduled outage times, making it more difficult to integrate a cooling water system retrofit into this period. For example, nuclear refueling outages are now often less than one month in duration.

A more realistic analysis would consider the possibility of longer outage time intervals. In addition, the additional outage times most likely would occur in Spring or Fall, and could result in temporary higher prices and reduced reliability if the shutdown coincided with a period of abnormally warm weather. Instead, however, the IPM modeled the assumed one month outage time for cooling towers averaged over a 7 month non-summer period, including the winter season when equipment installations are unlikely to occur.

EPA Response

See response in file "Comment Response 316bEFR.72.209.wpd", DCN# 6-4002.

Comment ID 316bEFR.072.210

Author Name Thomas R. Kuhn
Organization Edison Electric Institute

Subject Matter Code	10.04
	National Benefits

ASSESSMENT OF THE EPA ECONOMIC BENEFITS ANALYSIS

The consideration of the benefits associated with the proposed new requirements for cooling water intake structures at existing generating facilities allows EPA to better compare regulatory alternatives and choose the alternative that meets statutory requirements in the way that results in the greatest net benefit to society EPA's proposal — specifically, the inclusion of a site-specific benefit-cost test — provides the necessary flexibility that recognizes that the installation of specified technologies may not provide benefits that warrant the costs of their installation at all facilities. Thus, the inclusion of this benefit-cost test provides an alternative mechanism for avoiding imposition of new requirements where they will not provide a net benefit to society. However, some of the methodologies used by the Agency to both estimate the benefits of the regulatory alternatives and extrapolate the benefits from individual case studies to national estimates have significant flaws.

A. Description of EPA Methodology

EPA relied on case studies as a means of generating benefit estimates for its regulatory alternatives. EPA's methodology consisted of four steps:

1. Estimation of losses in fish and fisheries yield as a result of impingement and entrainment (I&E) at facilities for which the Agency had case study data.

2. Correlation of I&E case study data to facility flow.

3. Valuation of I&E losses per unit of flow for a variety of water body types and locations.

4. Extrapolation of the value of losses from the case study facilities to generate a national estimate.

EPA's basic method for extrapolation relied of the development of flow and angler day indices for each case study facility. The index is used to extrapolate based on the flow (or angler days) at the case study facility relative to the total flow (or angler days) at all facilities located on the same waterbody grouping. Baseline loss estimates for a waterbody grouping are calculated by dividing the estimated losses at the case study facility by each index and then taking the average of the two calculated values.

For example, the Tampa Bay case study facilities had a midpoint baseline loss estimate of $809,000 for impingement. These facilities were also estimated to account for 19.24 percent of the flow and 20.28 percent of the angler days for all Gulf Coast facilities. The baseline impingement loss estimates for all Gulf Coast facilities was, therefore, calculated as the average of $4,204,000 – $809,000/0.1924 – and $3,989,000 – $809,000/0.2028. <FN 2>

The following chart shows the source of baseline loss estimate information and the relative contribution of each case study to the overall estimate of baseline losses.

[see hard copy for table] <FN 3, 4, 5>

Using this general framework, EPA estimates the benefits of its preferred option at $735 million. The Agency estimates the benefit of a water body /capacity based option at just over $1 billion and an option requiring the universal retrofit of cooling towers at $1.2 billion.

B. Discussion of Issues

In performing this analysis, EPA made a number of simplifying assumptions and methodological errors that overestimated the benefits estimates for all of these options. This assessment identified 4 major issues affecting the validity of the EPA benefits estimates:

1. The methodology for extrapolating national benefits estimates from case studies is flawed
2. The valuation methodologies chosen by the Agency are problematic.
3. Double-counting of angler days resulted in an inflation of estimated benefits.
4. Estimates of I&E impacts (and benefits) are not proportional to cooling water flows.

Each of these issues is discussed in more detail in the following sections.

1. The methodology for extrapolating national benefits estimates from case studies is flawed

The benefits estimates are based upon an extrapolation from five of case studies, supplemented with information from six other studies. This process has two serious problems: (a) the case studies are not representative; and, (b) the small sample of case study facilities magnifies any biases.

a) The choice of case study facilities does not constitute a representative sample that can be used as the basis for extrapolation to national estimates of benefits: EPA chose case studies based on those facilities that had the greatest amount of available data. As a result, the sample facilities are not a random (or representative) sample of the affected population. Moreover, the facilities that have the most data are likely to be the facilities that have come under the most scrutiny under the existing program. These facilities are more likely to be representative of facilities where concern with I&E impacts may have existed, not of the general population of facilities. Any extrapolation from these facilities, therefore, will overstate the impacts of I&E losses, and consequently, overstate the benefits of I&E controls.

b) A small sample size magnifies the bias associated with individual studies: The concern over the bias on the sample facilities exacerbates the bias that is created by extrapolating from a very small sample, in many cases a single facility, to the entire population. This magnifies the upward bias in the estimate at individual facilities. For example, the Salem case study is the basis for 55 of the total baseline loss estimates.

2. The valuation methodologies chosen by EPA are problematic

EPA makes a number of egregious methodological errors that are not supportable by resource economics, nor are they consistent with the EPA's own Guidelines for Preparing Economic Analyses. These shortcomings are discussed in great detail in comments filed by UWAG and others on the proposed rule. This section highlights some of the methodological issues that are likely to have the greatest impact on the conclusions drawn from EPA's assessment of the benefits.

a) EPA ignores sound science in favor of a baseless "precautionary approach." The appropriate method of valuing losses associated with the operation of cooling water intake structures is based on the changes in fisheries stocks and related catch levels. This has long been recognized as the correct approach by both biologists and economists. A large body of peer reviewed research supports this approach through the use of bioeconomic models such as "stock recruitment" models. EPA chooses to replace this large body of peer reviewed science with a normative approach thinly disguised as scientific. EPA labels this "a precautionary approach." This approach appears to serve no purpose other than to inflate the benefits estimates through the application of a number of questionable to clearly invalid methodologies.

b) Avoided cost methodologies, such as Habitat Replacement Cost, have no basis in economic theory or practice: EPA used habitat replacement cost as a means of estimating the benefits of reducing I&E in five case studies. The "values" from two of these studies were extrapolated to 38 other facilities. In total, the Habitat Replacement Cost methodology is responsible for about 25 percent of the total estimated benefits of the regulation. Moreover, any additional benefits associated with the EPA's Waterbody/Capacity-based option will come disproportionately from HRC values, since the benefits estimation for facilities on oceans is derived entirely from this methodology.

Habitat replacement cost is an avoided cost method of estimating value. Avoided cost methodologies attempt to impute value based on the cost of replacing a good by some other means. In EPA's case studies, the habitat replacement cost is always significantly higher than the estimated value of lost organisms. Because replacement cost does not tell us anything about the demand side of the equation, however, it is useless as a means of estimating value. Put another way, just because we can spend money on a good, does not mean we are willing to – the true measure of value. All the avoided cost methodology does is describe an arbitrary point on the supply curve – it cannot describe the value of a good.

EPA also uses an avoided cost methodology for measuring the value of forage species losses as part of its "precautionary approach" in some of the studies that do not rely on HRC. While this methodology is not discussed in detail here, it is invalid for all of the same reasons as HRC, and leads to an overstatement of costs in each of the instances where it is used.

The limitations of avoided cost methodologies are well accepted in environmental and resource economics. "A particularly inappropriate use of costs to measure benefits is the replacement cost approach, especially when it is not based on revealed preference (as in the cases of aversive or preventative behavior, or shadow project approach). Engineering replacement or remediation cost estimates are totally devoid of any "revealed preference" content; therefore, they have no foundation in social welfare economics and cannot be taken as measures of value. They lie along a supply curve, but we have no information at what point this curve interacts with a demand (or preference) function." <FN 6>

As an illustration of the limitations of avoided cost methodologies, we will take an example from outside of environmental regulation. Say that someone threatens to put a two inch scratch in your car unless you pay her $100. Such a scratch would cost $200 to repair. EPA's methodology would suggest that the value of avoiding the scratch in your car is $200 and you should pay the fee, making everyone better off by $100. This may seem to make intuitive sense, however, there is insufficient information in this example to be able to draw this conclusion.

For example, we do not know where on the vehicle this scratch will be made. If it is on the door, we may have one response, whereas if it is inside the trunk, we may have a completely different response. Even though the two scratches cost the same amount to repair, the value of that repair is very different depending on how we perceive the scratch.

Similarly, you could be selling the car and you know that the scratch will only result in a $50 reduction in the price you can get for the car. Again, the value avoiding the scratch has nothing to do with the cost of repairing it. In fact, there are an infinite number of ways of dealing with the scratch, up to and including replacing the entire car. Avoided cost would suggest that the cost of whichever solution was arbitrarily chosen as the basis of comparison is the value of avoiding the scratch.

Lastly, you have no underlying information about the underlying condition of the car. It could be a junk heap where an additional scratch would not be noticed. In this case, the marginal value of avoiding the next two inch scratch would be near zero. Again, the cost of repairing the scratch gives us no valid information on its value.

By now it should be clear that avoided cost is an invalid means of assessing value. To make matters worse, the particular replacement cost chosen by EPA, Habitat Replacement Cost, is invalid. EPA asserts that replacement of habitat is superior to more direct (and generally cheaper) forms of replacement because habitat creation generates additional benefits such as groundwater filtration and flood control. While it is likely that these benefits exist, they have nothing to do with the resource that is lost through impingement and entrainment. In fact, the value of these additional benefits should be subtracted from the cost of creating new habitat to isolate the cost of replacing individual organisms.

EPA also incorrectly uses HRC as a means of assessing the value of forage species and to infer the non-use value of these resources. Appropriate methodologies exist for assessing the forgone values of these organisms. For example, bio-energy models can be used to assess the contribution of lost forage to higher trophic levels that can be assessed using more direct
methods. It should also be noted that biomass lost through I&E is not, in fact, destroyed. It is merely consumed by different species than may otherwise consume those organisms. For very low trophic levels and life stages there may be little impact on the overall ecosystems. While there are also more direct means of assessing non-use value, such as contingent valuation, these methods are also problematic. The state of the science on these methods still makes it difficult to properly differentiate between use and non-use value.

These fundamental methodological concerns indicate that any conclusions drawn from this portion of EPA's benefits assessment are invalid. Replacement cost methodologies have no basis in welfare economics and should not be used in the manner that EPA has attempted to use them.

c) Societal Revealed Preference is an inappropriate measure of value: In its two San Francisco Bay studies EPA uses an "innovative" approach they term societal revealed preference. In this instance the innovation appears to be ignoring principles of sound economics and invalidating the basis of benefit-cost analysis.

Like habitat replacement cost, this method does nothing more than look at costs and deem them to be benefits. Under this approach all governmentally imposed costs are assumed to be at least as great as the benefits There is no basis for this assumption in economic theory or empirical observation. If this assumption were true, there would be no need to do benefit-cost analysis of government regulation. Where the avoided costs methodologies make the false assumption that if you can spend money on a good, it must be worth the price, the societal revealed preference assumes that if someone makes you spend money on a good, it must be worth the price. Neither of these assumptions is very compelling. Any conclusions drawn from application of this methodology are completely invalid.

d) EPA's use of a "rule of thumb" to estimate non-use values is completely arbitrary: EPA uses a unique rule of thumb that assumes that non-use values associated with a good, in this case recreational fishing, is equal to 50 percent of the use value. There is absolutely no basis for this assumption and its use in these studies inflates the costs artificially.

e) EPA inflates the benefits estimate by valuing losses further up the value chain than is appropriate: The EPA develops a series of multipliers to translate dockside market value into larger numbers to reflect secondary economic benefits. These multipliers are not based on any significant empirical data. Moreover, they ignore the additional value added at each step of the market chain, leading to an upward bias in the perceived contribution of losses to social cost. Lastly, they lead to an unfair comparison of costs and benefits, since the costs associated with reducing impingement and entrainment are measured at the equivalent of the dockside and are not adjusted by similar multipliers to account for their movement through the value chain. For these reasons, EPA's benefits estimates should be based on dockside loss estimates only.

f) EPA application of otherwise valid approaches was flawed: Some of the approaches used by the EPA, such as random utility models, do have a sound foundation in economic theory. However, application of these models to individual case study facilities was uneven. EPA relied on questionable "benefits transfer" and other approaches to draw conclusions that may not be applicable to the actual facility being studied.

These shortcomings are best discussed in the context of the individual case studies. This discussion is beyond the scope of this paper. The reader should refer to the comments submitted by individual companies and by the Utility Water Act Group for a more detailed discussion of potential misapplication of these methods.

3. Double counting of angler days results in an inflation of the estimated benefits

EPA extrapolates baseline losses from case study facilities based on an "angler day index "This index is based on the number of angler days estimated to occur within 120 miles of the case study facility relative to the number of angler days estimated to occur within 120 miles of all other facilities in the same waterbody grouping Angler days were computed for any county in which a facility was located plus any county in which 50 percent of the population of that county lived within 120 miles of a facility.

Unfortunately, the EPA did not account for facilities that were located within 120 miles of each other. This results in a much larger number of angler days in the denominator of the angler day index equation. This larger denominator, in turn results in a lower index for the case study facility, which leads to a larger multiplier of the baseline losses at the case study facility and a significant upward bias in the extrapolated value of baseline losses.

The facilities covered by the proposed rule were mapped in order to determine how prevalent this overlap of these areas of influence might be, This mapping exercise demonstrated that 100% of the areas in the eastern half of the United States fall within the area of influence of at least two facilities.

Another approach to assessing the degree of double counting involves looking at the counties whose angler days would be counted more than once The analysis showed that only 5 percent of the counties in the United States are correctly incorporated into the denominator of the angler day index. Another 14 percent were not miscounted because they are not within 120 miles of any facility. 49 percent of the counties were counted at least ten times.

4. Estimates of I&E impacts (and benefits) are not proportional to cooling water flows

EPA assumes that I&E impacts are directly correlated with flow at a facility. However, EPA's own data in the one instance where it composed multiple facilities in the same pool indicates that this proportionality assumption is incorrect. Moreover, in the case extrapolating impingement losses, there is not even much of an intuitive link between flow and impingement. Impingement is likely to be affected by temporal factors, biological factors, and intake velocity long before total flow becomes a factor. When combined with the fact that the sample facility is likely to have an uncharacteristically high impact per unit of flow, the affect of the assumption will be to overstate the benefits.

C. Conclusions and recommendations for Re-analysis

EPA's valuation of the benefits of its proposal and alternatives is fraught with methodological errors. Thirty-one percent of the benefits estimated by the Agency are based, in whole or in part, on cost-based methodologies that have no basis in economic theory or practice. The remaining 69 percent are inflated through the use of questionable methodologies. 55 percent of the benefits estimated by the EPA are based on a single case study. The extrapolation methodology chosen by the Agency also creates a significant upward bias in the benefits estimates.

Prior to promulgation of a final rule, the EPA must correct these errors so that its final determination of the correct regulatory approach is based on the best available science and analysis.

EPA Response

The four main comments in this section are addressed in turn:
1. The methodology for extrapolating national benefits estimates from case studies is flawed.

In response to this comment and others like it, EPA has reviewed and revised the case study approach to estimating national benefits. For the section 316(b) Phase II benefits cost-benefit analysis EPA examined impingement and entrainment (I&E) losses, and the economic benefits of reducing these losses, at the regional level. All extrapolation is based on losses per unit of average annual operational flow.

The estimated benefits were then aggregated across all regions to yield a national benefit estimate. The primary objective of the regional approach is to refine the scale of resolution of the benefits case studies conducted for proposal, so that extrapolations were within regions rather than nation-wide. In addition to extrapolating at a regional level only, EPA also collected and analyzed data for a greater number of facilities.

Thus, for the analysis for the final rule, extrapolation was needed for a smaller number of facilities, was based on a broader range of analyzed facilities, and was performed between facilities in the same region.

2. The valuation methodologies chosen by the Agency are problematic.
EPA has addressed this issues in the cost-benefit analyses for the NODA and for the final Section 316(b) Phase II rule.
Please refer to EPA's detailed response to the following comments:

#316b.EFR.005.035 (HRC methodology)
#316b.EFR.005.006 (societal revealed preference methodology)
#316b.EFR.005.029 (commercial fishing methods)

In the cost-benefit analyses for the NODA and for the final Section 316(b) Phase II rule, EPA did not use the 50% rule-of-thumb to estimate non-use benefits.

EPA no longer uses hatchery costs to estimate impacts on forage species. Instead EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule. See Chapter A5: Methods Used to Evaluate I&E.

EPA no longer uses a benefits transfer approach to estimate recreational losses and benefits. Rather, EPA has developed a random utility model (RUM) to estimate benefits for each region. For further detail on the new methods please refer to the regional study document, Chapter A11: Estimating Benefits with a Random Utility Model (RUM).

3. Double-counting of angler days resulted in an inflation of estimated benefits.

In the cost-benefit analysis of the benefits for the final Section 316(b) Phase II rule, EPA no longer uses the angling index to extrapolate benefits.

4. Estimates of I&E impacts (and benefits) are not proportional to cooling water flows.

As noted in the response to #1, all extrapolation is based on losses per unit of average annual operational flow. EPA's new regional extrapolation methods are designed to better address temporal factors, biological factors, and intake velocity.

NERA REPORT ON THE VALUATION OF POWER COSTS IN ASSESSING THE COSTS OF ALTERNATIVES UNDER SECTION 316(b) OF THE CLEAN WATER ACT

Prepared for Edison Electric Institute

August 2002

EXECUTIVE SUMMARY

This report reviews the U S Environmental Protection Agency's ("EPA") valuation of energy penalties due to regulatory alternatives for existing facilities under Section 316(b) of the Clean Water Act ("Section 316(b)"). On April 9, 2002, EPA issued a proposed rule ("316(b) Phase II Proposed Rule," 67 FR 17121) that would establish requirements for cooling water intake structures ("CWIS") for in-scope existing power producing facilities. The proposal involves methodologies for determining the "best technology available" ("BTA") that Phase II facilities with CWIS would be required to adopt. In support of its Section 316(b) Phase II Proposed Rule, EPA released an Economic and Benefits Analysis ("EBA") as well as several detailed case studies of the benefits of Section 316(b) alternatives. In contrast to the thousands of pages devoted to benefits assessment, the EBA provides very little discussion of costs and only four pages on energy penalties. Energy penalties include the power losses due to installation of various compliance technologies, such as cooling towers. <FN 1> The value of the energy penalties can be substantial, comprising the majority of the overall social cost for some Section 316(b) control technologies.

The EPA's methodology for valuing power losses—that is, the dollar values of the power losses—uses estimates of the average historical revenue per kilowatt-hour for the owner of the affected facility to measure future values. This valuation methodology is too simplistic and does not provide an adequate basis for estimating this important component of the costs of Section 316(b) regulatory alternatives. Perhaps more importantly, the valuation methodology provides misleading guidance to permitting agencies and permit applicants that will be faced with implementing whatever approach is ultimately promulgated in any final Section 316(b) rule for Phase II facilities.

This report provides an alternative framework for valuing power losses that is both practical and more accurate than the simple methodology developed by EPA. Well-established alternatives are available that provide sound and practical estimates of the dollar value of energy penalties due to Section 316(b) compliance alternatives. This report summarizes three practical alternatives that can overcome the disadvantages of the EPA methodology. Generation owners and permit issuers should be encouraged to implement these alternative methodologies in order to base individual Section 316(b) decisions on accurate and complete benefit-cost analyses.

A. Limitations of the EPA Methodology for Valuing Power Losses

Power losses represent one component of a full benefit-cost assessment of alternative Section 316(b) controls. Implementing a given Section 316(b) alternative— such as retrofitting a unit with a cooling tower— leads to social benefits and social costs. <FN 2> A benefit-cost analysis includes evaluation of alternative approaches and identification of the alternative that would maximize net benefits (i.e., benefits minus costs). <FN 3> To provide useful information, however, the benefit-cost analysis must be based upon sound estimates of the various benefit and cost components. With regard to energy penalties, sound analysis requires accurate assessments both of the power losses and of the dollar values of these effects. This report focuses on the second item in these calculations— placing a dollar value on power losses.

EPA's methodology for estimating the dollar value of power costs consists of calculating the historical average annual revenue for each utility and using that historical average to measure the social cost of future projected energy losses. This methodology is incorrect for several reasons.

2. The average revenue values do not reflect the enormous differences over the course of a year in the cost of power. Many control options involve valuing losses in particular months or seasons.

3. The average revenue values do not necessarily incorporate the costs incurred to replace losses in capacity or the losses in the ability of the unit to operate at peak level (and thereby avoid deterioration in the reliability of electric supply). In many markets, capacity is effectively a separate "product" that would not be included in energy prices. Any effects on capacity should be included as elements of social costs.

4. The historic sales revenue may not properly incorporate future emission costs, in part because the emission regulation regime may be different in the future. The historic prices used by EPA do not reflect recent characteristics of emissions markets, including developments in NOx markets and implementation of Phase II of the Clean Air Act SO2 cap-and-trade program.

Well-established methodologies are available to overcome these difficulties and provide forward-looking and complete estimates of the value of power lost as a result of Section 316(b) control technologies.

B. Sound Methods of Valuing Power Costs

This report describes three types of models that can be readily used to measure the social cost of power losses resulting from regulatory requirements that could be promulgated as part of a final rule under Section 316(b). The three alternatives are the following:

1. Cost-based modeling;

2. Futures prices and extrapolations; and

3. Modeling of market prices using econometric models.

All three can provide forward-looking and complete estimates of energy penalties. The choice of which method is more appropriate depends upon several factors, including cost (in light of existing modeling capabilities), data availability, and the individual utility's role in the national energy market. (For example, cost-based modeling may be more appropriate in the case of a utility with a load-serving responsibility; the social cost analysis then focuses on how the integrated utility would replace the energy and capacity lost due to the Section 316(b) alternative.)

1. Cost-Based Modeling

Cost-based models have been developed over decades to simulate costs in an integrated electricity system .These models provide a highly detailed representation of electricity generation, transmission and dispatch .The basic approach is referred to as a cost-based model because the models focus on the production costs of meeting given levels of electricity demand at different time periods over the course of each year. Prominent cost-based models include PROMOD and GE-MAPS. The GE-MAPS model for New York, for example, includes all generating units in the New York Independent System Operator ("ISO"), the New England ISO, and the Pennsylvania-New Jersey-Maryland Interconnection ("PJM"), as well as possible supply from Canada and the East Central Area Reliability Council ("ECAR"). The units include those likely to come into service over time.

These models can overcome the disadvantages of the EPA historical approach. The models are forward looking, can be used to assess the social costs at different periods of the year, and can incorporate capacity and emissions costs through extensions of the basic modeling approach. The models are used to predict the generation sources that replace power lost due to a Section 316(b) compliance alternative; this information is used to calculate the cost of the replacement power. Emissions costs are included directly in the production-cost model results if emissions are included in cap-and-trade programs, in which case future allowance prices are included in the production costs. Incorporating capacity costs involves estimating the costs of adding capacity necessary to maintain the same system reliability.

2. Futures Markets

In many regions of the country, electricity is traded, with prices quoted and available in a futures market. The futures market represents the current market value of future electricity production; quotes are available for different time periods, including different months and on- and off-peak periods.

Use of futures market prices to forecast the value of future power losses avoids the expense of developing a detailed representation of the electricity system. Market prices are used as measures of the expected social costs of future power losses. These prices represent the value (at the margin) of reduced generation and thus provide a measure of future social costs based upon actual market price information rather than simulated electricity system/market results. Because futures prices are available only for several years, the method must be extended by developing projections based upon the likely future costs of additional generation (including capacity and emissions effects).

This modeling approach also overcomes the disadvantages of the EPA approach. Like the cost-based method, the use of futures market prices sometimes must be supplemented by additional analyses of capacity and emissions costs Some electricity systems include separate capacity markets, which can be used to provide social cost estimates for capacity changes. Futures prices include costs of emissions subject to cap-and-trade programs; the costs of other emissions can be estimated separately.

3. Econometric Modeling of Future Prices

The econometric modeling method also involves the use of market prices to measure social costs. Rather than using futures prices, however, this method uses historical price information to develop econometric estimates of the factors that influence electricity prices, including demand-supply balances, weather patterns, and other factors that influence real world prices. <FN 4> These relationships can be used either directly to estimate future prices—in various relevant time periods—or as a supplement to the basic estimates provided by the cost-based methodology. The objective in both applications is to provide estimates of the future set of market prices in the electricity market in which the in-scope facility participates. These projected future market prices are then used in conjunction with the future power losses to calculate the social cost of replacement power.

As with the other two methods, the econometric modeling approach~ overcomes the disadvantages of the EPA method. The detailed statistical relationships allow estimates of future prices in detailed time periods. As with futures markets, whether capacity and emissions are included directly depends upon whether there is a separate capacity market and whether

emissions are subject to cap-and-trade programs both in the historical period and the future (relevant) period.

C. Conclusions and Recommendations

A sound methodology for valuing energy losses should have three important features (1) it should reflect future conditions, (2) it should allow for seasonal and other temporal differences, and (3) it should account for all types of potential costs (i.e., reductions in generation, capacity losses, and air emissions changes). EPA's methodology for estimating the value of lost power due to Section 316(b) alternatives is inadequate by all three criteria. Before issuing final Section 316(b) regulations, EPA should revise its methodology for valuing energy losses to correct these limitations.

Because the EPA's analyses can influence choices by Section 316(b) permit applicants and issuing authorities, it also would be useful for EPA to indicate the range of methodologies that would be appropriate to measure energy penalties in individual circumstances. The three basic methodologies outlined in this report all would provide conceptually sound and complete measures of the future social costs of energy penalties due to Section 316(b) control alternatives. The various methods differ in ease of application, in applicability in light of the state of deregulation in various markets, and in respect to how they capture the various components of replacement power costs (i.e., energy, capacity and emissions costs). The choice of methodology should be left to the individual applicant—taking into account cost and existing modeling capabilities—with review by permitting agencies focusing on the validity of the method and the sensibility of its application in the particular case.

I. INTRODUCTION

This report considers economic methodologies that can be used to value the replacement power costs of modifying cooling water intake structures ("CWIS") in response to potential requirements for electric facilities under Section 316(b) of the Clean Water Act Replacement power costs result from reductions in the energy and capacity of electric generating units as well as changes in emissions due to the effects on electricity markets. The report also evaluates the methodologies that the U S Environmental Protection Agency ("EPA") has used to value replacement power costs in the context of its evaluation of proposed policies to implement Section 316(b).

A. Background

In April 2002, EPA proposed regulations ("316(b) Phase II Proposed Rule," 67 FR 17121) implementing Section 316(b) of the Clean Water Act for certain existing facilities, including electricity generation facilities EPA at the same time released various technical documents, including an Economic and Benefits Analysis ("EBA," U S EPA 2002a) that outlines key elements of the methodologies EPA uses to assess the costs and benefits of the proposed regulatory requirements.

The EBA includes the methodologies EPA uses to assess the overall costs and benefits of the proposed Section 316(b) regulations as well as those of various regulatory alternatives The costs include several components related to energy costs involved in converting a cooling system from a once-through system to a re-circulating system with wet cooling tower or a dry cooling system The components identified in the EBA include a one-time, temporary outage of the plant when the new system is connected to the plant's existing cooling system, as well as an energy penalty from the operation of the re-circulating or dry cooling system, which would constitute a long-term reduction in the available capacity of the facility. The EBA includes EPA' s monetary valuation of the energy penalty and the cost of downtime.

B. Need for the Study

The EBA contains a relatively short description of EPA's methodology for valuing power costs (U.S. EPA 2002a, p. Bl-8 to B1-9). This treatment contrasts with the detailed analyses of other components of costs as well as the dramatically greater attention given to benefits valuation, including lengthy and detailed case studies.

The relative lack of attention to power costs maybe explained by the fact that EPA estimates that the proposed rule will result in no energy penalties or connection outages, and thus that this category is not important (see US EPA 2002a, p B 1-16). This judgment appears to suggest that the proposed rule would not require any existing facility to switch to a recirculating system from a once-through system and that no other Section 316(b) technologies entail energy cost. Such conclusions would be important to confirm, but regardless of whether these judgments about the proposed rule are correct, the calculation of energy penalties due to potential Section 316(b) alternatives is important for several reasons:

-Alternatives to the proposed rule do involve the introduction of re-circulating systems and thus lead to energy penalties that are included in the EPA cost estimates.

-Permit writers evaluating Section 316(b) permits for individual facilities are likely to consider the possibility of switching to a re-circulating system..

-Other control alternatives short of a switch to a cooling tower—such as a requirement for seasonal flow controls or modifications of intake screens—do seem likely to involve energy penalties.

It is important, therefore, to develop valid methodologies that can be used to assess the likely power costs associated with Section 316(b) alternatives. The methodologies should be complete, identifying and valuing all of the costs.

EPA’s methodology is an historic methodology that is based on the average revenue that utilities have received from power sales over the 1995 to 1999 period. This methodology has an inherent flaw. It assumes that the social costs of replacement power can be measured by reference to the average revenue per unit of electricity sold over an historic period. This is wrong for several reasons, including the following:

1. The historical period is not necessarily representative of the future,, particularly in terms of the demand-supply balance. EPA’s historical prices include surplus sales in shoulder and off-peak hours, which do not reflect prices in hours when capacity is constrained. The methodology should be forward-looking rather than backward-looking to reflect future conditions.

2. The average revenue values do not reflect the enormous differences over the course of a year in the cost of power. Many control options involve valuing losses in particular months or seasons.

3. The average revenue values do not necessarily incorporate the costs incurred to replace losses in capacity or the losses in the ability of the unit to operate at peak level (and thereby avoid deterioration in the reliability of electric supply). In many markets, capacity is effectively a separate “product” that would not be included in energy prices. Any effects on capacity should be included as elements of social costs.

4. The historic sales revenue may not properly incorporate future emission costs, in part because the emission regulation regime may be different in the future .The historic prices used by EPA do not reflect recent characteristics of emissions markets, including developments in NOx markets and implementation of Phase II of the Clean Air Act SO2 cap-and-trade program.

The net result is that the EPA materials do not provide appropriate guidance for estimating power costs related to Section 316(b) compliance alternatives. <FN 5>

In addition to the need to be complete in assessing all potential energy costs, it is also important to assess the relative advantages and disadvantages of alternative methods that involve greater or lesser data development, modeling, and overall cost. One of the critical elements of any cost analysis methodology is that it be sensitive to the costs of implementation. It would not make sense, for example, to require detailed and expensive modeling to assess power costs in cases in which relatively small penalties are involved. Similarly, using crude rules of thumb where power costs are an important component—whose value could alter substantially the Section 316(b) cost-benefit assessment—would not be sensible.

It also is important to clarify that these valuations are focused on estimating the resource costs related to Section 316(b) alternatives (i.e., the costs that will be incurred by society—also referred to as social costs). Deregulation in many areas of the country has shifted the burden of environmental compliance costs from customers to generating facility owners.

From an economic efficiency perspective—which is an appropriate perspective for a cost-benefit assessment of Section 316(b) alternatives—it is irrelevant whether customers or plant owners ultimately bear the costs.

C. Objectives of this Study

The objectives of this study can be listed as follows.

-Identify the situations in which power costs will be incurred and the types of power costs involved as a result of Section 316(b) requirements at an electricity generation facility.

-Critically review EPA's treatment of power costs related to Section 316(b) alternatives.

-Develop recommendations for methods of valuing power costs that are:

---Consistent with sound economic methodology;

---Achievable at reasonable cost, in light of the data that are available; and

---Understandable to those that will implement the techniques, as well as to those who will review the studies.

-Provide examples of how some of the methods could be implemented.

D. Outline of the Report

This report is organized as follows. Chapter II provides an overview of the circumstances in which Section 316(b) compliance alternatives could give rise to energy costs as well as the general components of those costs. In light of this overview, the chapter provides a review of the approach in the EBA, including general assessments of its limitations. These limitations include the possibility that some potentially important components of energy costs are omitted, as well as the fact that it employs a relatively simplistic method for calculating the one cost component that is included. Chapter III discusses three methodologies that can be used to measure the full social costs of power reductions associated with Section 316(b) compliance alternatives and discusses the situations in which the various methods may be most effectively applied. Chapter IV discusses the issues associated with developing estimates for elements thatmight not necessarily be included in the modeling, specifically the value of lost capacity and air emission costs. Chapter V provides brief concluding remarks.

II. OVERVIEW OF POTENTIAL POWER COSTS DUE TO SECTION 316(B) CONTROL ALTERNATIVES AND EVALUATION OF EPA VALUATION METHODOLOGY

This chapter provides an overview of the potential components of power costs associated with various potential Section 316(b) control technologies. The chapter also considers EPA's approach to valuation in light of this overview.

A. Situations Leading to Power Costs Due to Potential Section 316(b) Control Technologies

As noted by EPA, a technology installed to comply with possible Section 316(b) regulations could lead to electricity-related costs in two major ways:

1. Construction outage. Implementation of the technology may require that the facility be shut down for a period of time. In the case of the retrofit of a cooling tower for a once-through system, the facility typically would have to be shut down while the new system is added.

2. Ongoing power losses. Implementation of the technology may involve losses in the output of the facility, either over the course of the year or for certain periods. Requirements to reduce flow during periods of high biological activity, for example, would entail ongoing power losses during those periods.

Note that these two situations differ in the circumstances but not the nature of the power costs. The general methodology for evaluating both types of energy penalties is similar. Consider an example of installing a cooling tower that requires a six-month construction outage and a reduction of five percent in the ongoing generation of the unit. These two situations would reduce generation at the plant, one for six months and the other over the remaining life of the facility. There is no conceptual reason to value the lost kilowatt-hours differently in these two cases. (As noted below, the situations may differ in terms of whether costs would be saved at the facility; but the basic method of valuing the reduced output should not differ in the two circumstances.) There may be some practical differences in the modeling, but it is useful to be clear that the general nature of the penalty is the same in both cases.

This general rule—that situations do not change the conceptual approach to assessing the value of lost power—extends to the situation in which adopting a given control alternative would make operation of a unit uneconomic. Suppose that a requirement to retrofit with a cooling tower would lead a facility to shut down <FN 6> The kilowatts lost in this case—equal to the amount that otherwise would have been generated by the unit—would be valued using the same methodologies as for a construction outage or operating penalty. Indeed, one could think of a premature shutdown as an extension of either of these other cases.

B. Components of Power Costs

Power costs include several distinct categories. The following are the three general cost categories that could be relevant for any given control technology:
1. Generation;
2. Capacity; and
3. Air emissions.

1. Electricity Generation

The Section 316(b) control technologies can decrease the output of the unit. So long as this output is being provided at a time when this power has social benefits, these decreases represent a cost to society. A unit provides a social benefit whenever it would be more costly to replace the unit's generation with some other unit's generation or whenever demand could not be met without the unit's generation. Utility plants in both regulated and deregulated areas have substantial incentives to run only when the social benefits of electricity production exceed the costs.

2. Electricity Capacity

The requirement that supply and demand for electricity must be in continual balance to avoid losses in voltage or even blackouts creates an additional social value for electricity generators—the value of generating capacity. At any given time, large amounts of nongenerating, but potentially generating, capacity are required. Without this capacity, the social costs of power would be much higher, since a kilowatt-hour lost due to blackout has a much greater value (perhaps 50 to 100 times) higher than the marginal kilowatt-hour because of the emergency services (and other high-value uses) that might be lost.

These considerations mean that electricity capacity has a value in addition to the actual electricity generated. As a rough conceptual approximation, the value of each kilowatt of capacity is equal to the product of two values (1) the probability that the system will in fact run short of capacity (a figure that depends on the supply-demand balance at any given time); and (2) the value of lost kilowatt-hours.

3. Air Emissions

Electricity generation can lead to various other external effects, the most notable of which might be air emissions. Many generators produce air emissions, most notably CO2, SO2, NOx, and particulates. <FN 7> Changes in the output of one unit and replacement of this power by other units will lead to changes in emissions, and therefore to social cost. These changes in social cost represent additional costs or benefits.

C. Evaluation of EPA's Power Cost Methodology

This section provides an evaluation of the methodology for assessing, power costs contained in EPA's EBA. We consider the components that are covered as well as the methodology used to evaluate the components that are evaluated.

1. The EBA Methodology for Estimating the Value of Lost Generation is Deficient

The EBA methodology focuses on estimating reduced revenues to the individual facility whose kilowatt-hours are reduced due to the installation of a cooling tower:

The energy penalty and the connection outage represent a cost to the facilities that incur them. For the energy penalty, this cost manifests itself as a reduction in revenues, (the same amount of fuel is required to produce less electricity available for sale). For the connection outage, this cost is a loss in revenues offset by a simultaneous reduction in fuel costs (while the plant is out of service, it loses revenues but also does not incur variable costs of production) (U.S. EPA 2002a, p. B 1-8).

The EBA implemented this approach by estimating the average wholesale price received by each utility. This calculation involved estimating each utility's revenues for resale and dividing by its sales for resale. <FN 8> This calculation provides EPA's estimate of the average revenue that the utility owner would lose for each kilowatt-hour of reduced production.

This set of values has several deficiencies as a set of values that can be used to assess the social costs of reduced electricity generation due to Section 316(b) alternatives.

a. Changes in Facility Revenue are Not Necessarily a Measure of Social Cost

The recent EPA Guidelines for performing economic analyses provide a definition of social costs:

The total social cost is the sum of the opportunity costs incurred by society because of a new regulatory policy; the opportunity costs are the value of the goods and services lost by society resulting from the use of resources to comply with and implement the regulation, and from reductions in output (U S EPA 2000, p. 113).

The implication of this definition is that lost generation should be valued at its value to consumers if the output is not compensated for by increased generation elsewhere, or at the additional resource costs required to compensate for the lost generation if such compensation is projected to occur. Such. values would include losses in consumer and producer surplus associated with any rise in the price (and decrease in the output) of electricity.

As noted above, if the change in generation is relatively small, the price of electricity is not likely to be affected by the Section 316(b) alternative. <FN 9> In this situation, the social cost of reduced generation at one facility could be measured by the increase in cost to provide the equivalent generation at other facilities. For a large change in generation, the effects of price changes on consumer surplus would also have to be considered.

Note also that the revenue lost to a utility from reduced generation sales is not necessarily equal to the added costs at other facilities to compensate for, that reduction, or the market price of electricity Although the utility’s revenue loss certainly is a cost to the utility, this cost would not necessarily measure the total cost to society. As the EPA Guidelines make clear, it is social costs that should be used in benefit-cost assessments.

b. Historical Information May Not Reflect the Future

A second deficiency of the EBA approach is its focus on historical information The values to be included in a benefit-cost analysis of potential regulatory alternatives under Section 316(b) should reflect expectations about the value of relevant parameters in the relevant future timeframe—namely, the period between when the retrofit is introduced and when the unit would be retired. For example, if a facility were retrofitted in 2005 and the facility were scheduled for retirement in 2025, the benefit-cost assessment would require values for the period from 2005 to 2025.

The EBA approach is based upon information from 1995 to 1999, without any effort to update or project values into the future. Although such projections are of course uncertain, a projection that the value of generation would be constant at the historical value seems too crude, particularly since there are reasons to suspect that the relevant social costs will be higher in the future as a result of developments in electricity markets.

One reason for higher future social costs is that the utility sales from 1995 to 1999 most likely include surplus power sales, as well as sales at peak hours. Surplus power is the power available in excess of load requirements from the existing capacity owned by the utility. Because the period from 1995 to 1999 was characterized by substantial excess capacity, the average revenue from power sold during this period is likely to be lower than it will be in the future, when capacity is expected to become more constrained. As a result, the estimates in the EBA may not be representative of the future value of power losses that would be anticipated as a consequence of various regulatory alternatives for existing sources under Section 316(b).

c. Average Values Do Not Allow for the Wide Variability in the Social Cost of Generation in Different Time Periods (Months, Years)

A third deficiency or limitation of the EBA approach is its focus on an average annual value. The social cost of electricity generation vanes dramatically over the course of a year. Many of the Section 316(b) compliance alternatives will have different effects on electricity use over the course of a year (e g, requirements to reduce flow in periods of high biological activity. Using an average value obscures such differences and prevents the methodology from determining accurately the social costs of losses in particular seasons or months.

This means that the EBA approach should calculate potential electricity generation losses by month and also provide information on replacement cost estimates that differ by month. In the case of a three-month connection outage, for example, it would be important to assess the likely months of the outage and the relevant monthly prices. EPA's use of average annual values is too crude a methodology.

2. The EBA May Exclude Two Important Categories of Power Costs

The EBA focuses on just one of the three categories of power costs identified above, the value of lost generation. The relatively brief description of the monetary valuation (p. B 1-8) includes only a discussion of the methodology to value lost kilowatt-hours. EPA does not appear to account for the two other categories identified above:

-Capacity. Implementation of modifications to the CWIS can reduce a unit's capacity, not just its electricity generation. This loss in capacity has a social cost that should be included in a complete assessment of energy costs.

-Air emissions. Shifts in generation due to modifications to the CWIS typically will lead to changes in air emissions or changes in the costs of meeting air emission targets. These changes—which could be positive' or negative—constitute social costs (or benefits) that should be included in a complete assessment of energy costs.

These elements can be significant parts of the overall social costs of energy penalties due to Section 316(b) alternatives.

D. Summary

Various Section 316(b) alternatives involve energy penalties that should be evaluated as part of a complete social cost analysis. The EPA methodology contained in the EBA provides a simple method based upon historical information This simple method does not provide an accurate or complete assessment. The following chapter provides examples of three general approaches that can provide accurate and complete estimates of the relevant energy penalties.

[comment continued in 316bEFR.072.302]

Footnotes

1 This report uses several roughly equivalent terms to describe electricity losses due to Section 316(b) compliance technologies, including power losses, energy penalties and replacement costs. The energy losses include various potential losses, including capacity reductions as well as penalties due to on-going operations of compliance technologies (such as a reduction in unit efficiency due to increased turbine back-pressure and an increase in auxiliary power requirements to operate the cooling tower).

4 Note that although this method uses historical prices, the use is very different than in the EPA methodology. In the EPA methodology, historic prices are used directly as measures of future prices. In contrast, the econometric method uses historical prices only as data to develop statistical models. These statistical models then are used in conj unction with projections of future underlying conditions (e.g., demand, temperature, capacity additions) to project future prices.

5 This report does not discuss issues related to the specific power losses due to various control technologies. The limitations listed here concern the unit value of the replacement power required. There also may be further concerns about the quantity of replacement power required. EPA's analysis appears to imply that that replacement power costs result only from cooling tower retrofits, but not from other CWIS modifications, such as screens or variable speed pumps. Other evidence suggests that other CWIS modifications can affect power. generation. Although we do not consider the quantity of replacement power that would be required as a result of specific CWIS modifications, the estimates of power losses will of course affect the cost of 316(b) compliance.

6 Assessing whether the unit would shut down would involve modeling the relevant power markets based upon the revised cost of the unit (with retrofit). The major difference in the modeling results is that electricity prices may be affected and thus the assumption that overall electricity demand is not affected would not hold.

7 Recently, regulatory attention has also included interest in certain metals found in fossil fuels, such as mercury.

8 The resale sales are used to reflect wholesale prices, rather than retail prices that reflect the price of additional value-added services provided by the company.

9 Market prices would change if the change were substantial, which would be the case (for example) if a large unit were to out of service (e.g., for a connection) or if 316(b) requirements lead to premature retirement of a large unit.

EPA Response

EXECUTIVE SUMMARY / INTRODUCTION

The commenter criticizes EPA's methodology of assigning monetary values to the energy penalty of cooling towers and the cost associated with installation downtime. The commenter states:

"EPA's methodology for estimating the dollar value of power costs consists of calculating the historical average annual revenue for each utility and using that historical average to measure the social cost of future projected energy losses. This methodology is incorrect for several reasons.

1. The historical period is not necessarily representative of the future, particularly in terms of the demand-supply balance. EPA's historical prices include surplus sales in shoulder and off-peak hours, which do not reflect prices in hours when capacity is constrained. The methodology should be forward-looking rather than backward-looking to reflect future conditions.

2. The average revenue values do not reflect the enormous differences over the course of a year in the cost of power. Many control options involve valuing losses in particular months or seasons.

3. The average revenue values do not necessarily incorporate the costs incurred to replace losses in capacity or the losses in the ability of the unit to operate at peak level (and thereby avoid deterioration in the reliability of electric supply). In many markets, capacity is effectively a separate "product" that would not be included in energy prices. Any effects on capacity should be included as elements of social costs.

4. The historic sales revenue may not properly incorporate future emission costs, in part because the emission regulation regime may be different in the future. The historic prices used by EPA do not reflect recent characteristics of emissions markets, including developments in NOX markets and implementation of Phase II of the Clean Air Act SO2 cap-and-trade program."

EPA RESPONSE:
EPA notes that for the Notice of Data Availability and the final rule, EPA changed its methodology of valuing power losses. Instead of relying on historical average revenues, EPA used revenue projections from the Integrated Planning Model (IPM), which was used to support EPA's economic impact analysis, including potential impacts on facilities and the energy market. This model corrects/accounts for each of the faults listed by the commenter:

1. The IPM is forward looking.
2. The IPM takes into account seasonal variations when estimating prices and determining revenues.
3. The IPM takes into account the value of capacity. This is expressed in the form of capacity prices and capacity revenues.
4. The IPM base case includes current federal and state air quality requirements, including future implementation of SO2 and NOx requirements of Title IV of the CAA and the NOx SIP call as implemented through a cap and trade program.

The commenter outlines three available methodologies that overcome the alleged short-comings of EPA's proposal methodologies (see response to comment 316bEFR.072.302 in subject matter code 9.03).

Finally, the commenter makes two related assertions:
"The choice of methodology [of estimating the cost of power losses] should be left to the individual applicant— taking into account cost and existing modeling capabilities— with review by permitting agencies focusing on the validity of the method and the sensibility of its application in the particular case."

and

"[T]he EPA materials do not provide appropriate guidance for estimating power costs related to Section 316(b) compliance alternatives."

EPA RESPONSE:
EPA notes that the analysis conducted in support of the national Phase II regulation is not intended to provide guidance to individual permit applicants or permitting authorities. EPA believes that the methodologies used in this analysis are the most appropriate to estimate effects on a national level. However, national modeling approaches always rely on assumptions and simplifications that, on average, yield robust results, but may not provide the best estimate for each individual facility.

II. OVERVIEW OF POTENTIAL POWER COSTS DUE TO SECTION 316(B) CONTROL ALTERNATIVES AND EVALUATION OF EPA VALUATION METHODOLOGY

The commenter “provides an overview of the potential components of power costs associated with various potential Section 316(b) control technologies. The chapter also considers EPA’s approach to valuation in light of this overview.”

The commenter states that electricity-related costs associated with (1) construction outage and (2) ongoing power losses “differ in the circumstances but not the nature of the power costs.” EPA agrees with this statement. The commenter further states that this principle extends to premature closures, the situation in which the final Phase II rule would lead a facility to shut down. Under this approach, a premature closure would be valued in terms of electricity production lost. EPA agrees that this approach, if implemented correctly, is one approach of valuing the cost of a premature closure. EPA notes that under this approach, to avoid double-counting, the Agency would have to subtract regulatory compliance costs estimated for each generating unit that would pre-maturely close from the estimate of total social cost. However, EPA used a different approach. The decision of a facility, in the face of regulatory compliance costs, to close rather than to comply with the rule implies that the net present value (NPV) of the facility’s future operations is less than the NPV of the compliance costs. As such, EPA’s compliance costs provide an upper bound or ceiling of the value of any generating unit projected to close as a result of the final Phase II rule.

The commenter lists three cost categories that might entail power costs:
1. Generation;
2. Capacity; and
3. Air emissions.

1. The commenter alleges that EPA’s methodology for estimating the value of lost generation is deficient for the following reasons:

(a) “Changes in Facility Revenue are Not Necessarily a Measure of Social Cost”
The commenter states that “lost generation should be valued at its value to consumers if the output is not compensated for by increased generation elsewhere, or at the additional resource costs required to compensate for the lost generation if such compensation is projected to occur. Such values would include losses in consumer and producer surplus associated with any rise in the price (and decrease in the output) of electricity.”

EPA RESPONSE:
EPA agrees with the commenter’s concept for valuing the social cost of generation capability lost due to the 316(b) rule. Further, EPA judges that its analysis of the cost of lost generation provides a reasonable approximation of this concept. For its analysis, EPA assumes that consumer demand will be met by alternative generation resources to those affected by installation outage, energy penalty (though none of the technologies expected to be installed for the final rule entail energy penalties), or premature retirement of capacity. As a result, the appropriate social cost concept is the amount by which the electricity production cost of facilities that replace the energy not produced due to outage or other generation losses exceeds the production cost of the Phase II facilities experiencing the

installation outages. In addition, the social cost should include the cost to society of any reductions in system reliability or other capacity reduction effects resulting from the loss in generating capacity. Because all demand is assumed to be met by the replacement energy sources, there will be no changes in producer and/or consumer surplus resulting from reduced total consumption. Thus, the Agency focused on this increased cost to society, regardless of its distribution between producers and consumers.

For the final rule analysis, EPA used the IPM-based estimate of net revenue loss in 316(b) facilities to value the social cost of lost generation. The IPM analysis incorporates a forecast of future electricity prices; these prices include both an energy price and a capacity price. In addition, because IPM assumes competitive, deregulated market conditions as the framework for its analysis, the social cost of replacement energy (including both energy and capacity price effects) will generally be very close to the net price (price less short run production cost) otherwise received in the market by the generating units experiencing installation outages or generating loss effects – that is, replacement energy is assumed to be supplied by a generating unit(s) whose production cost is essentially equal to the price otherwise prevailing in the market. Given the very small overall effects of the 316(b) final rule on total capacity and capacity margins in the electricity market regions, EPA judges that the extent to which yet higher production cost units would need to be called into service is small and thus that this framework provides a reasonable approximation of the social cost of lost generation.

EPA acknowledges that other analytic frameworks could be used to estimate the total effect of lost generation, including the incremental production cost of replacement energy and the cost to society of lost capacity per se. Indeed, the IPM framework is able to incorporate these effects; however, for the social cost analysis they cannot be isolated in terms of the individual components such as the social cost of lost generation. In addition to its principal cost analysis, EPA used the IPM framework to develop a total social cost estimate; this estimate confirmed the overall estimate of social cost developed by EPA for the final 316(b) rule (see DCN 6-4011).

(b) “Historical Information May Not Reflect the Future”
EPA RESPONSE:
EPA agrees with the commenter’s point. EPA notes that the information used in the valuation of power losses are forecasted values from the IPM. EPA therefore no longer relied on historical information for the valuation of power losses for the final rule.

(c) “Average Values Do Not Allow for the Wide Variability in the Social Cost of Generation in Different Time Periods (Months, Years)”
The commenter argues that “[t]he social cost of electricity generation varies dramatically over the course of a year.” As a result, the commenter states that EPA “should calculate potential electricity generation losses by month and also provide information on replacement cost estimates that differ by month.”

EPA RESPONSE:
As stated previously, for the final rule analysis, EPA used information generated by the IPM. EPA documented the potential limitation of its analysis of installation outages in Chapter B3 of the EBA. These limitations are due to an averaging of the downtime not over the entire year, but over the 7-month period, October though April, which includes the off-peak spring and fall periods, and the

winter period, which for most electric market regions is not the annual peak demand period. When calculating the cost of downtime, however, EPA used annual estimates generated by IPM, including the higher-priced peak demand period. While EPA generally agrees with the commenter's point, it notes that the average prices and revenues realized over the year, on a national level, are a good, if not conservative, proxy for the social cost of generation in different time periods. Facilities faced with the necessity of installation outages have an incentive to schedule these outages during off-peak periods when their revenue and profit losses would be minimized and when system-wide capacity reserve margins are greatest. Indeed, if facilities are able to schedule installation outages entirely during the off-peak spring and fall periods, the estimate of installation outage cost based on the annual average would be higher than the expected actual values. Given the strong incentive to schedule as much outage time during low-price periods, but the realities inherent in the need to maintain system reliability, EPA believes that the averages, as used by EPA, provide a good estimate that incorporates the potential variability due to differences in time periods.

2. The commenter alleges that EPA may have excluded power costs associated with capacity and air emissions.

-- "Capacity. Implementation of modifications to the CWIS can reduce a unit's capacity, not just its electricity generation. This loss in capacity has a social cost that should be included in a complete assessment of energy costs."

EPA RESPONSE:
EPA notes that the IPM analysis includes the cost associated with capacity losses. The value of capacity is explicitly considered in the form of capacity prices and revenues, which are included in EPA's estimate of the loss of outages.

-- "Air emissions. Shifts in generation due to modifications to the CWIS typically will lead to changes in air emissions or changes in the costs of meeting air emission targets. These changes— which could be positive or negative— constitute social costs (or benefits) that should be included in a complete assessment of energy costs."

EPA RESPONSE:
Changes in air emission technologies as a result of the final rule are explicitly analyzed in the IPM. The annualized increase in capital costs (estimated for run year 2010) as a result of such changes is less than $3 million. EPA finds that these costs are negligible in the overall context of the Phase II rule. Omission of these costs from the social cost estimate will not materially affect the decisions made by EPA.

[comment continued from 316bEFR.072.301]

III. METHODOLOGIES FOR VALUING ELECTRICITY LOSSES DUE TO SECTION 316(B) ALTERNATIVES

This chapter develops methodologies that can be used to value changes in electricity due to the implementation of potential Section 316(b) regulatory alternatives.

A. Conceptual Considerations

The loss of power due to the implementation of a Section 316(b) alternative could in theory be sufficient to alter electricity prices and thus overall electricity demand. But if the change is small relative to the overall market, the power and capacity lost will be replaced by power and capacity at other generating units. In this case, the social cost of the energy penalty is the added resource cost of providing the equivalent power under the new regulatory constraints of Section 316(b). The modeling approaches in this chapter generally assume that the demand-curtailment effect through higher price is negligible. This assumption will not be justified in cases in which the change would be substantial, such as the case in which a Section 316(b) requirement leads to the premature retirement of a major unit. Similar modeling approaches can be used in this case, but they would have to be expanded to include estimates of the social cost of reduced electricity consumption due to higher prices.

In the absence of price effects, the method to value electricity generation changes due to the implementation of Section 316(b) regulatory alternatives at a facility includes the following two potential categories:

-Additional resource costs at other facilities. The energy lost at the facility due to a given fish protection alternative would be replaced by increased generation and capacity at other units. This increased generation would result in increases in resource costs (e g, fuel, labor, materials, and emissions costs) at the other units, resulting in social costs.

-Cost savings at the facility (if any). If the unit is not operating, costs would not be incurred for fuel and variable operations and variable maintenance costs. For each kilowatt-hour of reduced energy at the facility, these fuel and variable operations and maintenance costs would not be incurred, and emissions savings would be realized. Consequently, these savings constitute reductions in social costs.

The second category depends on the specific costs at the individual facility. Note that these cost savings do not include capital costs and any fixed costs that would be incurred regardless of whether the facility was operating.

The net result of these calculations is an estimate of the value of the lost generation, i.e., the net additions in resource costs of producing the same generation at other facilities. These values could differ dramatically depending upon the time period of the lost generation (e.g., year, season) as well as its location (i.e., PJM or other power market).

B. Components of Resource Costs

The additional resource costs fall into three categories:
1. Generation costs;
2. Capacity costs; and
3. Emissions costs.

1. Generation Costs

The first set of costs relates to the direct costs of producing power: incremental fuel, incremental operating and maintenance costs and other direct consumables. The direct way to derive these costs requires a knowledge of which plants will supply the incremental power and knowledge of the specific costs at that unit.

2. Capacity Costs

The second set of costs relates to the cost of reliability, which is generally termed capacity cost. Society benefits not just from the energy provided by generating units but also from their capacity. Capacity above and beyond that which is needed at any given time to generate lowers the probability of catastrophic blackouts and brownouts. This capacity value can be a substantial part of the value of a generating unit. Indeed, for peaking generators that run very little, capacity value is the major component of total social value.

Conceptually, the value of capacity in any hour is equal to the expected un-served energy (“EUE”) times the value of lost load (“VOLL”). For example, if we have a one percent chance of losing one MWh, the expected loss is 0.01 MWh. If VOLL is equal to $5,000/MWh, the value of a MW of capacity in that hour is $50.00. Of course, in many hours, the probability of losing load is so small that the value of capacity is negligible. In other hours, particularly near the system peak, capacity can be extremely valuable.

If the need for capacity is sufficiently large, the optimal treatment is not to bear the higher costs of outage, but rather to construct new capacity. The cost of this added capacity then represents the social cost, since but for the implementation of Section 316(b) regulatory alternatives, this capacity could have been made proportionately smaller. Thus, the long-run cost of a loss of capacity is the capital cost of replacing that capacity through new construction or the delay in the retirement of units.

3. Emissions Costs

The third set of costs are indirect costs related to emissions costs, either because the incremental rights to emit a pollutant must be purchased in the market or because pollutants have costs that are borne by society, even if the individual emitter has no particular cost to pay. The calculation of the correct inputs to calculate these costs is sufficiently complicated that a fuller discussion is given in Chapter IV.

The information requirements to calculate all of these costs can be daunting, although such analysis is routinely performed by many utilities in their planning process so that useful results may have already been created for other purposes. In some cases there may be less complicated methods to create effective proxies for these costs. We turn to both the direct and indirect methods for estimating these costs in the next section.

C. Alternative Methodologies for Valuing Costs of Lost Electricity

This section provides an overview of the methodologies that might be employed to value reductions in electricity as a result of the installation of CWIS to comply with Section 316(b) regulations. We consider three general approaches:
1. Cost-based modeling;
2. Use of futures market prices; and
3. Modeling of market prices using econometric models

All three of these methodologies have the ability to be forward looking EPA's model takes historical revenues as representative of future revenues, whereas these models use historical information to model the future. In addition, all three of these models have the ability to take variability among different periods into account.

Finally, these models are all complete, taking into account generation, capacity, and air emissions costs. The issue of completeness, however, is quite complex and is discussed in more detail in the sections below.

1. Cost-Based Modeling

This approach to estimating the social costs of reductions in electricity focuses on the costs incurred to replace the reduced output.

a. Overview

Models to simulate costs in an integrated electricity market have been developed over decades. These models provide a highly detailed representation of electricity generation, transmission and dispatch. Electricity market modeling is a detailed approach to quantifying the social cost of providing replacement power cost that is appropriate when significant changes in power output are involved.

b. Basic Cost-Based Model

Cost-based models can be used to estimate the changes in resource costs due to reductions in generation at particular units. The models include detailed representations of the potential alternative generating units. These models can overcome the deficiencies of the EBA approach—they can be forward looking and provide estimates of the added costs of compensating for reductions in generation for detailed time periods within a year.

The basic approach is referred to as a production-cost model, because the models focus on the production costs of meeting given levels of electricity demand at different time periods over the course of each year. The standard methodology involves projection of future demands for electricity as well as detailed representations of the individual units in the relevant market, including units connected to the market through transmission interconnections. Prominent production-cost models include PROMOD and GE-MAPS The GE-MAPS model for New York, for example, includes all generating units in the New York Independent System Operator ("ISO"), the New England ISO, and the Pennsylvania-New Jersey-Maryland Interconnection ("PJM"), as well as possible supply from Canada and the East Central Area Reliability Council ("ECAR"). These units include those likely to come into service over time. Appendix A provides a description of the GE-MAPS model.

These models work by creating an optimal dispatch of the system at any point in time the model selects the set of units that would provide just enough generation to match projected load at the lowest cost. Available as outputs from such a model are:

Marginal costs;
Total emissions; and
Indices of reliability, e.g. expected unserved energy or reserve margin.

Electricity market models can be used to evaluate the effects of implementing a Section 316(b) alternative on the social costs of providing electricity services by comparing the results of two cases: (1) a baseline (i.e., assuming no Section 316(b) requirements); and (2) a case assuming the implementation of a Section 316(b) regulatory alternative.

These models can be used to estimate the social cost of reduced generation at a particular facility in various time periods. In order to do this, models simulate the operation of the relevant electricity market with and without the unit in service and accounting for replacement capacity (i.e., capacity added in response to the Section 316(b)-induced change), if appropriate. These two simulations can then be used to estimate the replacement power costs with and without the unit in each of the relevant time periods.

For small changes in power output, it may not make sense to model various scenarios explicitly. For example, if a facility were to derate by five percent, one could simply multiply the market price of electricity predicted by the model by the resulting change in generation at the affected facility. In such a situation, the market model could be used to estimate the hourly market prices for power. This approach works in the case of small changes in power output when the change would itself have only a marginal impact on system operation. While the cost of custom-assembling such an analysis can be quite large and is probably not worthwhile for smaller proposed modifications, there may be readily usable analyses that were prepared for other purposes. In such cases, only minor modifications might be necessary to derive the costs in question. The smaller the modification, the less likely the need to run two scenarios, which requires the modeling of the specific plant modifications. In such cases, the system-wide effects are so small that the marginal costs of energy and capacity can be used directly.

c. Accounting for All Categories of Cost

Electricity market models can capture the response of the systems to specific reductions in energy output, either temporary or permanent. These models can capture replacement energy costs in terms of fuel, variable operating and maintenance ("O&M") and purchased power. Further, these models can also capture differences in emissions, which may also be valued in the model. The modeling of emission costs includes both modeling how emissions from the various units affect the system dispatch and modeling the total emissions costs incurred. For emissions covered by cap-and-trade programs, this modeling involves projecting allowance prices in the relevant emissions markets.

These models generally do not account for capacity costs. Any replacement capacity is represented in the model, but the carrying cost of that replacement capacity must be accounted for outside of that model. Replacement capacity is represented in the model in order to maintain equivalent reliability to the situation where no power loss is experienced. Generally, a power reduction with permanent consequences will result in capacity replacement in a situation where a vertically integrated utility is planning to serve load. However, there may be situations where replacement is lagged or where, due to the temporary nature of the power loss, capacity is not replaced. In these situations, the capacity impacts should be measured as the loss in reliability, that is, the increase in expected un-served energy times the value to customers of that un-served energy. Some models are capable of this calculation. However, in order to fully capture these impacts, it is sometimes necessary to use a more detailed reliability model that captures the uncertainty in both the availability of supply and the uncertainty in load. In circumstances where the capacity margin is tight, a lag in replacement may result in substantial reliability impacts. Chapter IV describes how capacity costs, as well as air emissions costs, can be estimated in a separate analysis.

d. Summary

A typical electricity model analysis would explicitly represent the dispatch of the system, the reduction in power output, and replacement capacity if appropriate. A model analysis would then use the model to estimate the change in fuel costs, variable O&M costs, purchased power costs, and emission costs. The model analysis would then be supplemented with a further analysis to calculate the cost of replacement capacity.

Such modeling is particularly sensible when the Section 316(b) facility is owned by an integrated utility with a load-serving responsibility (though such utilities could use a market-price approach instead). Because load-serving entities have a responsibility to meet certain generation requirements, a cost-based model is likely an accurate reflection of the true social cost in these situations. The social cost analysis then focuses on how the integrated utility would replace the energy and capacity lost due to the implementation of Section 316(b) regulatory alternatives, including quantifying any emission costs that would be incurred. Because such modeling is a relatively complex and costly activity, it generally would not be sensible to develop an electricity model if the Section 316(b) alternatives have only a modest effect on power output.

2. Futures Prices and Extrapolations

The second method estimates social costs of reduced output indirectly by looking at observed prices in futures markets for wholesale electricity.

a. Overview

The future wholesale prices that are available in some regions can be used directly to develop estimates of the value of lost power. These prices represent the value (at the margin) of reduced generation due to Section 3 16(b) alternatives, i.e., the cost incurred by society to compensate for lost generation.

b. Basic Futures Price Model

Futures prices allow one to use actual market information rather than simulated market information to develop the forward-looking set of prices over various time periods. Thus, futures prices provide important information that is objective and can be easily obtained. The use of futures prices has some limitations, however.

For one thing, futures prices are only quoted for block products that have consistent delivery patterns. Hence, they can only be used to evaluate power reductions that would occur at reasonably constant levels over all peak hours or over all hours.

In addition, because futures markets generally only provide forward prices for one or two years in the future, prices for later years must be projected. Such projections use the futures prices as starting points. Escalation rates can be based on the change in total capital and operations costs of new capacity. To determine capital and operating costs in future years, individual cost components for new capacity are escalated. The individual cost components are then combined in each year to arrive at an aggregate energy cost escalation rate that can be used to escalate the monthly forward prices determined in the market. It is necessary to ensure that the forward cost converges to the estimated cost of new entry, since new entrants are expected to break even under long-run equilibrium.

c. Accounting for All Categories of Cost

Care must be exercised in evaluating futures-based prices to make sure that all three categories of cost (energy, capacity, and emissions) are included. In many regions, capacity is remunerated via a capacity market. Capacity targets are established and those entities that cannot demonstrate sufficient capacity are forced to pay a penalty, which can be regarded as a maximum value of capacity. Where this is the case, there are often observed market prices for capacity. Since capacity requires long lead times to construct, futures prices for capacity can establish going rates for capacity with fairly long lead times. Estimates of future prices can be constructed from the cost of new generation construction.

Generally, the cost of emissions that are subject to cap-and-trade programs will be included in futures prices. Adders for non-traded emissions may be required for emissions outside a cap-and-trade program Chapter IV provides the methodology for developing these types of adders as well as those for capacity costs.

d. Summary

For short-term power outputs of a constant level over all hours, futures prices can be directly used. In long-term applications, the futures prices must first converge toward market equilibrium and can then be escalated.

The use of future prices is well suited to situations where a market analysis is desired and a quick and objective market reference is sought. Generally, such an analysis is less costly than a cost-based model.

3. Modeling of Market Prices Using Econometric Models

A third way to estimate the social costs of replacement power costs is to use a market-price approach.

a. Overview

In lieu of futures prices, which are only available for the near-term and for blocks or constant levels of production, hourly market price forecasts can be developed on a long-term basis. As with futures prices, the use of a price forecast to represent social costs is valid from an economic perspective so long as all the relevant costs are internalized in the market price.

b. Basic Econometric Model

Where there is a reasonably large series of observed market prices, one can use statistical techniques to estimate future prices as a function of supply and demand balance and known uncertainties such as weather patterns that are not explicitly reflected in cost-based models. Because the aggregate potential supply of electricity changes very slowly, observations of prices at various levels of demand will effectively trace out the observed supply curve for power. Once adjustments are made to account for future generating capacity, predictions can be generated from econometric models that relate forecast prices to projected future supply-demand balances. Econometric models can also be used to adjust cost-based models in order to forecast hourly market prices.

c. Accounting for All Categories of Cost

The market price forecasts developed using these tools can include relevant social costs, including internalized emissions costs and capacity costs except those that would be compensated in a separate capacity market such as those that exist in New York, New England and PJM As with the other models, emissions costs are generally internalized when they are subject to cap-and-trade programs In most other situations, a separate valuation of emissions costs is necessary. Chapter IV provides the methodology for evaluating air emissions costs and capacity costs separately.

d. Summary

Econometric models can use historical information to model future prices. These models consider a number of factors in order to reflect the substantial price volatility that is often observed in electricity markets from period to period.

A market-price approach is especially suited for generation owners without a planning responsibility. Integrated utilities that retain a planning responsibility will be able to specify the changes to their costs of serving load resulting from a power reduction caused by a compliance alternative. However, generation owners without a planning responsibility will likely not replace power reductions.

D.Conclusions

The three methodologies outlined in this chapter can provide complete and economically sensible estimates of energy penalties from Section 316(b) alternatives. In some instances, these approaches can be even used in combination. For example, a production-cost model can be used to understand the relationships among units along the supply curve, and to forecast which units will be marginal suppliers of electricity in particular regions. One could use this analysis to form the input to an econometric approach that will better predict price behavior under future demand conditions. In certain cases, however, the methods may not include full estimates of capacity costs and emissions costs. The next chapter provides methods for supplementing the modeling in these cases.

[comment continued in 316bEFR.072.303]

Footnotes

10 A more detailed methodology might consider additional emissions such as fine particles and mercury.

11 This argument is an extension of the logic of the previous chapter in the context of estimating the value of changes in generation, for example, using a production cost model in a single scenario setting

12 Because the pollutants we consider here are primarily of regional or global concern, and because the emissions costs are a secondary component of overall social cost, it should be acceptable in this context to disregard the possibility that shifts in generation will result in differential exposure, because of the location of the generating stations. In some cases, however, for example, where this issue is salient in a permitting decision, the permitting authority may wish to consider the implications of changes in exposure. These can be better addressed using the differential analysis described in the first paragraph of this discussion.

13 Note that some of the facilities within the scope of the Section 3 16(b) Phase II Proposed Rule are nuclear generating stations, which have no emissions of NOx, SO2, or CO2.

14 CSI was recently introduced in the U.S. House of Representatives as H.R. 5266.

EPA Response

This comment presents methodologies to value changes in electricity generation due to the implementation of potential Section 316(b) regulatory alternatives.” EPA has reviewed the considerations and methodologies presented by the commenter. EPA notes that its analysis of the economic impacts of the final Phase II rule uses the Integrated Planning Model (IPM), which is a cost-based model, one of the methodologies suggested by the commenter. The IPM exhibits all the attributes of a cost-based model.

IV. METHODOLOGIES FOR ESTIMATING COSTS NOT INCORPORATED IN MODELS

Changes in capacity and emissions costs may not be included in the modeling results. There are, however, means of including these factors explicitly. This chapter discusses methodologies that can be used to assess capacity and emissions costs when these are not reflected in the methodologies described in Chapter III.

A. Estimating Capacity Costs When Not Explicitly Captured in the Methodology

1. Overview

In the long run, a reasonable measure of capacity costs is the cost of replacement peaking capacity. This capacity provides very little energy and thus represents a pure reliability replacement. The calculation of the cost of such capacity is an essential feature of any study that values capacity losses over an extended period of time.

In the short run, however, this cost may over- or understate capacity costs. If capacity is abundant, it may be cheaper in the short run simply to bear the increased risks of shortages and advance the date slightly at which the next capacity increment is required. Under these circumstances, using the cost of replacement peaking capacity may overstate capacity costs. On the other hand, if a CWIS modification is required suddenly, this proxy may understate capacity costs, because planning and construction of new capacity typically requires several years.

For modifications that entail small changes of capacity in an otherwise appropriately sized generating system, the proxy of the costs of a new peaking unit is probably a close approximation to the correct costs. For large changes, or in systems that face tight constraints on new construction, however, direct simulation of the costs of decreased reliability may be necessary. This section provides a sketch of modeling techniques that can be used to estimate the cost of lost capacity when either the production-cost approach or market-based approach employed has not already included a reliability-based component. The key to the modeling of capacity value involves modeling its two components, EUE and VOLL.

2. Modeling the Expected Unserved Energy (EUE)

EUE can be estimated with all probabilistic production cost models (e.g. PROMOD) that allow the supply-demand balancer to randomly fluctuate. Even where the model estimates EUE, one should ensure that the estimate includes both outages due to supply uncertainty and outages due to demand uncertainty. For those that do not (e.g. GE-MAPS), we can use the outputs from runs that predict supply-demand balance hour-by-hour to calculate an EUE in each hour. This is done by taking data on the outage rates of individual generating equipment and transmission lines and performing Monte

Carlo studies to calculate the probability that insufficient capacity will exist in a particular area to serve load. Even where the production-cost approach does not provide a useful EUE figure, simulations can fairly readily determine a reasonable figure for the probability of lost load at any particular supply-demand balance.

Econometric-based models use as their main predictive variable the supply-demand balance at any time. Consequently, the same sort of Monte Carlo analysis can be used to create estimates of EUE. In futures-based analyses, a separate analysis of supply-demand balance will generally be required to carry out the same sort of analysis.

3. Modeling the Value of Lost Load (VOLL)

VOLL is modeled by means of a number of survey techniques. Statisticians studying VOLL continue to produce a large body of literature that is constantly refining its techniques. Because VOLL varies from time to time and even from customer to customer, any measure is necessarily an approximation. Figures of $5,000-$6,000 per lost MWh, however, are fairly typical.

B. Estimating Emissions Costs When Not Explicitly Captured in the Methodology

This section considers how emissions costs can be included in the energy modeling. We evaluate three types of emissions that are of regulatory interest: <FN 10>

1. Sulfur dioxide (SO2);
2. Nitrogen oxides (NOx); and
3. Carbon dioxide (C02)

The section discusses methods to estimate allowance prices for SO2 and NOx, pollutants that are regulated under cap-and-trade systems. Under a cap-and-trade approach, a regional or national cap limits the total amount of emissions from facilities subject to the regulation. Facilities must hold an allowance for each ton of pollutant emitted, and allowances may be traded among participants. In this case, the value of excess (or reduced) emissions at participating facilities is given by the system-wide marginal cost of abatement, which, in an efficient permit market, will equal the market price of an allowance.

We also consider how to measure emissions impacts where a cap-and-trade system does not apply, using NOx as the most significant element. Finally, we consider how to deal with differences in CO2 emissions, which represent additional complications because of uncertainty in future domestic and international regulations.

We begin with an overview of conceptual issues.

1. Conceptual Issues

Emissions costs can be an important component of total social cost in two situations. The more general case concerns a regional or national shift in generation that would occur as a consequence of a policy shift affecting many facilities. This case would apply for example to analysis of the benefits and costs of an EPA regulatory alternative under Section 316(b) that has the potential to alter generation at many facilities. In this case, assuming that the change is significant, one would use the models described in the previous chapter to forecast future electricity generation under two scenarios: a baseline scenario representing the world in the absence of the regulation, and a control scenario representing implementation of the regulation. In some cases, these models will fully incorporate emissions costs. If not, the analyst can estimate emissions costs separately under the two scenarios and compare the difference in order to obtain the net effect of emissions changes on social cost.

A second case applies when one considers a policy shift that will affect one facility or perhaps have a small effect on a few facilities. This case would apply, for example, when a permitting authority wishes to consider the implications of a permit requirement that would result in reduced power output from the affected generating station. Provided that the shift in generation is small, it may be safe to assume that power prices will remain unchanged. Accordingly, it may not be necessary to generate two scenarios in order to estimate the emissions costs. <FN 11> Instead, one may be able to obtain a reasonable approximation by comparing the emissions rate of the affected facility to the emissions rate of the facility or type of facility that is likely to replace any lost output. The difference in emissions rates multiplied by the magnitude of the shift in generation will approximate the net change in emissions. <FN 12> In the next several sections, we examine the application of this approach to specific types of emissions under various applicable air pollution regulatory regimes. Note that the considerations discussed in the following sections apply both to the particular facility or facilities directly affected by Section 316(b) regulations and to the facilities that would increase generation to compensate for power losses. <FN 13>

2. Sulfur Dioxide (SO2) Allowance Prices

Sulfur dioxide is emitted by coal- and oil-fired power plants and other sources. Utility emissions are currently regulated under the Clean Air Act's Acid Rain Program—one of the first successful examples of a cap-and-trade program.

a. Current Regulation

Title IV of the 1990 Clean Air Act mandates an allowance trading system for SO2 emissions from electric utilities (see Ellerman et. al. (2000) for details on the SO2 trading program). This program applies nationwide. The program, which was implemented in two phases, caps the allowable utility SO2 emissions and allows utilities to trade SO2 allowances. (An allowance gives the owner the right to emit one ton of SO2). Allowances also may be banked for use or trade in future years. The cap on Phase I plants (263 units) started at 7.1 million tons in 1995 and dropped to 6 million tons in 1999. In 2000, Phase II plants were added, expanding the universe of regulated facilities to include existing coal-, oil-, and gas-fired utility units serving generators with an output capacity of greater than 25 megawatts and all new utility units, or over 2,000 units in all. The current cap on annual emissions from this universe of facilities is 8.95 Mt SO2 per year.

b. Prospective Regulation

The future of SO2 regulation is unclear, but it is likely that implementation of existing Clean Air Act provisions (under Title I) will result in further reductions in allowable SO2 emissions, either for particular air quality regions or at a national level. EPA's 1997 revisions to the National Ambient Air Quality Standards ("NAAQS") for fine particles ("PM") increase the stringency of ambient PM standards, and apply them to particles with diameter of 2.5 microns or less, to which SO2 emissions contribute in the form of sulfate aerosols. As a result of litigation, EPA has not yet begun to implement these standards. However, it is likely that the revised PM NAAQS would result in more stringent SO2 standards, either in the form of a nationwide cap-and-trade program similar to the NOx SIP Call (discussed below) or in individual state permit requirements.

Congress is also considering additional controls on utility SO2 emissions. The Bush Administration has proposed to reduce SO2 emissions through the Clear Skies Initiative ("CSI"), which would amend the Clean Air Act through legislation. <FN 14> Under CSI, SO2 emissions from power generators would be capped at 4.5 million tons in 2010 and 3.0 million tons in 2018. Although the CSI may not become law, caps at these levels could be used as an indication of possible future controls.

c. How Social Costs of SO2 Can Be Modeled

Since emissions of SO2 are regulated by national cap-and-trade programs, one can measure the social cost of changes in SO2 emissions using SO2 allowance prices. Because SO2 emissions are capped, expected emissions of SO2 are unlikely to change, despite output reductions related to Section 316(b). Instead, we would expect those facilities providing replacement power to acquire SO2 allowances, if needed, to cover any emissions associated with their additional output. <FN 15> Because the replacement power facilities are likely to have emissions rates that are different from the affected in-scope facility's, overall emissions would change unless additional control measures were implemented. The SO2 allowance market would adjust accordingly, so that any potential increase in SO2 emissions would be controlled through increased use of abatement measures. <FN 16> The costs of any increased control measures would be included in the total social cost of electricity replacement. For small potential changes in emissions, we can calculate the cost of the control measures using the allowance price.

If production cost or other electricity models are used to evaluate the added costs of shifts in electricity generation, however, no additional modeling would be required to measure the social costs of these potential increases in SO2 emissions. In competitive wholesale energy markets—as reflected in these models—the prices would reflect the cost of all resources used by the marginal unit (i.e., the most expensive unit), including the cost of additional air emissions. Consequently, the wholesale market calculations used to estimate the social cost of changes in energy already would reflect the cost of additional SO2 emissions for replacement power. Thus, in this case, no additional calculations would be necessary to capture the cost of changes in SO2 emissions from other facilities.

If there were interest in projecting the impact of potential future air emissions regulations, either as a result of implementation of the 1997 PM NAAQS or as a result of legislative modifications to the Clean Air Act, it would be necessary to estimate the effect of these actions on SO2 permit prices EPA has already estimated the effects of the CSI proposal on future SO2 allowance prices. These estimates could be integrated with forecasts of wholesale prices to capture the emissions effect of regulations or permit modifications under Section 316(b) under a scenario that reflects prospective changes in air emissions limits.

3. Allowance Prices for Nitrogen Oxides (NOx)

NOx is emitted by stationary and mobile sources as a by-product of combustion. Utility NOx emissions are covered by various regional regulatory programs.

a. Current Regulation

In contrast to SO2, there are several cap and trade programs for NOx. In addition, NOx has been addressed on a regional and seasonal basis.

(1) Ozone Transport Commission NOx Budget Program

In 1994, a group of Northeastern states participating in the Ozone Transport Commission (OTC) committed themselves to achieving region-wide NOx emission reduction targets by 1999 and 2003 through an emissions trading program. (See NESCAUM / MARAMA (1996) for details on the NOx Budget Program.) The NOx Budget Program is a “cap-and-trade” program that allows large generators of NOx emissions to trade allowances to meet the emission targets in a cost-effective manner. Emission targets are limited to a five-month control period from May to September.

The participating states have committed to achieving a 75 percent reduction from 1990 levels in NOx emissions (55 percent in northern areas) by the year 2003. The target will be achieved in two stages, one in 1999 and the second more stringent stage coming into effect in 2003. Allowances are distributed based upon the allocation formulas established in each state’s implementing rule. Firms are allowed to trade emissions allowances, so long as they hold enough allowances to cover actual emissions. Allowances may be banked, though their value may be diminished if the quantity of banked allowances in the region is high.

(2) Section 126 Federal NOx Budget Trading Program

EPA has established a second federal NOx trading program under Section 126 of the Clean Air Act Section 126 provides that states may petition EPA to take action to address regional transport of NOx because of its contributions to ozone Eleven Northeast states and the District of Columbia petitioned EPA under this section to find that certain major stationary sources in upwind states emit NOx in violation of the Clean Air Act prohibition on amounts of emissions that contribute significantly to ozone non-attainment or maintenance problems in the petitioning State. In response to four of these petitions, in May 1999, EPA established the Federal NOx Budget Trading Program to address NOx emissions from 12 upwind states (DE, IN, KY, MD, MI, NC, NJ, NY, OH, PA, VA, and WV) and the District of Columbia. EPA issued the final program rules in January 2000 (64 FR 28250, May 25, 1999; 65 FR 2673, January 18, 2000). Under this program, electric utility generation sources in these states are subject to an annual ozone-season emissions limit of 289,983 tons, beginning in May 2004. <FN 17,18> These emissions targets are based on an emissions factor of 0.15 lb/mmBtu. (64 FR 28250, May 25, 1999; 65 FR2673, January 18, 2000; EPA 2002b)

(3) NOx State Implementation Plan (SIP) Call

The EPA has also promulgated regulations that will require 21 states and the District of Columbia to revise their SIPs to reduce NOx emissions. <FN 19> The so-called NOx SIP Call includes two major components:

-Individual State NOx Caps — State NOx caps (“budgets”) are based upon emissions targets for individual sources using standard emission factors and projected 2007 activity levels (U.S. EPA 1998). The emission targets for electric power sources are based on an emission factor of 0.15 lb/mmBtu, (roughly comparable to an 85 percent reduction in emissions for most units). Thus, many utilities in states with large amounts of coal-fired power have to make large reductions or trade for NOx allowances from utilities in other states.

-Cap-and-Trade Program for NOx — The SIP Call allows for a cap-and-trade program for NOx emissions during the ozone season across all 22 states Trading would be allowed among electric power and large industrial boilers, which together account for about 90 percent of the required emissions (US EPA 1998).

To address delays resulting from resolution of issues in litigation, the U S Court of Appeals for the DC Circuit ordered that the original 2003 implementation date for the NOx SIP call be extended to May 2004 EPA has also recently proposed that the implementation date for sources in two states--Georgia and Missouri--be extended to May 2005 (67 FR 8395, February 22, 2002).

(4) Other Regulations

In addition to the three federal cap-and-trade programs described above, states and regions (e.g., California's South Coast Air Quality Management District) have local regulations—and in some cases emission trading programs — that govern NOx emissions. Many electric utility sources are also subject to other federal regulations, for example, performance requirements under the New Source Review program, and Clean Air Act Title IV requirements. The Title IV requirements establish an effective emissions rate of between 0.4 and 0.86 lb/mmBTU for many boilers, depending on the type of boiler.

b. Prospective Regulation

As with SO2, utility NOx emissions may be subject to additional future regulations, either under a cap-and-trade framework or in the form of emissions rate limits. At least some of these standards are likely to involve year-round limits on NOx emissions. EPA's 1997 revisions to the PM NAAQS increase the stringency of the ambient PM standards, and focus them on particles with diameter of 2.5 microns or less. Although the science is still developing, EPA presently considers NOx to contribute to PM in the form of nitrate particles. Moreover, EPA's 1997 revisions to the NAAQS for ozone increase the stringency of these ambient air quality standards. As NOx is a primary precursor to ozone, it is likely that NOx would be further regulated in order to assist states in complying with the revised ozone NAAQS. Because of litigation, neither NAAQS has been implemented yet. Nevertheless, it is likely that implementation would occur within the next ten to twelve years.

Another possibility is that NOx would be included in legislative revisions to the Clean Air Act, such as those discussed above for SO2. For example, the Bush Administration has also proposed to reduce NOx emissions through CSI. Under CSI, NOx emissions from power generators would be capped at 2 1 million tons in 2008—1,582,000 tons in the East and 538,000 tons in the West—and 1 7 million tons in 2018 (1,162,000 tons in the East and 538,000 tons in the West). Although CSI may not be enacted, caps at this level could be used as an indication of possible future controls. In particular, the levels of the proposed Western caps are intended to reflect actions that are already planned in the West to address regional haze under the leadership of the Western Regional Air Partnership. Thus, even if the CSI is not adopted, this cap is indicative of the emissions constraints that Western generators may face.

c. How Social Costs of Capped NOx Can Be Modeled

For those sources for which one or more of the cap-and-trade programs described above sets the binding constraint on NOx emissions, the social cost of additional NOx emissions during the relevant season. <FN 20> would be reflected in the NOx permit prices for the program that sets the binding constraint on a source's emissions. As with SO2 emissions, the increased compliance costs associated with meeting the caps would be included in electricity market models that incorporate air emissions costs, including the opportunity cost of allowances used. If production-cost models are not used, social costs could be estimated by taking into account any differences in the emissions rates of the affected and replacement power facilities, as discussed above for SO2.

If there were interest in considering possible future NOx requirements as part of the development of cost estimates, EPA's projections of the effects of CSI on future NOx allowance prices could be integrated with existing market models. Appendix B provides an example of estimating future NOx allowance prices.

4. Modeling Social Cost of NOx Not Covered by a Cap-and-Trade Program

For NOx sources that are either (1) not covered by one of the existing regional programs or (2) face a binding constraint on emissions outside of one of these programs, emissions requirements will be determined by a technology requirement or emissions limit In these situations, an alternative methodology must be used to value the social costs of air emissions

NOx presents the most significant case of air emissions that must be valued this way, since SO2 emissions are covered by a national cap-and-trade program (CO2 emissions are discussed in the subsequent section.)

a. General Methodology

The social cost of the potential increase in NOx emissions could be a mix of increased compliance costs and increased emissions damages, or "dis-benefits." As noted above, the mix of these two types of social costs would depend upon how many and which sources were regulated in which way. The NOx emissions costs from these facilities will be determined by the marginal cost of control for excess tons of NOx, and to the extent that any such constraint is not initially binding (such that emissions can increase), the social cost will also include the disbenefits associated with the additional tons of NOx emissions.

Additional dis-benefits could be calculated using a series of steps:

1. Estimate changes in ambient air quality (PM and ozone) resulting from changes in NOx emissions;

2. Estimate changes in nitrogen and sulfur deposition resulting from changes in NOx emissions;

3. Estimate changes in exposure to PM and ozone.

4. Use concentration-response (C-R) functions to estimate effect of ambient air quality changes on human health;

5. Value the changes in human health endpoints using available valuation methods;

6. Add the aggregate monetized human health effects to other effects associated with changes in nitrogen and acid deposition to obtain the social cost of increased NOx emissions.

Figure 1 illustrates these steps.

Figure 1 Components of NOX Emissions Impact

[see hard copy for figure]

b. Specific Applications

In specific applications, it would be appropriate to use existing information on the likely dis-benefits of NOx emissions. Generally, these emissions are not likely to account for enough of the total energy penalty to justify an independent study of these various relationships.

5. Accounting for Differences in Carbon Dioxide (CO2) Emissions

Carbon dioxide (CO2) is emitted by a large number of sources that burn fossil fuels. Currently, CO2 is not subject to substantial regulation in the United States, although there is considerable international interest in regulating CO2 and other greenhouse gas emissions globally. Because of these regulatory uncertainties, it will be useful to develop a general methodology that relies upon judgments and the existing literature.

a. Current Regulation

No regulations currently constrain emissions of carbon dioxide (CO2) on a nationwide basis in the U.S. Two states, Massachusetts and Oregon, do, however, have some regulations on CO2 emissions from power plants. The Massachusetts program, which began in April 2001, limits CO2 from six generating stations to historical 1997-99 emissions beginning in 2004 for most plants and 2006 for new plants or plants that have made major modifications. Beginning in 2007 or, for those plants with the later deadline, in 2010, emissions will be capped at a level of 1,800 lb/MWh. Off-site reductions or sequestration may also be used to offset emissions. Under the Oregon program, which began in 1997, the Oregon Energy Facility Siting Council sets CO2 emissions standards for new facilities. For base load natural gas plants, the standard is 0.675 pounds of CO2 per kilowatt-hour, and for non-base-load power plants, the standard is 0 7 lb CO2/kWh, regardless of fuel type. With the Oregon program too, offsets can be used to meet the standards. Applicants also have the choice of paying $0.85 per ton of CO2 to Oregon Climate Trust in lieu of undertaking controls or offsets, thus, the Oregon program is more properly viewed as a tax program rather than a cap-and-trade program.

b. Prospective Regulations

Much of the discussion, of global regulation of greenhouse gas emissions is in the context of the Kyoto Protocol, which was signed in December 1997 but has not yet been ratified by sufficient numbers of countries to go into force. The Kyoto Protocol calls for significant reductions of greenhouse gas (GHG) emissions from Annex 1 countries (mainly developed countries) by the period 2008-2012. The Kyoto treaty set a U.S. target of reducing CO2 emissions by seven percent below 1990 emission rates during the 2008-2012 commitment period. The Bush Administration has indicated that the US will not ratify the Kyoto Protocol. Instead, in February 2002, President Bush announced a strategy on climate change that sets a voluntary goal of reducing greenhouse gas (including C02) emissions intensity by 18 percent over the next ten years, from 183 metric tons per million dollars of GDP to 151 metric tons per million dollars of GDP. Potential controls on utility CO2 emissions, which would establish a domestic cap-and-trade program for CO2, are being considered in Congress.

c. How Social Cost of CO2 Can Be Modeled

This section provides a general strategy for estimating the social costs associated with changes in CO2 emissions due to Section 316(b) control alternatives. This strategy involves a two-step process.

1. Project future regulatory requirements, and

2. In light of future regulatory requirements, develop projections of allowance prices and/or dis-benefits from additional CO2 emissions.

(1) Assess Prospective Regulations

The appropriate procedure for estimating the cost of changes in CO2 emissions is highly dependent on future regulatory requirements. Thus, the first step in evaluating these costs is to consider the likely future regulatory requirements. The regulatory requirements may consist of one or more of the following:

-No binding regulations or voluntary agreements.
-Voluntary agreements to reduce emissions;
-Emission limits;
-Cap-and-trade program.

Note that the judgments about which types of regulations are likely may differ over the time period being considered. It may be reasonable to assume, for example, that there will be no binding regulations in the next decade and a cap-and-trade program thereafter.

In addition to assessments of the general type, it would be necessary to develop assessments of the likely level of stringency (e.g., the level of any national utility cap on CO2 emissions). These assessments would set the stage for the second step, to develop specific values.

(2) Estimate Values Based on Literature

After evaluating the nature and extent of likely regulatory requirements, the analyses would include assessments of the likely allowance prices (cap-and-trade programs), compliance costs (binding emission limits), or dis-benefits (no regulations or non-binding emission limits).

Numerous estimates have been developed of likely CO2 allowance prices under alternative assumptions regarding the likelihood of international trading in CO2 allowances Although less numerous, there are studies that assess the likely dis-benefits of CO2 emissions.

C. Summary

Both capacity and emissions costs can be estimated separately if they are not included in the overall modeling approaches. These methods can supplement the modeling results. As with the general modeling, it would be important to assess the likely significance of these effects before undertaking major studies of these effects.

V. CONCLUDING REMARKS

The three methods discussed in this report all can be used to develop economically valid measures of the social costs of energy penalties due to various Section 316(b) regulatory alternatives. All three basic approaches can overcome the major difficulties of the simple approach used by EPA in the EBA. Because the EPA methods might influence the evaluation of Section 316(b) regulatory alternatives at a national level in this rulemaking as well as the development of Section 316(b) alternatives in a particular permit case, it is important that EPA modify its analyses to include one or more of these approaches, or at least note that other methodologies are appropriate to develop accurate and complete estimates of the social costs of energy penalties.

The choice among methods in a particular Section 316(b) application should be left to the Section 316(b) permit applicant—assuming all elements of social cost are included— because there is no one approach that is best in all situations. The choice of a particular modeling approach depends upon various factors:

-Availability and applicability. In some cases, the data or modeling framework may not be available. Regions that have forward prices do not cover all energy facilities, and thus the forward price approach may not be an option.

-Complexity and cost. The various approaches differ in their complexity and the cost of implementation. Moreover, the added cost depends upon the nature of the modeling the Section 316(b) applicant is doing for other purposes. For example, if a utility has an established model in-house, the added costs of doing model runs for Section 316(b) alternatives maybe modest.

-The size of the likely energy costs. The usefulness of developing detailed estimates will depend in part on the likely size of the Section 316(b) energy penalty. Clearly, a more complex and detailed model will be more appropriate where the penalties are large than if they are a small element of overall social cost

-Coverage. The choice of model also will depend upon its coverage—whether it□includes all relevant elements or if some elements (e.g., capacity) of social cost need to be developed outside the model.

-Input projections and other uncertain ties. Most of the modeling approaches require key inputs to be projected into the future. These inputs include natural gas prices, oil prices, coal prices, future capacity expansion, and future emission allowance prices. Uncertainties in these inputs create uncertainties in the overall projections. There are techniques that can be used to evaluate these uncertainties, although the techniques increase the cost of the modeling.

Although these factors may not point to a single modeling approach, the elements can be used to develop a methodology for calculating energy penalties due to Section 316(b) alternatives that is both economically sound and cost-effective in light of the specific circumstances.

Footnotes

15 It is possible that some of these allowances would come from the facility affected by 316(b).

16 Similarly, any potential reduction in overall emissions (due to a higher emissions rate at the affected in-scope facility) would result in reduced use of existing abatement measures.

17 The ozone season extends from May 1 to September 30.

18 The program implementation date was recently delayed from May 1, 2003 until May 31, 2004 (67 FR 21521, April 30, 2002).

19 The original rules included an additional state—Wisconsin—but EPA has proposed to exclude Wisconsin in response to court rulings.

20 If a source participates in a cap-and-trade program only during the ozone season, it will be necessary to value changes in non-ozone-season emissions using the methodologies described in the next section.

EPA Response

This comment discusses “methodologies that can be used to assess capacity and emissions costs when these are not reflected in the methodologies” (see comment 316bEFR.072.302 in subject matter code 9.03). Specifically, the commenter discusses two types of costs: (1) capacity costs and (2) emissions costs.

(1) The IPM, which was used for the economic impact analysis of the final Phase II rule, explicitly accounts for capacity costs.

(2) The IPM estimated changes in air emission technologies as a result of the final rule. The annualized increase in capital costs (estimated for run year 2010) as a result of such changes is less than $3 million. While the emissions allowance function in the IPM was not enabled for the section 316(b) Phase II analysis, EPA conducted an analysis to assess the changes in emissions of SO2, NOx, and CO2. These analyses showed minimal changes in emissions as a result of the final Phase II rule. In 2008, the year when some Phase II facilities were modeled to experience installation downtimes, the highest emissions increase was for NOx, which increased by less than 0.4% compared to the baseline. In all other years, the maximum increase for the three pollutants was less than 0.1%. The estimated change for SO2 in 2010 was a decrease of 0.5%. EPA therefore finds that omission of these emission changes and their societal cost (or benefit) from the social cost estimate will not materially affect the decisions made by EPA.

In the concluding remarks, the commenter notes several factors that should determine the choice of a particular modeling approach. Among other factors, the commenter notes that “[t]he usefulness of developing detailed estimates will depend in part on the likely size of the Section 316(b) energy penalty. Clearly, a more complex and detailed model will be more appropriate where the penalties are large than if they are a small element of overall social cost." EPA agrees with this comment and notes that the Phase II final rule is expected to cause no operational energy penalties with generating losses resulting only from temporary shutdown of facilities during installation of compliance equipment or, in very few instances, from earlier closure of older generating facilities. Given the limited energy effects of the final rule, EPA judges that the use of the IPM framework and the character of analyses that EPA has performed and reported for energy effects meet or exceed the commenter's recommendation on choice of a modeling approach.

APPENDIX A. PRODUCTION COST MODELS EXAMPLE OF GE-MAPS

Production cost models have been developed over the last decades to simulate the workings of electricity systems. This appendix provides a description of one prominent model, that developed by General Electric Energy Consulting. The model is the Multi-Area Production Simulation model, or MAPS. <FN 21>

A. GE-MAPS Capabilities

MAPS is a highly detailed model that calculates hour-by-hour production costs while recognizing the constraints on the dispatch of generation imposed by the transmission system. When the program was initially developed over twenty years ago, its primary use was as a generation and transmission planning tool to evaluate the impacts of transmission system constraints on the system production cost. In the current deregulated utility environment, the acronym MAPS may also stand for Market Assessment & Portfolio Strategies because of the model's usefulness in studying issues such as market
rower and the valuation of generating assets operating in a competitive environment.

The unique modeling capabilities of MAPS use a detailed electrical model of the entire transmission network, along with generation shift factors determined from a solved ac load flow, to calculate the real power flows for each generation dispatch. This enables the user to capture the economic penalties of redispatching the generation to satisfy transmission line flow limits and security constraints.

Separate dispatches of the interconnected system and the individual companies' own load and generation are performed to determine the economic interchange of energy between companies. Several methods of cost reconstruction are available to compute the individual company costs in the total system environment. The chronological nature of the hourly loads is modeled for all hours in the year. In the electrical representation, the loads are modeled by individual bus.

In addition to the traditional production costing results, MAPS can provide information on the hourly spot prices at individual buses and on the flows on selected transmission lines for all hours in the year, as well as identifying the companies responsible for the flows on a given line.

Because of its detailed representation of the transmission system, MAPS can be used to study issues that often cannot be adequately modeled with conventional production costing software. These issues include:

Market Structures — MAPS is being used extensively to model emerging market structures in different regions of the United States. It has been used to model the New York, New England, PJM and California ISOs for market power studies, stranded cost estimates, and project evaluations.

Transmission Access - MAPS calculates the hour spot price ($/MWh) at each bus modeled, thereby defining a key component of the total avoided cost that is used in formulating contracts for transmission access by non-utility generators and independent power producers.

Loop Flow or Uncompensated Wheeling — The detailed transmission modeling and cost reconstruction algorithms in MAPS combine to identify the companies contributing to the flow on a given transmission line and to define the production cost impact of that loading.

Transmission Bottlenecks — MAPS can determine which transmission lines and interfaces in the system are bottlenecks and how many hours during the year these lines are limiting. Next, the program can be used to assess, from an economic point of view, the feasibility of various methods, such as transmission line upgrades or the installation of phase-angle regulators for alleviating bottlenecks.

Evaluation of New Generation, Transmission, or Demand-Side Facilities — MAPS can evaluate which of the available alternatives under consideration has the most favorable impact on system operation in terms of production costs and transmission system loading.

Power Pooling — The cost reconstruction algorithms in MAPS allow individual company performance to be evaluated with and without pooling arrangements, so that the benefits associated with pool operations can be defined.

Table 1 shows how MAPS models the bulk power system and yields an accurate through-time simulation of system operation.

Table 1. MAPS Models the Bulk Power System

[see hard copy for table]

B. GE-MAPS Modeling

MAPS has evolved to study the management of a power system's generation and transmission resources to minimize generation production costs while considering transmission security. The modeling capabilities of MAPS are summarized below:

Time Frame — One year to several years with ability to skip years.

Company Models — Up to 175 companies.

Load Models — Up to 175 load forecasts. The load shapes can include all 365 days or automatically compress to a typical week (seven different day shapes) per month. The day shapes can be further compressed from 24 to 12 hours, with bi-hourly loads.

Generation — Up to 7,500 thermal units, 500 pondage plants, 300 run-of-river plants, 50 energy-storage plants, 15 external contracts, 300 units jointly owned, and 2,000 fuel types. Thermal units have full and partial outages, daily planned maintenance, fixed and variable operating and maintenance costs, minimum down-time, must-run capability, and up to four fuels at a unit.

Network Model — 30,000 buses, 60,000 lines, 100 phase-angle regulators and 10 multi-terminal High-Voltage Direct Current lines. Line or interface transmission limits may be set using operating nomograms as well as thermal, voltage and stability limits. Line or interface limits may be varied by generation availability. Transmission losses may vary as generation and loads vary, approximating the ac power flow behavior, or held constant, which is the usual production simulation assumption.

Marginal Costs — Marginal costs for an increment such as 100 MW can be identified by running two cases, one 100 MW higher, with or without the same commitment and pumped-storage hydro schedule. A separate routine prepares the cost difference summaries. Hourly bus spot prices are also computed.

Operating Reserves — Modeled on an area, company, pool and system basis.

Secure Dispatch — Up to 5,000 lines and interfaces and nomograms may be monitored. The effect of hundreds of different network outages is considered each study hour

Report Analyzer — MAPS allows the simulation results to be analyzed through a powerful report analyzer program, which incorporates full screen displays, customizable output reports, graphical displays and databases The built-in programming language allows the user to rapidly create custom reports.

Accounting — Separate commitment and dispatches are done for the system and for the company own-load assumptions, allowing cost reconstruction and cost splitting on a licensee-agreed basis. External economy contracts are studied separately after the base dispatch each hour.

Bottom Line — Annual fuel plus O&M costs for each company, fuel consumption, and generator capacity factors.

C. GE-MAPS Applications

The program's unique combination of generation, transmission, loads and transaction details has broadened the potential applications of a production simulation model. Since both generation and transmission are available simultaneously with MAPS, the user can easily evaluate the system and company impacts of non-utility generation siting and transmission considerations.

In addition to calculating the usual production cost quantities, MAPS is able to calculate the market clearing prices (marginal costs or bus spot prices) at each load and generation bus throughout the system. For the load buses, the price reflects the cost of generating the next increment of energy somewhere on the system, and the cost of delivering it from its source of generation to the specific bus. Because the production simulation in MAPS recognizes the constraints imposed by the transmission system, the market clearing prices include the costs associated with the incremental transmission losses as well as the costs incurred in redispatching the generation because of transmission system overloads. Figure 2 shows the variation in market clearing prices of two separate companies. The company wide clearing price is the weighted average of the clearing prices at the load buses.

Figure 2. Market Clearing Prices Vary with Time and Location

[see hard copy for figure]

MAPS is also able to calculate and constrain both the actual electrical flows on the transmission system and the scheduled flows assigned to individual contract paths. The actual real power flows on the network are based on the bus-specific location of the load and on the generation being dispatched to serve the load. The scheduled flows include firm company-to-company transactions that are delivered from the seller to the buyer over a negotiated path. The scheduled flows also include the generation from remotely owned units, which is delivered to the owning company over an assigned path, and generation that is delivered to remotely owned load.

The simultaneous modeling of actual and scheduled flows is especially important in modeling the Western region of the US where the scheduled flows often have a major impact on the operation of the system. Figure 3 shows the hourly flows on one of the WSCC interchange paths where the scheduled flows on the path are limiting while the actual flows are not, resulting in ‘the generation dispatch being constrained by scheduled rather than actual physical limits. This is important in identifying the contract paths that have available transfer capability and could be used to deliver power from potential new development sites.

Figure 3. Example of Hourly Actual and Scheduled Flows 300

[see hard copy for figure]

APPENDIX B. CASE STUDIES ON THE VALUATION OF LOST GENERATION, LOST CAPACITY, AND INCREASED AIR EMISSIONS

This appendix describes three examples of assigning dollar values to economic losses at power plants—in the form of lost generation, lost capacity, and increased air emissions. The examples given here are designed to demonstrate the method rather than the precise values, which will change over time as the underlying data changes.

D. Case Study on the Valuation of Lost Energy Generation

This appendix provides an example of developing dollar values for lost electricity generation resulting from Section 316(b) control alternatives. The methodology in this example is based upon the forward price approach. The example concerns the value of generation in the Pennsylvania-New Jersey-Maryland Interconnection (“PJM”). The example was developed in 2000 in the context of a specific Section 316(b) permit application. <FN 22> Nevertheless, the general methodologies discussed here—if not the specific dates and data—could be used to develop estimates for many facilities facing regulatory or permit requirements under Section 316(b).

1. Methodology for Calculating Cost of Replacement Energy

The cost of replacement energy to compensate for lost generation at the facility is calculated by multiplying prices for energy in PJM wholesale markets by the appropriate quantity of lost energy. The basic methodology for determining energy prices is as follows:

1. Year 2002. Monthly energy prices are based on the current forward prices for energy in 2002. Monthly energy prices are the hourly weighted average of on-peak, weeknight, and weekend prices. Forward market prices were provided by PSEG Energy Resources and Trade (2000).

2. Years 2003 to 2015. Energy prices are escalated using energy prices in 2002 as a starting point. Prices over this period are based on projected changes in the cost of new generation.

Escalation rates for the years 2003 to 2015 are based on the change in total capital and operations costs of new capacity, which is assumed to be a combined-cycle unit. To determine capital and operating costs in future years, individual cost components for a combined-cycle unit are escalated. The individual cost components are combined in each year to arrive at an aggregate energy cost escalation rate that is used to escalate the monthly forward prices for 2002. The following assumptions are used in developing the escalation rates for individual components and for aggregating these components:

-Construction Costs and Unit Heat Rates Based on ETA data (U S Department of Energy 1999)

-Natural Gas Prices. Natural gas prices over the period 2001 to 2005 are based on the assumption that current futures prices (as reported in the Wall Street Journal) trend toward EIA's natural gas price forecast for 2005 (U S Department of Energy 1999). Prices for the period 2005 to 2015 are based on the ETA natural gas price forecast (U S Department of Energy 1999).

-Firm Gas Reservation Charge and Gas Transportation Tax and Surcharge. Both the firm gas reservation charge and the gas transportation cost, tax and surcharges are assumed to remain constant in nominal terms (Federal Energy Regulatory Commission 2000).

-Fixed and Variable O&M. Fixed and variable O&M are escalated at the forecast GDP implicit price deflator, as reported by the ETA (US Department of Energy 1999).

-Utilization Rate. An 80 percent utilization rate is assumed.

Table B-1 provides the escalation rates for the individual cost components. Table B-2 provides estimates of the average energy costs for the period 2002 to 2015, weighted by facility generation. This table reflects the average cost of replacing generation at facility.

Table B-1. Escalation Factors Used in Estimating Future Cost of Potential Entrant

[see hard copy for table]

Table B-2. Monthly Average Energy Costs for 2002 to 2015

[see hard copy for table]

2. Construction Outages

The monthly cost of replacement energy during an outage is estimated by multiplying the quantity of lost energy (i.e., the quantity the facility would have otherwise generated) by the PJM wholesale market prices for peak, off-peak and weekend load periods. The quantity of lost energy is based on average monthly utilization levels in each load period for the years 1998 to 2000.

The cost of lost energy is estimated net of fuel and variable operations and maintenance savings at the facility, since these costs would not be incurred. The variable cost of energy production (including fuel and variable operations and maintenance) is $20 per megawatt-hour from October to April, and $25 per megawatt-hour during the ozone season (May to September) (Marusiak 2000). Total annual costs are calculated by summing the monthly costs for all months in which there is a construction outage. The total cost is calculated by summing annual energy costs across years, with appropriate discounting.

3. Changes in Continuing Operation Associated with All Intake Modifications and Closed-Cycle Cooling

For changes in continuing operation associated with all intake modifications and closed-cycle cooling, the cost of lost energy reflects only the cost of replacement energy. The cost of replacement energy for these changes to continuing operation is estimated for every month by multiplying the energy loss in each month (in MWH) by the wholesale energy market prices for peak, off-peak, and weekend periods. Energy losses reflect auxiliary power requirements for intake modifications and the combination of auxiliary power requirements and heat rate penalties for closed-cycle cooling systems. The annual cost of lost energy for each year is estimated by summing costs across months. The total cost is calculated by summing annual energy costs across years, with appropriate discounting. The magnitudes of the energy losses for each alternative depend on these auxiliary power requirements and reductions in plant efficiency.

4. Changes in Continuing Operations Associated with Seasonal Flow Reductions

There are two components to the cost of lost energy associated with seasonal flow reductions in the months of April, May, and June: <FN 23> (1) energy savings from reduced auxiliary power, and (2) energy losses that occur from reductions in energy generation due to the decline in cooling water flow. Auxiliary power savings is calculated for every month by multiplying the change in energy in each month by the monthly PJM wholesale market price for peak, off-peak, and weekend load periods. The annual cost of lost energy for each year is estimated by summing costs across months. The total cost is calculated by summing annual energy costs across years, with appropriate discounting. The magnitudes of the energy savings depend on auxiliary power requirements.

Seasonal flow reductions would also result in a reduction in energy generation, since the flow reductions would reduce the facility’s maximum generation capacity. The quantity of lost energy is the quantity of energy above this constrained capacity that the facility otherwise would have generated. The cost of energy losses is calculated for every month by multiplying the energy loss in each month by the monthly PJM wholesale market price for peak, off-peak, and weekend load periods. The variable cost of energy production (including fuel and variable operations and maintenance) is $20 per megawatt-hour from October to April, and $25 per megawatt-hour during the ozone season (May to September) (Marusiak 2000). Estimates are based on average monthly utilization levels in each load period for the years 1998 to 2000. Lost energy is estimated net of fuel and variable operations and maintenance savings at the facility, since these costs would not be incurred. The annual cost of lost energy for each year is estimated by summing costs across months.

The total cost is calculated by summing annual energy costs across years, with appropriate discounting.

E. Case Studies on the Valuation of Lost Capacity

This section provides an example of developing dollar values for lost capacity resulting from Section 316(b) control alternatives. The methodology in this example is based upon the forward price approach. The example concerns the value of capacity in the Pennsylvania-New Jersey-Maryland Interconnection ("PJM"). The example was developed in 2000 in the context of a specific Section 316(b) permit application. <FN 24> As above, the example is designed to demonstrate the method rather than the precise values, which will change over time as the underlying data changes. The methodology used here relies on forward market prices to forecast future energy prices.

1. Methodology for Calculating Costs of Lost Capacity

Estimates of the social cost of lost capacity for the facility are based on market price projections for the PJM installed-capacity ("I-Cap") market. Demand in this market is driven by capacity obligations on load serving entities ("LSEs") that are imposed by PJM to ensure that there is adequate capacity to maintain the reliability of the PJM system. The capacity obligation is defined as the amount of installed capacity necessary to meet the annual peak load plus a reserve component, which is typically 20 percent LSEs can obtain capacity through bilateral contracts or purchases on the I-Cap market conducted by PJM. <FN 25>

Capacity costs in the year 2002 and 2003 are based on forward market prices (PSEG Energy Resources and Trade 2000). Prices in the years 2004 to 2015 are based on an extrapolation of prices using prices in 2003 as a starting point. Escalation rates are based on an estimate of the change in capital cost for new capacity, which is assumed to be combined cycle gas generation. This real escalation rate ranges from 1.3 percent to 0.6 percent annually (Department of Energy 1999) Table B-3 presents the monthly capacity prices used in this study.

Table B-3. Monthly Capacity Prices for the Period 2002 to 2015

[see hard copy for table]

2. Construction Outages

The monthly cost of lost capacity for construction outages is estimated by multiplying the facility's monthly rating (in MW) by the PJM market capacity price (in $/MW-day) for each of the days during the outage. Annual capacity cost is calculated by adding the monthly capacity cost over the outage's duration. The total cost is calculated by summing the annual costs, with appropriate discounting.

3. Changes in Continuing Operation

The cost of lost capacity for changes in continuing operations are estimated under two different conditions:

1. Permanent reductions in capacity; or

2. Scheduled reduction in capacity due to construction outages or seasonal flow reductions.

The methodology for estimating the cost of lost capacity under each of these conditions is described below.

a. Permanent Reductions in Capacity

A permanent increase in load and/or decreased efficiency in a unit represents an effective change in the unit's capacity rating. The monthly cost of lost capacity for each alternative is estimated by multiplying the PJM capacity market price (in dollars per megawatt-month) by the effective monthly derate (in megawatts). Annual capacity cost is calculated by adding the monthly capacity cost over the outage's duration. The total cost is calculated by summing the annual costs, with appropriate discounting.

b. Construction Outages and Reductions for Seasonal Flow Reductions

The monthly cost of lost capacity for construction outages or seasonal flow reductions is estimated by multiplying the reduction in the facility's rated capacity for April, May and June (in megawatts) by the PJM market capacity price (in dollars per megawatt-month) for each of the days during the outage. Annual capacity cost is calculated by adding the monthly capacity cost over the outage's duration. The total cost is calculated by summing the annual costs, with appropriate discounting.

F. Case Study on the Valuation of Air Emissions

This section provides an example of developing dollar values for changes in air emissions resulting from Section 316(b) control alternatives. The example concerns the value of air emission changes relevant for a facility in the PJM. The example was developed in 2000 in the context of a specific Section 316(b) permit application. <FN 26> The example is designed to demonstrate the method rather than the precise values, which will change over time as the underlying data changes.

1. Sulfur Dioxide (SO2)

Some fish protection alternatives would lead to reductions in emissions from the facility over certain periods of time. During construction outages, for example, the facility would not produce emissions, though it would have had there been no outage. The social costs of these changes in emissions are calculated by multiplying forecast allowance prices per ton of emissions by the quantity of additional tons of emissions. Emissions from the plant are based on average utilization levels over the period 1998 to 2000, heat rate data for the plant (in kilowatt-hours per Btu), and SO2 content data (U S Department of Energy 1999)

Allowance price forecasts are based on the current allowance price index from Cantor Fitzgerald (2000) for future years. This index is based on the price of actual trades and current buyer and seller offers. (The average price for 2002 allowances over the three-month period from July to September 2000 was $154 per ton of SO2). Vintage permit prices were used to develop permit price estimates for the years 2003 and 2004. Vintage permits can be purchased today, but are not valid for use until the permit's vintage year, at which time they can be used for compliance or banked. <FN 27> Permit prices after the year 2004 are adjusted based on the change in vintage permit prices between 2003 and 2004, which are the last two years of vintage permit price data. The final values for permit prices used in each year are included in Table B-4.

Table B-4 Air Emissions Costs From Lost Power (Year 2000 $/Ton Emissions)

[see hard copy for table]

2. Oxides of Nitrogen (NOx)

For alternatives that would result in reduced NOx emissions from the plant, the methodology used to estimate these social cost savings is similar to the methodology used for SO2 emissions These emission savings are calculated by multiplying forecast allowance prices per ton of emissions times the quantity of additional tons of emissions. Emissions from the plant are based on average utilization levels over the period 1998 to 2000, heat rate data for the plant (in kilowatt-hours per Btu), and average NOx emission rates (U.S. EPA 1998a, U.S. EPA 1998b). Note that if the plant is equipped with SNCR scrubbers, the use of average NOx emission rates likely overstates the estimates of NOx emission savings.

Allowance price forecasts are based on the current allowance price index, for example from Cantor Fitzgerald (2000). This index was based on the price of actual trades and current buyer and seller offers. The average price for 2002 allowances over the three-month period from July to September 2000 was $538 per ton of NOx. At the time of the example study, vintage permit prices were not available for NOx permits beyond 2002. Consequently, prices for years beyond 2002 were based on SO2 vintage price adjustments. The final values for allowance prices used in each year are included in Table B-4.

Note that since NOx emissions would only lead to cost increases during the summer NOx season when emission caps are imposed, using permit prices for annual tons is likely to misstate the actual emission savings unless steps are taken to account for emissions during outside of the summer NOx season.

3. Carbon Dioxide (CO2)

The cost of CO2 emissions is based on increases in emissions at other facilities and, for some types of power losses, increases in emissions at the plant. Seasonal flow reductions and constructions outages would lead to both reductions in CO2 emissions at the plant and increases at other facilities. Changes in auxiliary power and heat rate penalties would lead only to changes in emissions at other facilities The cost of changes in emissions at other facilities and at the plant are estimated as follows:

Emission Changes at Other Facilities

-Period 2002 to 2004. The costs of CO2 emissions are based on the quantity of additional CO2 emissions from replacement power, multiplied by the disbenefits value per ton of emissions The quantity of additional CO2 emissions is based on PJM market simulations using the PROMOD model.

-Period 2005 to 2015. The costs of CO2 emissions are based on the incremental cost of electric power under a carbon-cap regime <FN 28> relative to business-as-usual conditions. The incremental cost (cost per kilowatt-hour) is multiplied by the quantity of auxiliary power to arrive at the cost of CO2 emissions.

Emission Changes at the plant

-Period 2002 to 2015. The savings (per kilowatt-hour) of reduced CO2 emissions at the facility is based on the cost per ton of emissions permits under a carbon-cap regime and the quantity of emissions generated by a unit of energy (i.e., tons CO2 per kilowatt-hour). Total costs are calculated by multiplying the emissions per unit of energy by the reduction in facility energy generation. These estimates are based on average utilization levels over the period 1998 to 2000, heat rate data for the facility (in kilowatt-hours per Btu), and CO2 content data (U.S. Environmental Protection Agency 1999).

The following sections provide further details on the calculation of CO2 costs.

a. CO2 Costs Due to Emissions Changes at Other Facilities

(1) CO2 Impacts 2002 to 2004

To arrive at a marginal impact value, an average is taken of studies estimating the social impact resulting from climate change, summarized in the IPCC's Climate Change 1995 (Bruce, Lee, and Haites 1996) monograph <FN 29> The report summarizes the marginal impact estimates at different future dates, assuming a "business as usual" policy where no additional regulations are instituted. Marginal impact estimates for years in between those presented are estimated by a linear interpolation of the marginal impact value for the two closest years. Table B-4 presents estimates of the marginal value of additional CO2 emissions used in this study.

(2) CO2 Costs: 2005 to 2015

Estimates of the cost of additional CO2 emissions from 2005 to 2015 are based on an estimate of the marginal cost of reducing CO2. This estimate is based on an analysis of the Kyoto Protocol by the Energy Information Administration (EIA) (U.S. Department of Energy 1998). ETA's analysis assumes that the U.S. achieves some emission reductions through international emissions trading so that the resulting annual domestic emissions are 9 percent above 1990 levels. <FN 30> The analysis also assumes that domestic reductions are achieved through an emissions trading program. <FN 31> Since this policy is the least-cost approach to achieving domestic reductions, estimates of the costs of additional CO2 emissions under these assumptions are conservative.

These additional social costs of CO2 emissions can be estimated by examining the change in electricity price with the assumption that a carbon-cap regime is imposed. Since replacement power for the plant will generate additional CO2 emissions, these increases must be offset by reductions from other facilities, resulting in additional costs. The price change that would occur under the CO2 caps reflects the change in resource costs at the unit providing replacement power (i.e., the marginal unit) to reduce CO2 emissions such that the emissions cap is maintained.

EIA's analysis provides estimates of the average annual electricity prices in the MAAC region under business-as-usual (BAU) conditions and under the implementation of the Kyoto Protocol. <FN 32> The cost of additional CO2 per megawatt-hour is thus the difference in prices between ETA's BAU and Kyoto scenarios. Table B-5 provides annual estimates of the incremental cost per megawatt-hour of additional CO2 abatement measures that would be required to maintain the desired emissions cap based upon ETA analysis.

TABLE B-5. Cost of Additional CO2 Emissions (2000$ / MWh)

[see hard copy for table]

b. Emission Changes at the Plant

(1) CO2 Impacts 2002 to 2007

As with changes emission changes at other facilities, the savings from emission changes at the facility over the period 2002 to 2007 are based on the marginal impacts of additional CO2 emissions Table B-5 presents estimates of the marginal value of additional CO2 emissions used in this study.

(2) CO2 Permit Costs: 2008 to 2015

Prices for CO2 allowances after 2008 are based on the ETA study of the Kyoto Protocol discussed in relation to CO2 costs from other facilities. Allowance prices used in this study are based on the same scenario discussed above (i.e., emissions at 1990 plus 9 percent levels). The permit costs in this case are $44 per ton of CO2 in 2010, and $38 per ton of CO2 in 2020. <FN 33> To calculate values between 2008 and 2021, a linear extrapolation of the 2010 and 2020 values is made. The permit prices used in the analyses are presented in Table B-5.

Footnotes

22 The calculations of energy costs were developed by National Economic Research Associates, Inc. as part of the permit application submitted by PSEG for the Mercer generating facility.

23 These months are the period of peak entrainment at the facility.

24 The calculations of energy costs were developed by National Economic Research Associates, Inc. as part of the permit application submitted by PSEG for the Mercer generating facility.

25 In the event that an LSE does not obtain adequate capacity to meet its obligation, it must pay a penalty set by PJM. That penalty is currently set at $177 per megawatt-day, although the penalty doubles to $354 per megawatt-day when capacity throughout PJM is deficient (i.e., there is inadequate capacity to fulfill the aggregate obligation of all LSEs). In practice, LSEs do not pay penalties, since capacity can be obtained more cheaply through bilateral contracts or wholesale markets.

26 The calculations of energy costs were developed by National Economic Research Associates, Inc. as part of the permit application submitted by PSEG for the Mercer generating facility.

27 In contrast, current allowances may be used in the current year or banked for future use. Ellerman et. al. (1997) discuss reasons for differences between current and vintage prices

28 At the time the original study was completed the US was still considering ratification of the Kyoto Protocol.

29 The values for studies by Cline were not included in the averages, since some of these studies assume zero discount rates. For each study, the mid-point of the range of values is used.

30 See Note 28.

31 The analysis assumes domestic implementation using a CO_2 tax. As EIA points out, however, the analysis and results are equivalent to that for an emissions trading program.

32 The MAAC region includes roughly the same geographic area as PJM.

33 These are converted from values of $129 per ton of carbon in 2010 and $123 per ton of carbon in 2020, using a conversion factor of 3.67 to convert CO_2 to carbon.

EPA Response

The commenter provides a description of a production cost model, GE-MAPS. EPA has reviewed this description. However, since the description does not contain a comment on the Phase II rule, EPA provides no further response. EPA notes that Chapter B3 of the Economic and Benefits Analysis (EBA) in support of the final rule contains a discussion of how EPA selected the IPM for the Phase II analysis (see DCN 6-0002).

The commenter also provides three examples of "assigning dollar values to economic losses at power plants— in the form of lost generation, lost capacity, and increased air emissions." EPA has reviewed these examples. However, since the examples "are designed to demonstrate the method rather than the precise values" and do not contain a comment on the Phase II rule, EPA provides no further response.

Benefit Estimation Methodology

IN-SCOPE FACILITY MAPS AND DESCRIPTION OF LOST ANGLER DAYS DOUBLE COUNTING

EDISON ELECTRIC INSTITUTE

To: Richard Bozek
From: Jeremy Snider
Date: July 25, 2002

Subject: EPA In-Scope Power Plants

The Project Consulting Group (PCG) was tasked to (i) graphically depict the 539 plants listed by EPA as 'in-scope' and (ii) determine the extent of EPA over-counting of lost angler days related to the number of plants within a 120-mile radius of a single county. PCG was able to map 530 of the 539 plants along with their 120-mile radii (or 'buffers'). All but two of these 530 plants had radii that overlapped the radius of at least one other plant.

Using mapping and database software, PCG calculated the degree to which at least 50% of a county's area (as a proxy for at least 50% of its population) was within 120 miles of one or more plants. 2,710 counties in 47 states plus the District of Columbia fell at least 50% within the 120-mile radii of the 530 identified in-scope plants. Of these, just 172 counties fell within only one plant's radius; the remaining 2,538 counties (94% of the total) are counted multiple times. In fact, more than half are counted 11 times or more (as much as 51 times). This means these counties fall within the 120-mile radii of this many plants.

Additionally, PCG was asked to identify the type of water (fresh or salt) the in-scope plants use for cooling. In most cases, specific data was available from plant operators on the cooling system used. In other cases, PCG inferred the water type from the body of water on which the plant was located. Of the 530 in-scope plants, 416 (78%) use fresh water for cooling; the other 114 (22%) use salt water.

The process involved in making these determinations is highly technical and required many steps. A summary of this process follows:

1) Created database file of EPA 'in-scope' plants. In order to be able to map the plants on EPA's list of in-scope facilities, we had to match them to a database of power plants in POWERmap, a mapping software application produced by Platts, a division of the McGraw Hill Companies. To do this, we first exported the entire list of plants from POWERmap into a Microsoft Access database. We then set up a form to facilitate the matching process. Environment's staff assistant, Donna Rutherford, matched a majority of the plants on the EPA list to plants in the database. PCG completed the matching process, finding plants who were not as easily identified. We succeeded in matching 530 of the 539 plants. 4 plants could not be identified. Another 5 are currently unaccounted for. We are cross-checking our work to track down these plants.

2) Created map of EPA plants and identified plants within 120 mile of each other. By linking the selected plants to POWERmap's map data, we were able to create a map of the 530 plants. We then created individual 120-mile radius 'buffers' around each plant. Using a mapping function that detects overlap, we found that all but two buffers directly overlapped another buffer.

3) Determined which county segments fell within plants' 120-mile buffer. To be able to calculate the percentage of a county falling within a plant's buffer, we had to separate each buffer into individual pieces for each county it overlapped. We essentially used the counties layer as a cookie cutter to slice through all of the buffers. In this way, we were able to create a unique combination of plant-buffer and county segment that would allow us to calculate the percentage of a county within a buffer and the number of times a county fell within different plant's buffers.

4) Calculated how many times individual counties were overlapped 50% or more by different plants' 120-mile buffers. To accomplish this, it was necessary to import the new plant-buffer-county segment data into Access. There we compared the area (in square miles) of a county segment associated with a plant (i e , falling within a plant's 120-mile buffer) with the total area of that county to determine the percentage overlap. We selected the county segments that were at least 50% the area of the whole county. As each county segment was associated with a plant, we were also able to count how many different plants' buffers overlapped a county by 50% or more.

5) Prepared report of counties and plants that overlap them (attached). We used the queries above as the basis for a report that shows for each affected county: (i) the in-scope plants, grouped by operator, whose 120-mile radii overlap that county by at least 50%; (ii) the percentage of the county's land area each plant's radius overlaps, and (iii) the number of plants whose radii overlap the county. This last value was considered to equal the extent of over counting.

6) Determined cooling water type for in-scope plants. PCG obtained data concerning the source of water used for cooling (fresh vs. saltwater) primarily from Utility Data Institute (UDI), as reported by plant operators. In some cases (approximately 40% of in-scope plants), data reported by plant operators were not sufficient to ascertain whether freshwater or saltwater is used in cooling. For those plants, the waterbody on which the plant is located was used to infer whether fresh or salt water is used for cooling. For example, plants located on an ocean, ocean harbor, tidal portion of a river, or ocean bay were considered to use saltwater. Plants located on inland harbors, inland rivers, lakes, or reservoirs were considered to use freshwater. This system may not result in 100% accuracy, but we believe it accurately reflects the broad picture.

7) Prepared maps of in-scope plants and affected counties. Two sets of maps were prepared to demonstrate the extent of overlap of multiple plants to counties The first set, "EPA In-Scope Power Plants", depicts the 528 plants whose 120-mile radius buffers overlap the buffer of at least one other in-scope plant. Maps are included for all 528 plants, as well as just those plants using freshwater cooling and those using saltwater cooling. The second set of maps, "Counties Affected by EPA In-Scope Power Plants", depicts for each county how many different plants are within 120 miles of at least 50% of the county's area. This is a graphic representation of the report by the same title. This set also includes individual maps for the counties affected by plants using freshwater cooling and by those using saltwater cooling.

[see hard copt for figures and tables]

EPA Response

In the cost-benefit analysis of the benefits for the final Section 316(b) Phase II rule, EPA no longer uses the angling index to extrapolate benefits. Rather, all benefits are now extrapolated based on average annual operational flow. Please see EPA's response to comment #316bEFR.041.041 for a discussion of issues related to extrapolation of losses and benefits.

EPA agrees that, when looking a 120-mile radius surrounding a plant, most facilities overlap with other facilities. Multiple facilities impinging and entraining aquatic organisms within an ecosystem can have a significantly larger effect on the ecosystem than a single facility. This is especially true with migrating species and other species that move inland and offshore on a seasonal basis, causing them to pass multiple CWIS on their journey. EPA believes that evaluation of I&E should be done at the watershed and regional level as well as on the plant level.

Response to Public Comment

---National Pollutant Discharge Elimination System--- Regulations Addressing Cooling Water Intake Structures for Phase II Existing Facilities

(40 CFR Parts 9, 122, 123, 124, and 125)

Subject Matter Code 3.01

Definition: Existing Facility

Applicability of Rule Needs to be Clarified:

The proposed rule, specifically, 40 CFR 125.91(a) states “This subpart applies to an existing facility, as defined in § 125.93, if it:

(1) Is a point source that uses or proposes to use a cooling water intake structure;

(2) Both generates and transmits electric power, or generates electric power but sells it to another entity for transmission;

(3) Has at least one cooling water intake structure that uses at least 25 percent of the water it withdraws for cooling purposes as specified in paragraph (c) of this section; and

(4) Has a design intake flow of 50 million gallons per day (MGD) or more. Facilities that meet these criteria are referred to as “Phase II existing facilities.”

However, the proposed rule as currently written under 40 CFR 125.91 Subpart J does not exclude existing facilities whose primary business is not power generation. This is not consistent with the language in the preamble to the proposed rule.

Specifically, Section IV of the preamble “Overview of Facility Characteristics (Cooling Water Systems & Intakes) for Industries Potentially Subject to Proposed Rule” states “Today’s rule does not apply to facilities whose primary business activity is not power generation, such as manufacturing facilities that produce electricity by cogeneration” (67 FR 17135).

Additionally, Section III of the preamble “Summary of Data Collection Activities” (67 FR 17131) states “Nonutility facilities are classified under SIC codes 4911 and 493 if the primary purpose of the facility is to generate electricity, and it is these non-utility facilities that are potentially subject to this rule.” EPA specifically states in the preamble the category of facilities that would meet the proposed cooling water intake structure criteria for existing facilities are electric power generation utilities and non-utility power producers (67 FR 17123).

While it is apparent from the preamble language that EPA intends to include only electric power generation utilities and non-utility power producing facilities whose primary business activity is power generation, it is important that the language in the final rule include this clarification. EPA should make clear that 40 CFR Part 125 Subpart J only applies to existing facilities whose primary business activity is power generation. Accordingly, we respectfully suggest adding to the end of 40 CFR 125.91(a)(1) “and power generation is the primary business activity of the facility.”

Definition: Existing Facility

EPA Needs to Define “Generates and Transmits”:

The proposed rule would apply to an existing facility that both “generates and transmits” electric power. However, EPA has not defined “generates and transmits” which is an explicit requirement of the applicability of 40 CFR 125.91 to an existing facility. In the absence of a definition of “generates and transmits”, it is unclear whether a facility that generates electrical power for internal use only would be considered an “existing facility” as defined in 40 CFR 125.93. EPA needs to define “generates and transmits” in the final regulation.

EPA Response

EPA has not defined “generates and transmits” in the final rule. The Agency does not believe that defining such common terms is necessary to ensure the scope of the rule is clear, especially in view of the clarifications EPA has included in the final rule. See response to 316bEFR050.002.

Option: Site-specific based 1977 Draft Guidance

Nearly 30 years of national and international research on cooling water intake structure (CWIS) impacts and fish protection technologies has demonstrated that impacts and technology effectiveness are a site-specific issue. EPA's 1977 draft guidance reflects this knowledge. Improvements to both the site-specific assessment process (as noted herein) and fish protection technologies since publication of that guidance help make that process much more effective. A structured site-specific approach, using EPA's own Ecological Risk Assessment process would allow for efficient determination of impacts and installation of effective fish protection technologies where those impacts are determined to be adverse.

EPA Response

EPA disagrees. Please refer to the preamble for a discussion of the framework of today's rule. Also refer to the preamble to the final rule for information as to why EPA is promulgating today's final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

RFC: Definition of "adverse environmental impact"

We continue to recommend defining "adverse environmental impact" (AEI). EPRI supports the definition -- adverse environmental impact is a reduction in one or more representative indicator species (RIS) that (1) creates an unacceptable risk to a population's ability to sustain itself, to support reasonably anticipated commercial or recreational harvests, or to perform its normal ecological function and (2) is attributable to operation of the cooling water intake structure. This definition embodies both scientific and social considerations.

EPA Response

Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define "adverse environmental impact" in today's final rule.

Comment ID 316bEFR.074.003

Author Name Doug Dixon

Organization EPRI (Electric Power Research Inst)

Subject Matter Code 6.0

Environmental Impacts

Nearly 30 years of historical data and analysis indicate that AEI attributable to CWIS are extremely limited or not occurring. New analyses funded by EPRI further indicate that water withdrawal impacts are insignificant relative to other environmental factors and that there is no direct relationship between water withdrawal and ecosystem health. Unlike in the 1970s when data and analyses were limited and aversion to risk was scientifically and socially justifiable, the data base and knowledge that exist today afford EPA the opportunity to avoid a stance of total aversion to any risk (or unnecessarily embracing the "precautionary approach").

EPA Response

EPA agrees that most facility-sponsored studies in the past 30 years have not shown a significant impact to fish populations that can be directly attributable to a specific cooling water intake structure. However, EPA does not believe that the facilities are causing zero impact to fish populations and the results of the studies point more to the fact it is extremely difficult to prove undeniably that the cooling water intake structure is at fault; indeed it may be impossible unless a facility commences or significantly changes operation and the nearby populations instantly crash in response. Many anthropogenic activities work concurrently on the environment. It is extremely difficult to separate the effects of any one factor. A facility will always be able to blame another factor and claim that it is not the real source of the problem. In addition, changes in the populations may be masked by the considerable natural variation in the size of fish populations. The intention of section 316(b) of the Clean Water Act is to minimize the adverse environmental impact specifically of cooling water intake structures and does not seek to eliminate stress on fisheries due to other factors such as habitat alteration, dredging, coastal development, overfishing, industrial pollution, nutrient pollution, wastewater runoff and climate change. There are a number of different stresses acting on the nation's fisheries at any one time. Section 316(b) is an important tool to reduce one stressor recognized by Congress: the continued killing of billions of fish yearly by cooling water intake structures. This rule will complement fishery management plans and water quality improvements that aim to reduce stress on the nation's fisheries.

Benefit Estimation Methodology

EPA's biological, engineering, and economic analyses that support the proposed rule have numerous conceptual and implementation flaws that result in grossly overestimating fish losses at CWIS and the potential economic benefits that may accrue from their protection. Drs. Lawrence Barnthouse (Appendix A) and Elgin Perry (Appendix B) both note the conceptual and parameter errors in estimating fish losses on a case study and national basis and, more importantly, note how the multiplicity of conservative parameter choices result in highly inflated fish losses due to impingement and entrainment. Dr. Ivar Strand (Professor Emeritus, Fisheries Economics, University of Maryland – Appendix C), further notes how EPA's economic analyses are flawed and inconsistent with EPA's own guidelines for performing economic benefits assessments. Dr. Strand makes several substantive recommendations that would improve the economics benefits analysis.

EPA Response

EPA disagrees with the assertion that EPA's I&E analysis is flawed. For responses to comments of Dr. Elgin Perry and Dr. Lawrence Barnthouse, please see EPA's responses to comment #316bEFR.029.105 regarding the age of impingement, Comment #316bEFR.306.092 regarding the detection of ecological impacts, Comment #316bEFR.074.101 regarding EPA's calculation of production foregone, Comment #316bEFR.074.042 regarding multiple conservatisms, Comment #316bEFR.005.009 regarding fish population modeling, and Comment #316bEFR.025.015 regarding compensation.

EPA disagrees that its analysis is inconsistent with the principles outlined in the EPA's Guidelines for Preparing Economic Analyses, United States EPA (EPA 240-R-00-003, DCN# 6-1931). For EPA's responses to comments on specific analyses please see the following comments.

For EPA's response to comments on the commercial fishery method, please see the response to comment # 316bEFR.323.016. For EPA responses to comments on the recreational fishery methods, please see comments # 316bEFR.041.452, 316bEFR306.320, and 316bEFR337.010.

For the final 316b rule analysis, EPA has not included quantitative measures of nonuse values due to unavoidable uncertainty in monetizing non-use values. The Agency, however, did explore several alternative non-use valuation methods to appreciate the potential magnitude of non-use values for the final rule, including meta-analysis and the benefit transfer method. For detail see Chapters A12, C6, D6, and G6 of the final Phase II Regional Studies Document (DCN # 6-0003).

Subject Matter Code 7.02
Performance standards

While we agree that high fish protection can be attained for some species and life stages with many of the technologies reviewed by EPA, we do believe that EPA has generally over-estimated or over-stated the long-term fish protection that can be attained in the performance standard ranges that are proposed for reducing impingement mortality and entrainment. The database of information from which EPA derives the proposed “standards” is a research database and not a database resulting from long-term compliance assessment. Field research was generally conducted under short-term optimal operational and environmental conditions. The data, therefore, does not represent long-term performance following routine operation & maintenance and exposure of the technology to the extremes of environmental conditions. Furthermore, the data does not demonstrate that standards can be achieved for all species and life stages. Other site-specific issues, as subsequently noted, may also impair performance during certain time periods. We, therefore, recommend caution in adoption of “performance standard ranges” based on the research database. Unlike “end of pipe” technologies that are not subject to performance confounding environmental elements, “front of pipe” technologies are heavily influence by them. EPA may wish to alternatively consider performance “targets” as a fish protection objective.

EPA Response

EPA has selected performance standards to facilitate a more streamlined approach to the permitting process and to provide a more consistent mitigation target on a national level. However, facilities can comply with the requirements of today's rule in a variety of ways. EPA thus maintains a desired flexibility in the implementation of the rule, thus allowing a facility to select measures that are appropriate to the site conditions and facility configuration.

Additional documentation has been collected and reviewed by EPA to further augment support for the performance standards and added to the Technology Efficacy database. This database, originally designed to act as a centralized bibliography of data EPA has reviewed during the course of the development of the final Phase II rule, has been expanded to allow users to query and compare basic data on technology performance and applicability. EPA recognizes that some may disagree with basing the performance standards on the wide range of data available in the database. While many documents do show some level of success in reducing impingement mortality or entrainment, other studies have shown the deployed technology to be unsuccessful or at best inconclusive. EPA did not view the varying degrees of success with regard to a specific technology as problematic, but rather as evidence that some technologies work in some applications but not in others.

Comment ID 316bEFR.074.006

Organization EPRI (Electric Power Research Inst)

Subject Matter Code 7.02

Performance standards

EPRI recommends that EPA consider accommodating for episodic events in the impingement and entrainment "targets" that may preclude a technology's ability to provide fish protection. Such episodic events include corn shuck loading in the central U.S., seasonal (and episodic) leaf and other debris loading, fish that are moribund or dead-on-arrival because of weather-related phenomena (e.g., winter fish kills or kills associated with sudden decreases in dissolved oxygen), and other site- and water body-specific episodic biological and physical phenomena. EPA may also wish to consider precluding the application of the standards to nuisance species whose ecosystem removal is a preferred aquatic resource management approach.

EPA Response

RFC: Proposed use of restoration measures

Research is increasingly demonstrating that aquatic community health and fish productivity is related to habitat quality and that aquatic habitat loss and alteration is one of the major factors responsible for fish population declines. More importantly, ecosystem research is finding that habitat loss and alteration may ultimately prove to be more deleterious to stock restoration efforts than over exploitation. Increasingly, resource management agencies are adopting management strategies designed to protect and restore critical aquatic habitat. EPRI strongly supports EPA's proposal to allow habitat restoration as an approach to mitigate for I&E losses. EPRI recently completed an interim report that provides an assessment of the state-of-science on restoration and habitat enhancement strategies for mitigating the impacts of I&E. This report is included in this comment package. The report concludes that restoration science is rapidly evolving, restoration projects are increasingly demonstrating success, and, most importantly, while projects can directly mitigate for I&E losses they also provide long-term ancillary environmental benefits. Unlike with CWIS fish protection hardware where population benefits are highly uncertain, fish population and other environmental benefits will result from effectively designed environmental enhancement and restoration projects.

EPA Response

EPA believes restoration science continues to progress, though uncertainties still remain. EPA believes the requirements in the final rule will help to reduce restoration measure uncertainty.

For a discussion of ancillary benefits from restoration measures, see EPA's response to comment 316bEFR.032.011.

EPA does not believe the uncertainty of the existence of population level effects from restoration measures will necessarily be significantly lower than that from the use of cooling water intake structure fish protection hardware. In some cases, EPA believes it can be higher because of the uncertainties associated with the design, implementation, and assessment of restoration measures. For a discussion of these uncertainties, see EPA's response to comment 316bEFR.206.055.

Proposed standards for Great Lakes

While estuaries, tidal rivers and coastal oceans are “unique” in the numbers of fish and invertebrates that are impinged and entrained and support key habitat for the maintenance of recreational and commercial fish, such a “unique” system does not exist for the Great Lakes. The Great Lakes uniqueness derives from international and national public policy and public concern over the drastic ecological changes that have occurred in the basin since colonization of North America. These changes mostly result from the deliberate and accidental introduction of non-native fish and invertebrates and mid-20th century commercial harvesting that was not sustainable. Our preliminary analysis indicates that the Great Lakes, unlike estuaries ant tidal rivers, are not productive systems, are generally depauperate of species, and those highly desirable species that they do support, their early life stages are not particularly vulnerable to power plant entrainment. The Great Lakes, in fact, are more like reservoirs than estuaries and tidal rivers. Prescriptive entrainment [mortality] reduction standards for the Great Lakes, therefore, do not appear necessary or justified by EPA’s own waterbody sensitivity criteria. Alternatively, it is highly unlikely that population-level benefits will accrue from entrainment protection in relation to other more pervasive stresses and impacts that are occurring in the Great Lakes system. We hope to further investigate this issue and provide more supportive technical documentation as part of our comments to the EPA NODA expected this fall.

RFC: Entrainment vs. entrainment mortality

EPA's determination that CWIS entrainment survival is 0% (based on its analysis of EPRI's 2000 Entrainment Survival Report) is scientifically untenable. Even EPA's re-calculations of entrainment survival in several of the study examples presented in Chapter A7 of the Case Study Methodology demonstrate that entrainment survival, while lower, still does occur. Entrainment survival monitoring methods have significantly advanced since the early 1970s and results collected since the late 1970s are valid. If EPA moves forward in their final rules with an impingement mortality reduction standard, EPRI recommends that entrainment mortality reduction should be similarly identified (not simply entrainment reduction).

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards.

Proposed standards for lakes and reservoirs

Reservoirs are highly managed artificial systems and prescriptive impingement mortality reduction standards are very difficult to scientifically support – in fact, analyses that we have recently funded and reported on herein (see Appendix E) indicate that cooling water reservoirs often support fish populations that are as healthy as, or more healthy than, non-cooling reservoirs. If there are any systems that EPA should consider evaluating or regulating on a site-specific basis, reservoirs are such systems. Scientific data indicates the reservoir impingement mortality reduction may only be appropriate when it is in the interest of fisheries management.

EPA Response

Please refer to the response to comment 316bEFR.041.551 for a discussion of the biology of reservoirs.

Author Name Doug Dixon

Organization EPRI (Electric Power Research Inst)

Subject Matter Code 19.0

Dry Cooling

EPRI supports EPA's conclusion that dry cooling is not a CWIS technology. It is also a technology that is not well suited for retrofit on existing power generating units. The lowest attainable steam condensing temperature at a plant using dry cooling must always exceed the ambient dry bulb temperature, even in new construction where direct systems using air-cooled condensers would be the technology of choice. In retrofit situations, where indirect systems with an intermediate, circulating water loop operating between the existing steam condenser and an air-cooled heat exchanger could be used, the attainable condensing temperature will be even higher. This inevitably results in additional thermal penalties to the cycle, further increased heat rate, emissions and operating costs.

EPA Response

The Agency agrees with the conclusion of the comment, as pertains to statements about the use of indirect dry cooling and its relative infeasibility for application in retrofit situations. The Agency still considers dry cooling to be an inappropriate technology for the basis of the final rule. See response to comment id 316bEFR.022.002.

Comment ID 316bEFR.074.012

Organization EPRI (Electric Power Research Inst)

Subject Matter Code 17.03.02

RFC: EPA rationale to not require closed-cycle

EPRI has completed a study of estimates and information available on the costs and impacts associated with the retrofit of recirculated wet cooling systems in place of once through cooling at existing stations (Appendix D). In light of our comments regarding the determination of AEI at existing stations, it seems prudent that any decision to require such capital expense and operating penalties would come only after careful site-specific evaluation of AEI and other alternative mitigation options and potential benefits. The study also found that EPA's estimates for these costs were comparable to the "easier" retrofit situations from studies and data collected. It is our conclusion that the cost to put in towers in many stations would be significantly higher due to site-specific issues.

EPA Response

The Agency determined that retrofitting cooling towers was not an acceptable basis for the final regulatory requirements, in part, based on the costs and uncertainties of the technology. Should the commenter's assertions indeed prove true (i.e., that EPA's estimates of cooling tower costs are underestimated), then this would only serve to reinforce and further support the Agency's decision not to utilize cooling towers as a basis for the final rule.

Subject Matter Code 12.02

RFC: Monitoring frequencies

EPRI recommends that EPA re-consider the need for prescriptive baseline monitoring and instead provide flexibility in the design and timing of such studies in accordance with the mitigation option pursued and the information needed to assess fish protection performance. EPRI has identified a number of factors that either preclude the need for baseline monitoring, make baseline monitoring extremely difficult or provide information of limited utility. These factors or issues include: (1) for some fish protection technologies (e.g., fine mesh traveling screens with fish return systems, aquatic fabric barriers) that are pursued, survival can be directly monitored or density differences in intake and discharge simultaneously monitored thereby precluding the need for a pre-baseline study; (2) shoreline monitoring for baseline characterization must take into consideration the fact that it may not capture the type and density of organisms due to the absence of a CWIS and the hydraulic environment it creates; and (3) extensive natural variability in estuarine and coastal areas because of fluctuating abiotic (weather) and biotic factors may make it more difficult (spatially and temporally) to develop the requisite precision in fish community characteristics (presence and relative abundance) for baseline characterization.

EPA Response

EPA believes that it has taken measures to streamline the baseline monitoring requirements, including allowing the use of historical data and/or data from other facilities if it is demonstrated to be reflective of the current conditions at the facility's intake structure (see § 125.95(b)(1)(ii); § 125.95(b)(2)(i); and § 125.95(b)(3)(iii)). Also see EPA's response to comment 316bEFR.034.005 for a discussion of the many streamlining efficiencies added to reduce burden in today's final rule.

Option: Site-specific determination of BTA

Finally, included in our comment package is the recently completed EPRI report - Evaluating the Effects of Power Plant Operations on Aquatic Communities: An Ecological Risk Assessment Framework for Clean Water Act § 316(b) Determinations. This report specifically describes how EPA's own Ecological Risk Assessment (ERA) approach can be used as a framework for performing site-specific 316(b) assessments. EPRI formally requests peer review of this report by the EPA Cooling Water Task Force – we also request that the Task Force forward the report to the EPA staff or team responsible for developing EPA's ERA approach for their peer-review as well.

EPA Response

EPA has considered the contents of the submittal in crafting the final rule, but does not believe it is appropriate to participate in a peer-review.

EPA does, however, note that the rule does not require a determination of whether an adverse environmental impact is occurring is a preliminary step in implementing 316(b). Please refer to the response to comment 316BEFR.313.001 for more information on EPA's position on minimum impacts at existing facilities.

Option: Site-specific determination of BTA

The one area, however, where the site-specific assessment process had limitations is that no standard framework for performing the assessments had ever been developed and applied. To address this limitation, EPRI has evaluated EPA's own Ecological Risk Assessment (ERA) process (EPA 1998) and has determined that the process offers an excellent conceptual framework for performing 316(b) assessments and determining BTA as required. Furthermore, EPRI has specifically developed or adapted the framework for performing 316(b) assessments. The results of EPRI's analysis are contained in the report – Evaluating the Effects of Power Plant Operations on Aquatic Communities: An Ecological Risk Assessment Framework for Clean Water Act § 316(b) Determinations (EPRI 2002a). Three copies of this report are appended to this comment letter. The following material is directly from the introductory chapter of this report:

Why Use ERA in 316B Assessments?

USEPA defines ecological risk assessment as "….a process that evaluates the likelihood that adverse ecological effects may occur or are occurring as a result of exposure to one or more stressors" (USEPA 1992). Since entrainment and impingement results in the exposure of aquatic organisms to physical and chemical stresses, it seems that a logical approach to assessing the risk of adverse environmental impact of cooling water withdrawals would be through the use of an ecological risk assessment framework, such as that provided by USEPA. Further, USEPA acknowledges using ERA concepts when developing the interpretation of AEI in the New Facilities Rule for §316(b) (Comment 316bNFR.040.004, USEPA 2002). Finally, since the USEPA ERA Guidelines "…set forth current scientific thinking and approaches for conducting and evaluating ecological risk assessments" (USEPA 1998), the approach described in the Guidelines should be a sound starting point for adapting ERA to the assessment of adverse environmental impact under §316(b).

In fact, the USEPA's ERA guidelines have much in common with technical approaches recently used for site-specific assessments of the potential for AEI under §316(b) (PGE 1998; PSEG 1999; Barnthouse et al. 2002). Common features include a tiered approach, differentiation between ecological effects and the adversity of those effects, inclusion of both prospective <FN 2> and retrospective assessments, and use of multiple lines of evidence (weight-of-evidence). In addition to the decision-making advantages listed above, the USEPA's ERA approach is fully scalable allowing assessment of the potential for AEI at all levels of complexity, ranging from the relatively straightforward qualitative evaluation (e.g., check sheets) to the most complex and controversial cases involving state-of-the-art quantitative modeling; all under the same assessment framework. In addition, incorporation of an initial screening within the problem formulation phase will ensure that CWISs with little potential for AEI can by-pass much of the assessment process and be rapidly and easily permitted. On the other hand, CWISs with a higher potential for AEI would be thoroughly evaluated using a logical and technically sound assessment process. For all of these reasons, we believe that use of an approach based on USEPA (1998) would bring consistency across §316(b) assessments (as well as across assessments of risk from a variety of other man-induced stressors) with a flexible, efficient, technically sound and widely accepted approach.

In addition to the use of ERA to assess AEI, USEPA's two-step environmental decision-making process (i.e., risk assessment/risk management) is identical to the two-step process traditionally used for site-specific determinations under §316(b) (AEI assessment/BTA determination). Consequently, it also appears logical to address the entire §316(b) under USEPA's risk assessment/risk management approach. Such an approach would be useful regardless of whether the determination follows the traditional two-step process or focuses solely on selecting among management alternatives to reduce aquatic organism loss. Following this approach, the assessment of potential ecological risk becomes one of several factors that must be considered in making a BTA (i.e., risk management) decision. Other factors receiving consideration in determining which is the most appropriate intake alternative for minimizing any adverse environmental impacts include economics, technology, collateral environmental consequences, and social aspects.

Detailed information on application of ERA to 316(b) determinations in contained in the report included herein. EPRI formally requests peer review of this report by the EPA Cooling Water Task Force – we also request that the Task Force forward the report to the EPA staff or team responsible for developing EPA's ERA approach for their peer-review as well.

In addition to completing the previous report, EPRI has also recently completed an additional report that provides guidance on the selection of a 316(b)-assessment method (EPRI 2002).   In 1999, EPRI prepared a catalog of the various methods and models for estimating fish losses and impacts on aquatic populations and communities due CWIS impingement and entrainment (EPRI 1999). That report, however, did not provide guidance on the selection of an appropriate assessment approach. Our new report provides such guidance. This report concludes that there are a wide variety of technically sound methods available to address potential cooling water withdrawal effects at various levels of complexity and sophistication. The most appropriate methods will vary from site to site; there is no one set of methods applicable to all plants and source waterbody types. Risk assessors (using the ERA framework) can plan their analysis to incorporate a logical progression of methods, beginning with relatively simple methods, and only proceeding onto more complex and costly methods when necessary to adequately address risk. In general, the most sophisticated methods should be limited to the few situations where determination of CWIS impacts on populations has been complex. Specific report recommendations are that the assessment should: (1) include all relevant information as part of multiple lines of evidence and base conclusions on the weight of evidence; (2) be carefully designed to explicitly address assessment endpoints and assessment measures most appropriate for the specific source waterbody and potentially affected populations and communities; (3) be conducted in a phased manner to ensure that available resources are targeted at the most important issues; (4) include both prospective and retrospective methods to the extent practical and appropriate to the context of the assessment; and (5) explicitly address uncertainty in estimating effects, preferably through quantitative means. The report discusses each of these specific recommendations in detail. Three copies of this report (EPRI 2002b) are included in this comment package. This report compliments our 1999 catalog of methods (EPRI 1999a), our adaptation of the EPA ERA framework for 316(b) assessments (EPRI 2002a), our technical update and review of fish protection technologies (EPRI 1999b), and our procedural guidelines for selecting BTA alternatives (EPRI 2000).

Footnotes

2 This report uses the term "prospective" as used in the ERA guidelines to describe methods that estimate expected effects. In other ecological risk assessment and impact assessment literature, the term "predictive" has often been used in an equivalent sense.

UWAG definition of "adverse environmental impact"

Need for Definition of AEI

EPRI has previously commented on the need to define the term "Adverse Environmental Impact" (AEI) and our support and encouragement for developing such a definition continues. Without such as definition, that which is being minimized is unclear or that which is being minimized for lack of definition (i.e., fish mortality due to impingement and entrainment) is a policy determination – one that is not consistent with other human endeavors (e.g., construction, transportation, agriculture, forestry and other resource development) that, while resulting in loss of aquatic and terrestrial life, are environmentally sustainable and socially acceptable. EPRI's scientific efforts have focused on developing tools and information to manage and support the sustainability of populations and communities. Individual members of any given population do not persist through time and cannot be sustained. Therefore, except for endangered and threatened species, where losses of individuals have been predetermined to have the potential for population level impact, the individual or individual losses are not appropriate endpoints for an AEI definition.

Our supported definition has recognized that it must encompass both scientific and social elements. Toward this end, EPRI has worked with the Utility Water Act Group (UWAG) and our members to develop a potential definition; i.e., -- adverse environmental impact is a reduction in one or more representative indicator species (RIS) that (1) creates an unacceptable risk to a population's ability to sustain itself, to support reasonably anticipated commercial or recreational harvests, or to perform its normal ecological function and (2) is attributable to operation of the cooling water intake structure.

EPA Response

Please see the response to comment 316bEFR.002.019 for the discussion on the definitions EPA rejected for adverse environmental impact in this rulemaking.

RFC: Definition of "adverse environmental impact"

In August of 2000, in association with the Annual Meeting of the American Fisheries Society, EPRI sponsored the symposium Defining and Assessing Adverse Environmental Impact Under Clean Water Act §316(b). At that time, 20 papers were orally presented – of that total, 17 papers have now been finalized according to professional peer-review comments. These papers include:

-Maryland power plant cooling-water intake regulations and their application in evaluation of adverse environmental impact. McLean, R., W. A. Richkus, S. P. Schreiner, and D. Fluke. Pages 1-11.

-Scientific and societal considerations in selecting assessment endpoints for environmental decision making. Strange, E. M., J. Lipton, D. Beltman, and B. D. Synder. Pages 12-20.

-Adverse environmental impact: 30-year search for a definition. Mayhew, D. A., P. H. Muessig, and L. D. Jensen. Pages 21-29.

-Uncertainty and conservatism in assessing environmental impact under §316(b): lessons from the Hudson River Case. Young, J. R., and W. P. Dey. Pages 30-40.

-A holistic look at minimizing adverse environmental impact under Section 316(b) of the Clean Water Act. Veil, J. A., M. G. Puder, D. J. Littleton, and N. Johnson. Pages 41-57.

-Modeling possible cooling-water intake system impacts on Ohio River Fish Populations. Perry, E., G. Seegert, J. Vondruska, T. Lohner, and R. Lewis. Pages 58-80.

-A process for evaluating adverse environmental impact by cooling-water system entrainment at a California power plant. Ehrler, C. P., J. R. Steinbeck, E. A. Laman, J. B. Hedgepeth, J. R. Skalski, and D. L. Mayer. Pages 81-105.

-Comparing Clean Water Act Section 316(b) policy options. Kadvany, J. Pages 106-138.

-Using attainment of the designated aquatic life use to determine adverse environmental impact. Seegert, G. Pages 139-146.

-Defining "adverse environmental impact" and making §316(b) decisions: a fisheries management approach. Bailey, D. E., and K. A. N. Bulleit. Pages 147-168.

-Indicators of AEI applied to the Delaware Estuary. Barnthouse, L. W., D. G. Heimbuch, V. C. Anthony, R. W. Hilborn, and R. A. Myers. Pages 169-189.

-Adverse environmental impact: a consultant's perspective. Wells, A. W., and T. L. Englert. Pages 190-203.

-Proposed methods and endpoints for defining and assessing adverse environmental impact (AEI) on fish communities/populations in Tennessee River reservoirs. Hickman, G. D., and M. L. Brown. Pages 204-218.

-Minimizing adverse environmental impact: how murky the waters? Super, R. W., and D. K. Gordon. Pages 219-237.

-Measurement error affects risk estimates for recruitment to the Hudson River stock of striped bass. Dunning, D. J., Q. E. Ross, S. B. Munch, and L. R. Ginzburg. Pages 238-253.

-Use of equivalent loss models under Section 316(b) of the Clean Water Act. Dey, W. Pages 254-270.

-A blueprint for the problem formulation phase of EPA-type ecological risk assessments for 316(b) determinations. Van Winkle, W., W. P. Dey, S. M. Jinks, M. S. Bevelhimer, and C. C. Coutant. Pages 271-298.

All of the above papers are included in this filing. Except for the paper by Super and Gordon of the Riverkeeper Organization who offer an alternative interpretation of the requirements of 316(b), all the papers note the scientific and societal considerations for defining adversity, and most explicitly offer an aquatic population or community-based definition, or they recommend the development of one.

EPA Response

EPA acknowledges receipt and has reviewed the papers mentioned. Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define "adverse environmental impact" in today's final rule.

RFC: Definition of "adverse environmental impact"

Relative to our recommendation for the need for a definition of AEI, we would also like to note that the EPA ERA framework allows for, or can accommodate, alternate definitions of increasing complexity. Using the ERA framework, the level of assessment complexity would be driven by the potential for adversity, allowing for an efficient use of available assessment and mitigation resources. Section 5 of the EPRI report discusses adversity indicators in more detail; however, basic types of risk description of increasing complexity include:

-Qualitative analysis of representative species (RS)(or "species of concern") susceptibility and vulnerability to entrainment and impingement;

-Quantitative comparison of the estimates of losses to indicators of the capacity of RS populations to sustain such losses;

-Interpretation of the significance of changes in population abundance projected using population models; and

-Evaluation of the status or health of RS populations and fish and macroinvertebrate communities in the waterbody. This may include an evaluation of multi-year trends in abundance, diversity, and species composition, and the strength of evidence for causal links between any observed declines and CWIS operation, where such data are available.

Examples of the indicators that would typically be used in §316(b) assessments to characterize the risks to assessment endpoints using the various measures of effect are shown in Table 5-1 of the EPRI ERA report.

EPA Response

Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define "adverse environmental impact" in today's final rule. For these reasons, EPA has also elected not to adopt the ecological risk assessment framework for section 316(b) determinations in the NPDES permitting program.

Overview of I & E effects on organisms

New Water Withdrawal Impact Information

EPRI is currently funding the Oak Ridge National Laboratory to investigate the relationship between water withdrawal (cooling, irrigation, public supply, hydropower) and the health of fish populations and communities in the water body from which it is withdrawn. As of the preparation of these comments, the report had not completed the standard professional peer review that we require for reports from our program. However, since there is key information relative to the impacts of CWIS and the EPA 316(b) rule-making effort, we feel that it is important that the data and findings from the analyses become part of the public record. Key chapters from the final DRAFT report are included in Appendix E. The complete finalized report will be submitted to EPA as soon as it is available.

The essential question investigated in this effort is whether the numbers of fish that are intercepted and diverted by an artificial water intake, and the magnitude of damages that are incurred by fish populations in the water body, are proportionate to the volume of water withdrawn (or alternatively, whether other environmental or biological factors predominate). The study thus tested the hypothesis of a dose-response model relating volume of water withdrawn (as the “dose”) to the status of fish populations (the “response”). A corollary question is whether there is some lower threshold of water intake volume in relation to water body volume below which the numbers of fish involved are inconsequential for survival of fish populations (consistent with a threshold dose-response model). We analyzed many types of withdrawals from water storage reservoirs as well as CWIS in order to have a wider range of withdrawal volumes for identifying a possible dose-response pattern (note: the aquatic environment does not discern between withdrawal use patterns).

The ORNL project team approached the analyses in six parts: (1) provision of background information on CWIS and discussions of a dose-response model approach, a hierarchical framework to view potential biological impacts, and the definition of adverse environmental impacts; (2) characterization of the withdrawal of surface waters throughout the United States from perspectives of geographic distribution and use type; (3) original data analyses to determine if there is a relationship between the amount of water withdrawn from reservoir systems (via normal reservoir discharge and/or CWIS withdrawal) and various measures of a fish population or community health; (4) analysis of the potential impacts of low-volume water withdrawal; (5) summarization of previous studies that provide insight into the relationship between intake volume and population-level effects; and (6) summarization of the importance of other factors that contribute to the risk of environmental impact of CWIS, such as location of intake, temporal effects, species characteristics, water body type, and cumulative effects of other sources of mortality.

The reviews and analyses did not find a compelling dose-response relationship between volume of water withdrawn and status of fish populations, although especially high volumes of reservoir discharges have affected certain susceptible fish species (volumes that exceed those of CWIS). For most withdrawal volumes there was no correlation with fish populations. The research concluded the following:

-The analysis performed with data for Texas, Tennessee Valley Authority, and reservoirs included in the National Reservoir Research Program were not able to identify conclusive evidence for a relationship between population- or community-level effects and rate of water withdrawal, either as a direct measure (i.e., mean annual discharge) or as a function of water body volume (i.e., residence time). A few significant relationships were found (see Tables 3-4 and 3-6 in Appendix E), but even some of those (e.g., mean annual discharge versus total fish biomass in the Texas reservoirs) were counter to the expectation of a negative effect on fish populations as discharge (or withdrawal) increased. Withdrawal rates investigated range from 1 to 5,200 MGD. There was a possible relationship for Texas hydropower reservoirs when water body volume was considered. Systems with residence times less than 25-50 days (i.e., withdrawal rates of 2-4%) suggest some response. However, cooling reservoirs in Texas with low residence times (< 8 days) often supported abundant fish populations.

-Reservoirs used for cooling are likely to have more productive fish populations than reservoirs not used for cooling, regardless of the volume of water withdrawal. This finding is based on analyses of reservoirs used for cooling in Texas and on comparative studies of cooling reservoirs in Illinois conducted by EPRI in the mid-1980s. In a direct comparison of fish community health in Illinois, the cooling reservoir was shown to maintain a highly productive fish community in spite of (or perhaps because of) power plant cooling. There was ample abundance of fish food organisms for maintaining a highly productive sports fishery. Entrainment and impingement, while not measured but certainly occurring, was of minor importance for the dynamics of fish populations when compared to other reservoirs.

-A 1996 U.S. Nuclear Regulatory Commission study (to support relicensing of U.S. nuclear power plants) demonstrates the subjective opinions of resource agencies that entrainment and impingement are problems at large nuclear power stations. The hard, quantitative evidence for such concerns is lacking in most cases. No general relationship between volume of water withdrawn and effects on fish populations could be shown (i.e., no general dose-response relationship). The NRC report concludes that site-specific analyses are essential because it was site-specific circumstances (often unique) that caused the episodic occurrence of high levels of fish losses.

-There does not seem to be a dose-response pattern between volume of water withdrawn and effects on fish populations. Where long time series of data on the factors affecting fish productivity along with data on fish population dynamics are available, volumetric flow relationships have not ranked high as determining factors.

-There is a hierarchy of effects of water withdrawal that must be understood when adversity is to be judged: relationships between plant size and water withdrawal --> numbers (or biomass) of organisms entrained or impinged --> number (biomass) killed --> proportion of organisms in the waterbody affected --> population effects at the species level --> community effects at the multi-species level.

-Overall Case Study Analysis Conclusion (See Appendix E-2): Case studies provide strong empirical evidence that large water withdrawals do not imply large effects on fish populations. The Hudson River power plants have withdrawn over 6,400 MGD for over 25 years (4,200 of that in a sensitive segment for entrainable fish); yet extensive monitoring has shown little impact. When change has occurred to some populations it is in conflict with power-plant-related mechanisms and likely has other causes. The Nuclear Regulatory Commission found little empirical evidence for actual damage from entrainment and impingement in its review of five nuclear plants with withdrawal rates ranging between 486 and 2,785 MGD. Despite this information, it found that natural resource agencies subjectively considered entrainment and impingement to be a problem. It therefore recommended including case-by-case analyses in its nuclear plant relicensing actions. Studies by TVA of Wheeler Reservoir (Browns Ferry Nuclear Plant) showed no significant changes in fish populations beyond the normal increases and decreases in a small percentage of species. Dutch studies found that whereas cooling-water flow rate and numbers entrained or impinged varied proportionately in most plants, the effect on fish populations was the reverse—populations were in better shape with power plant cooling because of the combined effects of thermal (stimulatory) and intake effects. Intake type and water body type dominated over cooling-water volumes in determining numbers of organisms entrained and impinged. The Dutch researchers stressed viewing the cooling system effects in totality and on a case-by-case basis. A detailed study of the fisheries of a reservoir used for cooling in Illinois (691 MGD) and reference reservoirs showed that the combined effect of heating and water circulation in the cooling lake did not yield fish populations greatly different from those in reservoirs not used for cooling. The available studies in the literature provide a poor scientific basis in empirical data for regulating power plant intake systems on the basis of the volume of cooling-water use.

Site-specific analyses, undertaken with knowledge of the potential effects of water withdrawal, remain essential for predicting or monitoring fish population effects of water intakes. Site-specific details of the environment and specific fish populations appear to predominate over a simple dose-response model in determining whether populations are affected by specific water withdrawal rates. Details on all the analyses performed are presented in Appendix E. EPRI anticipates completing the peer-review and revising the report before the end of the 2002.

Subject Matter Code 11.0
Role of Restoration

Restoration/Enhancement as a I&E Mitigation Approach

Research is increasingly demonstrating that aquatic community health and fish productivity is related to habitat quality and that aquatic habitat loss and alteration is one of the major factors responsible for fish population declines. As Langton et al. (1996) note, habitat loss and alteration may ultimately prove to be more deleterious to stock restoration efforts than over exploitation. Increasingly, resource management agencies are adopting management strategies designed to protect and restore critical aquatic habitat (Langton et al. 1996; Minns 1997; Fluharty 2000; Saunders et al. 2002). EPRI strongly supports EPA's proposal to allow restoration as an approach to mitigate for I&E losses.

EPRI has initiated research on the state-of-science and feasibility of using restoration or environmental enhancement as an approach for mitigating CWIS impacts. Research is being performed for EPRI by Argonne National Laboratory. We have now completed our interim report Enhancement Strategies for Mitigating Potential Operational Impacts of Cooling Water Intake Structures (EPRI Report 1005337, July 2002) and copies are included in this filing. This interim report describes environmental enhancement or restoration approaches that may be applicable for mitigating impingement and entrainment impacts associated with CWISs. These approaches are described with respect to their underlying objectives, implementation and operational requirements, costs, current use by government and the private sector, and advantages and limitations for potentially mitigating CWIS operational impacts.

Environmental enhancement and trading strategies were evaluated against a variety of technical, ecological, regulatory, and operational parameters, including technological status, ability to target CWIS impacts, and the current level-of-use and state-of-the-science. A variety of sources were used to collect information for evaluation in this report, including scientific journals; technical publications; conference and workshop proceedings; government, non-governmental organizations (NGO), and private sector publications and websites; and personal communications with technical and regulatory experts. The project team did not comparatively evaluate the various enhancement and trading approaches, but rather addressed each on its own merits.

Enhancement approaches fell into two general categories: 1) those that directly address fish numbers; and 2) those that address habitat. Stocking addresses fish numbers, and may mitigate CWIS impacts by replacing fish directly affected by impingement or entrainment. Habitat enhancement approaches may mitigate impacts by providing more or better quality habitat to support fish reproduction, growth and survival. These approaches include restoration of fish passage, creation or restoration of wetlands and submerged aquatic vegetation beds, and creation of artificial habitats such as reefs. These enhancement approaches are widely used by a variety of government agencies and NGOs to successfully manage, restore, and/or protect fisheries resources in marine and freshwater environments. Trading approaches could include: 1) fish-for-fish trading that allows a cooling water user that provides greater CWIS impact reductions than required by its permit to trade those excess reductions to a second cooling water user; and 2) pollutants-for-fish trading that allows a cooling water user to have relaxed CWIS impact limits in its permit in exchange for reducing the load of key pollutants. Each enhancement and trading approach has its own set of design, implementation, operation, and cost requirements and constraints, as well as unique regulatory implications. These factors are discussed in detail in the EPRI report.

EPA Response

As described in sections 125.94 and 125.95 of the final rule, facilities may apply to the Director to use restoration measures to comply with the performance requirements of the final rule.

Under the final rule, state permitting agencies may develop trading programs. For additional discussion of trading programs, see the preamble to the final rule.

Cooling system costs (e.g., dry, wet, recirculating)

Cost of Retrofitting Cooling Towers

The recently completed EPRI report Cooling System Retrofit Cost Analysis (July 2002) is included in its entirety in Appendix D. This study provides estimates and analyses of the costs of retrofitting electric power generating plants, designed for and operating on once-through cooling systems, with recirculated cooling systems using mechanical draft cooling towers. A brief discussion of the environmental impacts of recirculated cooling in comparison to those of once-through cooling is also included.

The approach to the analysis of the retrofit costs involved:

1. The gathering of data from utility sources of cost estimates made for retrofits at individual plants

2. A review and analysis of cost estimating methodologies by the Environmental Protection agency, Stone & Webster Engineering Company, the Washington Group and the National Energy Technology Laboratory, and

3. A comparison of the results of the several estimates with the individual plant data.

The conclusions of the analysis were:

1. Retrofit costs are highly variable from plant to plant. The results of this study support EPA's assertion that the costs to retrofit recirculated cooling will vary dramatically from site to site. As described in Chapter 3, the retrofit costs at each of the plants for which we have detailed data were dominated by site-specific adjustments rather than by simple scale factors based on size or flow rate.

2. This variability cannot be well accounted for by correlating factors such as $/kW or $/gpm of circulating water flow normally found to be satisfactory for new plant cost correlations

3. Differences in individual plant costs cannot be accounted for by differences in plant type (fossil vs. nuclear) or by cooling water source type (fresh, brackish, saline)

4. The variability is the result of site-specific factors associated with difficulties particularly related to the fact that retrofits present special constraints to on-site construction projects

5. Plant retrofits can be roughly assigned a "degree of difficulty classification" as "easy', "average" or "difficult" retrofits.

i. The costs for the easiest of the projects (lower bound of the individual plant data) are roughly consistent with the costs estimated for cooling system construction at new facilities and fall in the range of $125/gpm.

ii. The average difficulty projects costs cluster around $200/gpm +/- 20%

iii. The more difficult projects range from $250 to $300/gpm with a few ranging as high as $700 to $900/gpm

6. Significant costs, in addition to the initial capital costs, result from cooling system retrofits including

i. Additional requirements for operating power in the range of 1 to 1.5% of plant capacity

ii. Additional maintenance costs, primarily associated with water treatment requirements in the range of 1 to 3% of system capital costs annually.

iii. Additional fuel costs resulting from efficiency reductions imposed on the plant by the inherent limitations of recirculated cooling systems in the range of 1% on an annual average basis.

EPA Response

Author Name Doug Dixon
Organization EPRI (Electric Power Research Inst)

Subject Matter Code 6.08
Non-aquatic impacts

Recirculated cooling, while reducing water withdrawals for natural waterbodies relative to once-through cooling, has environmental impacts associated with evaporation losses, discharge of blowdown, discharge and disposal of waste water and solid waste, emissions of drift, visible plumes, additional air emissions from increased fuel consumption and noise, that are not present with once-through systems.

EPA Response

The Agency determined that retrofitting cooling towers was not an acceptable basis for the final regulatory requirements, in part, based on the uncertainties of the technology.

Impingement and Entrainment Assessments

EPA's proposed rule notes protection for "all species and their life stages". Protecting and assessing the protection of individuals of "all species and their life stages" is impossible. To attain such a goal, one would need to monitor forever and spend infinite time in a laboratory identifying species. While we believe that this is not the intent of EPA's proposal, we recommend clarification to avoid future confusion. In keeping with EPRI's recommendation that the process should be driven by a level of adversity that a population may be experiencing, a subset of species of concern, or representative species (RS), or representative indicator species (RIS) should be selected for evaluating a technology's performance. This subset of organisms should be representative of species (and their key life stages) that are of recreational and commercial importance or have been otherwise identified by the permitting authority as species of concern. In many locations, particularly where impingement and entrainment is predominantly driven one species, protection of "total" number of organisms may be the preferred approach.

EPA Response

For an explanation of EPA's monitoring requirements, please refer to the preamble to today's final rule and EPA's response to comment 316bEFR.307.027. For a discussion of how compliance is to be determined, please see EPA's responses to comments 316bEFR.017.003 and 316bEFR.063.005. Also please see the final rule preamble for a discussion of the Technology Installation and Operation Plan.

EPRI also recommends that EPA provide provisions for exclusion of nuisance species from protection requirements. Nuisance species <FN 3> being determined on a site-specific basis in accordance with fishery management goals

Footnotes

3 “Nuisance” species differ from exotic or non-native species because the latter, though non-native, may be desirable in the system such as salmon in the Great Lakes. Sometimes nuisance species can also be native such as the northern pikeminnow in the Columbia River basin where bounties exist for deliberate reduction in their population size to reduce predation on out-migrating juvenile salmon.

Proposed standards for tidal rivers and estuaries

EPA stratifies the rule according to water body type noting that (page 17140):

“Because different waterbody types have different potential for adverse environmental impact, the requirements proposed to minimize adverse environmental impact would vary by waterbody type. For example, estuaries and tidal rivers have a higher potential for adverse environmental impact because they contain essential habitat and nursery areas for the vast majority of commercial and recreational important species of shell and finfish, including many species that are subject to intensive fishing pressures. Therefore, these areas require as higher level of control that includes both impingement and entrainment controls. Organisms entrained may include small species of fish and immature life stages (eggs and larvae) of many species that lack sufficient mobility to move away from the area of the intake structure. The reproductive strategies of many estuarine species include pelagic or planktonic larvae, which are very susceptible to entrainment.”

(Page 17141):

“Therefore, EPA is proposing to vary technology-based performance requirements by waterbody type, requiring more effective controls in waterbodies with higher overall productivity or greater sensitivity to impingement and entrainment.”

“EPA believes that the Great Lakes are a unique system that should be protected to a greater extent than other lakes and reservoirs. The Agency is therefore proposing to specify entrainment controls as well as impingement controls for the Great Lakes.”

We concur with EPA that fish and shellfish in estuaries and tidal rivers have a higher level of CWIS impingement and entrainment. This is because, as noted by EPA, organisms in these waterbodies have evolved a life history strategy that involves the production of large numbers of eggs and larvae to insure survival (Winemiller and Rose 1992, 1993). Dramatic as the impingement and entrainment numbers are for estuarine and tidal river plants, the numbers must be viewed against the extremely high numbers of eggs produced. While impingement and entrainment numbers are high, it does not imply that adverse impact or sensitivity is similarly high.

We similarly concur with EPA that estuaries and tidal rivers support habitat for commercially and recreationally important fish. However, not all habitat is equal in quality, therefore, potential adverse impact is a site-specific issue. EPRI recently completed a project that evaluates the state-of-science relative to assessing the quality of spawning and nursery habitat and, therefore, the potential for adverse environmental impact from impingement and entrainment processes (EPRI 2002c). This report principally concludes that federal and state resource agencies have the requisite knowledge on the quality of spawning and nursery habitat to support site-specific impact assessments. Furthermore, the report notes that in its absence, methods are available for documenting habitat quality and inferring the potential for AEI.

While we understand EPA’s logic (and concur with many parts of it) relative to entrainment control in estuaries and tidal rivers, we do not understand how that logic leads to similarly identifying the Great Lakes as waterbodies requiring similar protection. Yes, the Great Lakes are unique relative to hydrology, morphology, community evolution, and public and private concern; however, they are not unique in terms of productivity and vulnerability as compared to estuaries and tidal rivers. Yes, there is tremendous public and private concern and yes, the Great Lakes have drastically changed over the past century. This change overwhelmingly is the result of accidental and deliberate introduction of exotic species (Ragotzkie 1983; Fabrizio et al. 2000; Kitchell et al. 2000). We believe the "uniqueness" of the system results more from the public and scientific community concern over what some have coined as an "invasional meltdown" (Ricciardi 2001) rather than to sensitivity to entrainment as EPA postulates for estuaries and tidal rivers.

In relation to estuaries, tidal rivers, and reservoirs, the Great Lakes are not particularly productive and support a limited number of species. Scott and Crossman (1973) note that the Great Lakes are depauperate in species largely as a result of the "recent" retreat of Pleistocene ice. Furthermore, they note that the Atlantic Region of Canada, which encompasses all of the Great Lakes, the St. Lawrence River and all other waters in the Lakes and River drainage basin have a total freshwater fish fauna of only 142 species. This in comparison to the State of Ohio which has approximately 170 species.

Comprehensive comparison studies of primary productivity across various terrestrial and aquatic systems are generally limited. Dodds (2001) analyses which incorporated analyses of Oglesby (1977), however, notes that lakes and streams (including the Great Lakes) are an order of magnitude lower in primary productivity compared to estuaries, coral reefs, and freshwater wetlands. The open ocean (excluding coastal areas) was the only general ecosystem that had lower primary production than lakes and streams. Downing et al. (1990) assembled estimates of the biological production of entire lake fish communities covering a wide range of geographic areas and trophic status around the world. He then plotted fish production against primary production and found a strong linear relationship. The four lowest points in his relationship came from fisheries yield data from Lakes Superior, Huron, Michigan and Ontario. He did note that these low values may result from the collection of productivity data during the 1970s when the fishery was over-exploited (but naturally supported fisheries have not recovered since) or impacted by invasive species.

Downing et al. (1990) and Downing and Plante (1993) further reported that the productivity of entire fish communities was well correlated with the primary productivity of the ecosystem in which they live. Specifically, they noted that fish population production is strongly correlated with algal production and total phosphorous concentration, both an indicator of trophic status. Recent analyses by Ludsin et al. (2001) for Lake Erie using fish population data from 1969-1996 found similar results. In their completely natural or unimpaired state, the Great Lakes are oligotrophic and the upper Great Lakes (Superior and Huron) remain so today. The lower Great Lakes, particularly Erie and Ontario, because of anthropogenic impacts, are eutrophic; however, due to phosphorous abatement programs and the invasion of zebra mussels, both are rapidly returning to oligotrophic conditions (Ludsin et al. 2001).

Areas of the Great Lakes that do support higher levels of production can be found at the mouths of tributaries to the Lakes. In fact, there has been a recent call for delineating such locations as estuaries (Herdendorf 1990; Dyer 1990; Odum 1990; Schubel and Pritchard 1990). EPA discussed this issue during development of Phase I 316(b) regulation. EPRI subsequently commented that EPA miss-understood the content of the discussion in that the high productivity did not apply to the Great Lakes in general, only to areas where there is a mixing of water masses, such as at the mouths of tributaries. High productivity in these areas is not unusual. Willis and Magnuson (2000) found similar high species composition among four site types (lake, lake-mouth, stream-mouth, and stream). Comparison of species richness, rarefaction species diversity, and species density all supported the same pattern: stream-mouth sites contained the highest number of species, followed by stream sites, lake-mouth sites, and lake sites, even though lake and lake-mouth sites yielded more individuals and were larger in area and volume.

The Great Lakes fish community that existed during the 1970s when most of the 316(b) demonstrations (and extremely high impingement episodes) occurred (Michaud 2000), no longer exists. As previously noted, the system has been buffeted by inadvertent invasions of marine species followed by large-scale experimental introduction of several species of Pacific and Atlantic salmon plus several nonnative species of trout. Alewife invaded the upper Great Lakes during the 1960s and rapidly or explosively proliferated and their annual natural winter die-off created intolerable nuisance conditions along the shores. It also created severe clogging problems for CWIS. The presence of alewife in the Lakes also led to the high impingement numbers recorded in the historical literature (Michaud 2000). Salmon, in fact, were originally introduced into the lakes to control the alewife population (Ragotzkie 1983). The introduction of salmon was a huge success, both as control for the alewife population and as a multi-million dollar sport fishery. The fish community is now drastically different and continues to change because of the zebra mussel invasion (Frabrizio et al. 2000; Kitchell et al. 2000). In fact, the full extent of the zebra mussel infestation is yet to be realized; increased water clarity is dramatic -- this increased clarity is due to reduction in zooplankton and phytoplankton by the filtering action of the mussels. This reduction will likely lead to further reduction in overall productivity of the Lakes, at least in respect to fish communities. The Great Lakes are tremendous visible features on our landscape and considerable national and international attention and energy has been focused on resolution of its problems -- this focus and energy, however, should not necessarily be miss-interpreted that the Lakes are highly productive requiring an increased level of fish protection equivalent to that proposed for estuaries and tidal rivers.

Collectivity, these results suggest that the Great Lakes do not have the same level of uniqueness that EPA discusses for estuaries and tidal rivers and, therefore, are not as likely to experience AEI (or no more likely to experience AEI than low-volume river intakes and intakes on reservoirs). EPRI, however, will further investigate this issue and submit final comments on the issue as part of our response to the expected EPA NODA.

EPA Response

With respect to the standards for tidal rivers and estuaries, please refer to the response to comment 316bEFR.025.014.

With respect to the standards for the Great Lakes, please refer to the response to comment 316bEFR.025.013.

Performance standards

Can the Proposed Performance Standards be Achieved?

EPRI and our expert consultant, Alden Research Laboratory (Alden), have reviewed EPA's analysis of fish protection technologies – data principally provided by EPRI/Alden in our 1999 technology update report (EPRI 1999b). In general, EPA has accurately characterized impingement technology reduction performance. However, while impingement mortality can generally be reduced by 80-95%, there will be some site specific conditions at many plants that may preclude attaining this performance standard range. Also as important, the ability of the technologies to provide average protection within the performance range (i.e., compliance) over some performance measurement period (e.g., months, one-year, two-years, permit period) is not well documented – most performance studies have been conducted over short-periods of time – that is, technology performance has never been evaluated against a performance standard. Relative to EPA's proposed entrainment reduction standard of between 60-90%, we believe that EPA may be over-stating expected performance – the current data base on entrainment reduction is to limited to comfortably conclude that the proposed performance range can be attained. Finally, relative to both performance standards, EPA does not consider or discuss how natural phenomena (i.e., physical and biological debris loading) outside the control of a CWIS operator, can completely preclude or impede a technology's selection and performance.

Subject Matter Code 7.02

Performance standards

A key point relative to the performance of fish protection technologies that EPA must consider when establishing performance standards is that the database of performance findings is inherently biased in the high performance direction. This is because the database results from site-specific assessments and BTA alternative considerations that have been followed since the mid-1970s. Essentially, engineering assessments of a limited number of pre-determined feasible technologies (i.e., generally following the procedural guidelines documented in the EPRI 2000a report) resulted in the selection of a technology with reasonably high fish protection performance expectations. Subsequent research or compliance monitoring later confirmed the high performance that was anticipated. These are the results noted in the literature and the EPRI (1999a) report (i.e., the system and process precluded selection of poor performing technologies) Because of this bias, it may be inappropriate to conclude that high performances recorded can be standardized for the industry.

EPA Response

EPA reviewed many technologies in developing the performance standards for today's rule but, as discussed by the commenter, focused primarily on those technologies that could reasonable be deployed at a wide range of facilities. The data presented in Chapter 3 of the Technology Development Document, and discussed elsewhere in today's rule, show that the performance standards are technologically and economically feasible for the majority of Phase II existing facilities. EPA does not believe it is warranted to discuss poor-performing or ineffective technologies within the scope of today's rule and somehow "average" their performance in with other, more successful technologies when developing performance standards.

EPA also recognizes that exceptional performance of a technology may not be able to be duplicated at every other facility. Today's rule adopts ranges for both the impingement mortality and entrainment reduction in recognition of the inherent variability of aquatic environments and facility configurations.

Performance standards

The following are additional comments on analyses – in general, we do note that EPA has not provided adequate scientific support in the rule record for the impingement and entrainment reduction standards. However, it appears that the standard(s) are achievable for at least some selected species and lifestages. For improving impingement survival, EPA focuses on modified Ristroph screens and associated fish handling features. For entrainment, EPA reviews in detail three technologies: (1) wedge wire screens; (2) aquatic filter barriers; and (3) fine mesh screens. The ability of these technologies to meet the performance standard is discussed below. Also discussed in this section are EPRI/Alden's comments on the EPA Technical Development Document.

Accounting for Natural Phenomena

EPA's proposed rule is relatively silent on issues associated with natural phenomena that may preclude a technology's selection or a technology's performance and ultimately how a technology's "compliance" is evaluated. Unlike with "end-of-pipe" technologies that are not subject to the vagaries of nature and whose performance can be somewhat effectively controlled, CWIS fish protection technologies are "front-of-pipe" and fully subject to the forces and vagaries of nature. The forces and events may preclude selecting a technology or impeded the performance of a specific technology during some period of the year or during some type of event. For example, during the mid-west corn harvesting period, river transport of heavy loads of corn shucks frequently can cause fine (and coarse) mesh screen collapse. Similarly, biological (e.g., large woody debris and leaves) and physical (e.g., sediment) debris in stormwater runoff can preclude the performance (and substantially damage) of a technology. Estuaries and coastal locations around the U.S. frequently experience periods of ctenophore, jellyfish, and SAV (e.g., hydrilla, kelp, eelgrass) loading. Natural die-off of forage species in rivers, lakes (including Great Lakes) and reservoirs is also common during winter periods (Loar et al. 1978) or periods of low-dissolved oxygen. The hydraulic forces of a CWIS will cause these "dead-on-arrival" (DOAs) or "moribund-on-arrival" (MOAs) fish to collect and clog intakes and preclude the fish protection performance of a technology. These MOAs and DOAs should not be counted against a technology's performance, nor should a technology be expected to perform at some pre-determined or expected level when such loading occurs.

EPA Response

EPA has decided to give the Director the authority to determine methods of evaluating compliance. Thus, the Director will specify species and life stages of concern. The Director may choose to require evaluation of all species or of certain indicator species; or the Director may elect to verify compliance using biomass as a metric. EPA believes that as each situation will be somewhat unique, it should be left to the Director to determine whether biomass or actual numbers are a more appropriate unit. The Director may also authorize a facility to demonstrate compliance using a Technology Installation and Operation Plan.

EPA has determined that a uniform averaging period would not be appropriate; rather, the Director will be best suited to make all such determinations by evaluating these and other factors for each facility on a case-by-case basis. The Director will be able to make determinations regarding averaging periods based upon site-specific factors, such as biological assemblage at the site, annual and diel fluctuations in concentration and populations present, and the selected compliance alternative.

Impingement Mortality Reduction - Modified Ristroph Screens

Ristroph screens have been shown to improve fish survival and have been installed at some power plants. Improvements have been made to the Ristroph screen design through extensive laboratory and field experimentation that have resulted in greatly increased fish survival rates. The most recent biological evaluation of this design was conducted at the Salem Generating Station on Delaware Bay in New Jersey. A series of impingement survival studies has been conducted in recent years to provide estimates of impingement survival rates. White perch impingement survival rate estimates ranged from 98 percent in December to 93 percent in April. Estimates for weakfish ranged from 88 percent in September to 18 percent in July. For bay anchovy, survival estimates ranged from 72 percent in November to 20 percent in July. Atlantic croaker survival estimates ranged from 98 percent in November to 58 percent in April. The estimated survival for spot was 93 percent in November (November was the only month in which a significant number of spot were collected). Alosa species combined produced survival estimates that ranged from 82 percent in April to 78 percent in November.

The Salem screens represent the current state-of-the-art in reducing impingement mortality. It is clear that survival is species-specific and can vary within species on a seasonal basis. It can also be expected that site-specific factors will influence survival potential. All of the other modified traveling screens that have been evaluated for impingement mortality have not incorporated the improved design features that exist at Salem. Therefore, the database needed to predict actual reductions on a site-by-site basis does not currently exist. However, the high survival rates observed at Salem, even for fragile species such as bay anchovy and Alosa spp., indicate the potential for improving survival at other sites. Since the baseline for the proposed rule is a shoreline intake with no fish protection provisions, the baseline mortality can be assumed to be 100 percent. As such, the 80-95 percent reduction in impingement mortality appears to be achievable for at least some species.

EPA Response

EPA appreciates the additional information submitted by the commenter and notes that additional information for the Salem facility has been included in a revised Chapter 3 of the Technology Development Document. EPA agrees with the commenter that fish handling and return systems like those deployed at Salem and other facilities demonstrate a wide applicability to many facilities in different circumstances. Although not universally deployable, fish handling and return systems are some of the most successful and studied impingement control technologies.

Performance standards

Entrainment Reduction

A reduction in entrainment, potentially in the 60 – 90 percent range proposed by EPA, may be achieved for some species by all three of the technologies that EPA presents in support of their proposed performance standard. The operative words are "potentially", "may", and "some species" because the database for measuring performance is still extremely limited. It is not clear that simply reducing entrainment will provide a biological benefit unless the technology also does not result in substantial mortality of organisms. In anticipation that EPA may change the standard to address entrainment mortality, the following discussion addresses both entrainment and mortality.

EPA Response

Today's rule preserves the standard of a 60-90 percent reduction in entrainment, not entrainment mortality. EPA agrees that data regarding entrainment reduction technologies are more limited than for other technologies, but believes that performance is justified. See also response to comment 316bEFR.067.003.

Comment ID 316bEFR.074.032

Organization EPRI (Electric Power Research Inst)

Subject Matter Code 7.03

Available I&E technologies

Wedge Wire Screens

Wedge wire screens can incorporate slot sizes as small as 0.5 mm. Therefore, they are capable of reducing entrainment of most eggs and larvae. While large-scale applications of wedge wire screens have not been evaluated biologically, these installations and other laboratory and field studies indicate that this technology not only is practicable to install and maintain in a variety of waterbody types, but also has a high potential for protecting entrainable organisms without substantial injury. Open questions that need to be addressed include:

-What is the optimal screen slot size and slot velocity needed to achieve maximum exclusion without impingement?

-What is the optimal cross-flow or approach velocity needed to achieve maximum exclusion without impingement?

-Can biofouling be controlled in marine and brackish water environments?

The first question is currently being address in laboratory studies sponsored by EPRI and EPA. These results, coupled with future field studies, should fill in many data gaps. The second question will need to be addressed by conducting studies in marine and brackish water environments. Developing the full potential for wedge wire screens should lead to its eventual acceptance as a technology for reducing entrainment of many species/life stages in a variety of waterbody types. Where suitable physical, hydraulic and environmental conditions exist, it is likely that this technology can offer a high level of fish protection; however, whether protection will average in the 60-90 percent range proposed by EPA will need to be determined following long-term monitoring.

EPA Response

EPA agrees with the commenter that wedgewire screens show great potential in reducing impingement and entrainment of eggs and larvae that otherwise might be susceptible to these impacts. Further study by EPRI or other organizations is welcome.

Sample facilities/technologies

Aquatic Filter Barrier

While the AFB has only been evaluated in detail at one river location (Lovett Station on the Hudson River), results of multi-year evaluations at this full-scale installation indicate that this technology has the potential for minimizing entrainment of early organism life stages and eliminating impingement. When the boom integrity was maintained at Lovett, it was highly effective in preventing organism passage. The airburst system for removing sediment and algae appears to be reasonably effective. Some improvements are needed to further automate the system. One manufacturer (Gunderboom, Inc.) is in the process of deploying booms at other sites across the U.S. and further refinement of this technology can be expected in the near future. Open questions that need to be addressed include:

-Does organism interaction with the AFB result in entrainment, injury, or mortality?

-Can a reliable anchoring system be developed that prevents failures and gaps from occurring?

-Will the boom be maintainable in other water body types?

As with wedge wire screens, these questions will be answered by current and future evaluations of the AFB in the laboratory (ongoing EPRI studies) and at other sites. Assuming that these engineering issues can be resolved, the AFB offers the potential to greatly reduce entrainment at CWIS possibly within the range (60 - 90 percent) proposed by EPA as a standard.

EPA Response

EPA agrees that the aquatic filter barrier is a promising technology that has demonstrated significant reductions in both entrainment and impingement when integrity of the system is maintained. EPA encourages the use of new and innovative technologies to address adverse impacts associated with cooling water intake structures and welcomes continued study and evaluation of these technologies.

Organization EPRI (Electric Power Research Inst)

Subject Matter Code 7.03

Available I&E technologies

Fine Mesh Screens

The available laboratory and field data indicate that fine mesh traveling screens have the potential not only to meet the entrainment reduction performance standard but to achieve survival levels with early fish and invertebrate life stages that may reach levels of 60 percent or higher.

This potential is best illustrated with the available laboratory data that has been collected under controlled conditions. In field studies, little attempt has yet been made to determine the factors that most influence survival and to identify whether changes in design or operation (particularly screen travel speed) can improve survival. Clearly, some species/life stages such as bay anchovy larvae are fragile and may not survive to the 60 percent level following collection with fine mesh screens. However, for many species, the potential to obtain high survival rates under conditions existing at CWIS is evident. With further development and evaluation of fine mesh screens, it would appear that survival rates of 60 percent or higher may be achievable for many species.

EPA Response

EPA appreciates the data and notes the success of fine mesh screens in meeting the performance standards with regard to entrainment reductions. For further discussion of fine mesh screens, see Chapter 3 of the Technology Development Document.

Performance standards

Technology Evaluation Summary

The available literature generally supports the concept that modified Ristroph screens (coarse mesh), physical barriers and some behavioral technologies may have the potential to reduce impingement mortality for some species (but not all) by 80 – 95 percent and that wedge wire screens, the AFB and fine mesh screens may have the potential to reduce entrainment by 60 – 90 percent from the baseline. As physical barriers to passage, all of these technologies should be effective in meeting the entrainment reduction standard provided that they can be designed at a given site to screen the earliest life stages. While none of the technologies has been developed or studied to the degree necessary to draw conclusions regarding wide-spread applicability at CWISs, they have all been studied under sufficiently stringent conditions with a wide variety of species to support their inclusion as technologies that generally support EPA's proposed performance standards. If EPA changes the entrainment performance standard to address entrainment mortality, it would appear that these technologies have the potential to protect many species/life stages, possibly to the 60 – 90 percent level.

EPA Response

Comment supports the rule. No response necessary.

Performance standards

In summary, while we believe high fish protection performance can be attained with impingement and entrainment mortality reduction technologies, (1) the ability of a technology to average out within the performance standard range proposed by EPA is not well documented and (2) performance measurement must account for natural factors, outside the control of CWIS operators, that will reduce performance.

EPA Response

TDD related comments

Review of Technical Development Document (TDD)

EPRI/Alden has also reviewed Chapter 3 and attachments of EPA's Technical Development Document for the proposed rule. The purpose of this review was to determine whether EPA's performance standard (80-95 percent reduction in impingement mortality and 60-90 percent reduction in entrainment) is further supported by the information presented.

The data, as presented by EPA, generally does support their proposal to use a uniform national technology standard. However, many generalizations and statements are supported by the selective use of available data and generally overstate the potential for individual power plant operators to meet a uniform standard on a site-specific basis, as we have also noted above. With few exceptions, EPA's effectiveness estimates combine data across species, life stages, environmental, and operational conditions. While not incorrect, this unscientific approach masks any site-, species-, and life stage-specific variability in the data.

In the case of modified (Ristroph) traveling screens, EPA used only a small number of the total available installations for which survival data exists. It is unclear what criteria were used by USEPA to determine which data to include in their analysis. Eliminated from consideration were data collected from Roseton, Danskammer, Oyster Creek, Oswego, Bowline, Belle River, Dunkirk and Mystic. EPA acknowledged limitations in the scope of their data collection efforts and their reliance on such sources as EPRI's Fish Protection at Cooling Water Intakes, Status Report (1999) and ASCE's Design of Water Intake Structures for Fish Protection (1982). EPA notes that "EPRI's analysis was primarily a literature collection and review effort and was not intended to be an exhaustive compilation and analysis of all data," and yet EPA chose to look at only a fraction of the data contained therein.

EPA focuses on fine-mesh screens, wedge wire screens, and ABS, since they hold potential to fulfill the entrainment reduction performance standard proposed. Other technologies are either downplayed or ignored entirely, e.g., high velocity screens (such as Eicher screens or Modular Inclined Screens [MIS]), strobe light, air bubble curtains, or hybrid systems that utilize combinations of behavioral technologies. EPA states in Section 3.4 that "the Agency has focused on technologies that have shown significant promise at the laboratory, pilot-scale, and/or full-scale levels in consistently minimizing impingement and/or entrainment." Without explicitly endorsing one technology over another, EPA has implied that certain technologies would be unable to achieve performance standards for any species under any condition. In Alden's opinion, several of the omitted technologies could be used alone or in combination for the protection of certain species and life stages. In the case of the MIS, laboratory and pilot-scale studies indicate that high latent survival rates can be achieve with a wide range of species.

In conclusion, the information presented in the TDD loosely supports the proposed performance standard. However, the selective use of data is considered unscientific. A review of all available data indicates the ability of any given technology will vary by environmental factors (such as water body type, debris loading, etc.) and the species and lifestages to be protected.

EPA Response

EPA believes these technologies are available and practicable for the category of existing facilities as a whole. EPA recognizes, however, that this will not be the case for some individual facilities. EPA has codified a site-specific compliance alternative to account for these situations. In addition, EPA has authorized compliance to be demonstrated pursuant to a Technology Installation and Operation Plan in order to account for the fact that biological variability and other factors may interfere with the consistent achievement of the national performance standards even when the model technologies are installed and properly operated.

Submittal of required information

Baseline Characterization and Compliance Monitoring

EPRI has reviewed EPA's proposed baseline characterization and technology performance monitoring requirements. Conceptually, both are relatively straightforward; however, they may not be practical or always necessary as proposed because of site-specific issues as well as demonstrated historical performance of the technology. Because of the following issues, EPA may wish to provide permitters and permittees maximum flexibility in determining the necessity, type and scope of baseline and performance monitoring. Key issues for consideration include:

-Variability: extreme variability on numerous spatial and temporal (annual, decadal, centuries) scales is well known and documented in fisheries science, particularly in estuarine areas (Sissenwine 1984). It may be impossible to capture this variability in short-term field monitoring.

-Performance Can Be Directly Measured without Baseline: for some technologies, performance can be directly measured without the need for a baseline characterization. For example, impingement survival can be directly measured in a fish return system following improvements (Ristroph screens, collection buckets, spray and return troughs) to traveling screens. Similarly, if an aquatic fabric barrier system is implemented, fish densities outside and inside (or in the discharge channel) the fabric barrier can be directly measured to assess performance. No doubt, with careful experimental design and analysis for other technologies, sampling designs that will permit directly assessing fish protection performance of a technology can be identified.

-Other Factors: the ability to use the shoreline baseline configuration to assess credit for historical fish protection work is a commendable ideal. There will be, however, factors that may preclude collection of realistic baseline data if the CWIS had been located on a shoreline. For example, the Seabrook Power Station is located onshore in an estuarine marsh environment while the CWIS is offshore with a velocity cap that withdraws water from a deep location in the ocean. The habitat in these two locations is very different and supports very different species assemblages. Only minimal sampling has been conducted near the shoreline to define the populations of fish and invertebrates that exist there. In the absence of such data, it will not be possible to estimate the level of I&E that might have occurred if the intake had been located near shore in the marsh area. To acquire such data would require lengthy field sampling over a prolonged period (years). More importantly, the CWIS creates hydraulic forces and processes that can attract fish to an intake structure. The absence of the hydraulic forces (and the physical structures that support the CWIS which will also attract fish) may preclude the collection of information on fish presence had the structure been present on the shoreline.

EPA further suggests that the baseline "could be estimated by evaluating existing data from a facility nearby without impingement and/or entrainment control technology (if relevant) or by evaluating the abundance of organisms in the source waterbody in the vicinity of the intake structure that may be susceptible to impingement and/or entrainment." This approach is not considered scientifically defensible. Many biological, engineering, and hydrologic/hydraulic factors (zone of influence) determine whether an organism will interact with a CWIS and whether or not the organism will survive that interaction. Assessing the mere presence or absence of organisms at a nearby facility or in the same waterbody does not give an accurate picture of the potential for I&E at a non-existing baseline CWIS. The composition and abundance of I&E organisms can be very different for two CWIS situated close to one another. For example, observations of shad impingement at the Marshall Steam Station showed high variability in the numbers impinged between adjacent screens despite similarities in flow and velocity (Loar et al. 1978). EPA's approach, while commendable in its ideal, fails to capture the site-specific nature of I&E at CWIS.

For these reasons, we recommend maximum flexibility in the necessity and design of baseline characterization. Most importantly, we recommend elimination of the prescriptive baseline characterization requirement, unless it is in the interest of the permittee to demonstrate existing performance and can be done so in a scientifically defensible manner.

EPA Response

Please see response to comment 316bEFR.034.013 for a discussion on calculation baseline.

Today's final rule requires that monitoring be conducted in accordance with the verification monitoring plan (125.95(b)(7), the Technology Installation and Operation Plan (125.95(b)(4)(ii)), if selected, and, if applicable, the Restoration Plan required at 125.95(b)(5). The Director may consider additional monitoring requirements as well. Specific study parameters may be proposed by the applicant for review and approval by the Director.

RFC: Entrainment vs. entrainment mortality

Author Name Doug Dixon

Organization EPRI (Electric Power Research Inst)

Entrainment Survival Review

EPRI has reviewed, from a scientific and risk management point of view, EPA's decision to base the proposed §316(b) performance standard on entrainment, rather than entrainment survival. Detailed comments resulting from review of sections VI.A.7 and VI.A.8.b of the proposed rule and the support document on entrainment survival, Ch A7, are provided in Appendix F. Comments of Dr. Charles Coutant of Oak Ridge National Laboratory on the general issue of entrainment survival are also provided below. The major findings and recommendations resulting from EPRI's review include:

-The proposed rule's exclusion of entrainment survival from the BTA performance standard is scientifically flawed;

-The proposed rule's exclusion of entrainment survival from the BTA performance standard can be ecologically unprotective and would not provide comparability in quantifying resource impacts among facilities and waterbodies;

-To provide a solid scientific and resource management foundation for BTA determination, the performance standard should be based on realistic estimates of entrainment losses (i.e., entrainment mortality) and be linked to protection of higher biological levels of organization.

-EPA's evaluation does not reflect consideration of the evolution of entrainment survival study methods—methods have matured and later methods do allow for valid estimates of entrainment survival with appropriate levels of precision.

-EPA's assumption of 100% entrainment mortality is not supported by the overwhelming evidence of substantial entrainment survival of many species that has been found in studies conducted to date, and is not justified by the concerns USEPA presented in Ch A7.

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards. Please see response to comment 316bEFR.002.015 regarding the inclusion of entrainment survival estimates in site-specific benefit analysis. Please see the response to comment 316bEFR.306.506 for the discussion regarding EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule.

RFC: Entrainment vs. entrainment mortality

Independent of the proposed EPA rule, Dr. Charles Coutant of Oak Ridge National Laboratory provided the following general entrainment survival comments to EPRI in an email dated February 21, 2002:

I have been fortunate in my career to have been listened to quite a bit. But one thing that I harped on 30 years ago was nearly completely ignored: mortality during entrainment is NOT 100 percent (when biocides are not purposely being applied for biofilm control) and we can take steps to provide predictability (Coutant, C. C. 1971. Effects on organisms of entrainment in cooling water: steps toward predictability. Nuclear Safety 12(6): 600-607). A large share of the mortality for most entrained organisms, when it occurs, is due to elevated temperature not the mechanical stresses of going through condenser tubes and pumps (Kedl, R. J., and C. C. Coutant. 1976. Survival of juvenile fishes receiving thermal and mechanical stresses in a simulated power-plant condenser. Pages 394-400 in G. W. Esch and R. W. McFarlane, editors. Thermal Ecology II. ERDA Symposium Series CONF-750425. National Technical Information Center, Oak Ridge, Tennessee). Small fish are very resiliant to bending and twisting. The predominant thermal effect (sans biocides) follows a straightforward dose-response model that can be established in the laboratory and tested in the field. Thus, combinations of actual temperature of exposure (not delta T) and duration of exposure in the condensers, piping, and outfall plume can be used very easily to establish whether or not entrained organisms will suffer mortality, or conversely, cooling systems can be designed to minimize entrainment mortality (Coutant, C. C. 1973. Heat and Temperature. Pages 151-171 (plus appendix tables and references) in Water Quality Criteria 1972, A Report of the Committee on Water Quality, Environmental Studies Board, National Academy of Sciences/National Academy of Engineering, Washington, DC). The dose-response model works for direct mortality and indirect effects such as succeptibility to predation (Coutant, C. C. 1973. Effect of thermal shock on vulnerability of juvenile salmonids to predation. J. Fish. Res. Board Can. 30:965-973). Cooling towers, with their extended durations at high temperatures, severe physical stresses, and frequent use of biocides generally do kill 100 percent of the entrained organisms (sufficiently so that we can justifiably assume 100 percent). Most of this knowledge was well accepted and encyclopedia quality by the early 1980s. It became part of international approaches to power plant cooling (Majewski, W., and D. C. Miller, editors. 1979. Predicting the effects of power plant once-through cooling on aquatic systems. Technical papers in hydrology, UNESCO, Paris; International Atomic energy Agency. 1980. Environmental effects of cooling systems. Technical Report Series No. 202, Vienna).

Field studies to confirm these relationships are notoriously difficult to conduct, largely because the rigors of sampling are worse for the entrained organisms than those of the exposure. Many field studies showed higher mortality at the intake than in the discharge, indicating severe sampling problems. Ecological Analysts developed a much more benign sampling device to remedy some of the problems. When the entrainment studies were done carefully, they clearly substantiated the dose-response to temperature and the generally low component of mortality due to physical/mechanical stresses. The recent EPRI report documents many of these studies.

In conclusion, EPA's final note on entrainment survival that states "…it is clear that the number of relevant variables that collectively determine any entrainment survival rate is so large that the studies conducted to date should be viewed as a provocative set of anecdotes that demonstrate the need for further study, but do not provide a sufficient basis for making predictions” is not supported by the state-of-science and the scientific community.

EPA Response

EPA thanks the commenter for this submission; however, there is nothing in it that contradicts EPA's conclusion the entrainment survival is highly variable and unpredictable, and studies to estimate entrainment survival are difficult to conduct.

Methods to Evaluate I&E

Review of Methodology Used by EPA to Evaluate Impacts of Entrainment and Impingement Losses on Commercial and Recreational Harvests

Dr. Lawrence Barnthouse, at the request of EPRI, performed a detailed evaluation of the methodology used by EPA to estimate impingement and entrainment losses at CWIS. Dr. Barnthouse's detailed comments are included in Appendix A. The following is a summary of his comments.

He found that, although generally consistent with methods used in other similar assessments, the methodology as documented contains two significant errors. Without reproducing EPA's calculations, he could not confirm whether the calculations are wrong or the documentation is wrong. Even when correctly applied, EPA's methodology is highly sensitive to estimates of natural mortality rates in early life stages of fish, and in particular to assumptions made concerning the temporal distribution of entrainment and impingement mortality within life stages. Because it ignores biological compensation, EPA's methodology should overstate the benefits of alternative intake technologies. Despite EPA's arguments to the contrary, recent advances in understanding of biological compensation appear to provide a basis for developing quantification methods suitable for benefits analysis.

When he examined life history parameter values used in selected case studies, he found that different case studies often used different parameter values for the same species, leading to greatly differing estimates of the impacts of any given level of entrainment or impingement mortality. Some of the values used imply implausibly high or low population growth rates, and for the Delaware Estuary case study EPA's estimates of annual harvest and production foregone due to entrainment and impingement of spot and Atlantic croaker are more than an order of magnitude greater than the commercial harvests of these species over the same period. These results indicate the presence of a major bias in EPA's calculations, although without a detailed evaluation of the calculations it is not possible to determine the source of the bias.

The documentation provided by EPA, both for the methodology itself and for the individual case studies, is unclear and incomplete. Despite the incompleteness of the documentation, it is evident even from his brief examination of the case studies that EPA did not take appropriate care in developing parameter estimates for the models that were used, and did not perform "reality checks" to ensure that results of the calculations were realistic and reliable.

Although Dr. Barnthouse did not perform an exhaustive evaluation of all species or a statistical sampling of species evaluated by EPA, it appears that most of the assumptions chosen by EPA lead to overestimation of the impacts, not to a balance of overestimates and underestimates as claimed by EPA. A more detailed evaluation of the case studies would be needed to determine the magnitude of the overestimation, but at least in the case of the Delaware Estuary case study the harvest reduction and production foregone estimates appear to be greatly inflated.

EPA Response

Regarding the sensitivity of EPA's I&E estimates to natural mortality rates, please see the discussion in Chapter A6 of EPA's Regional Analysis Document (DCN #6-0003)

Please see EPA's response to Comment 316bEFR.025.015 for a discussion of compensation in the context of EPA's analysis.

While it is true that EPA sometimes used different life history parameter values for the same species located in different regions, this was done at the recommendation of local fisheries experts to reflect regional differences and thereby improve region-specific estimates.

In terms of life history data, EPA disagrees with the commenter's assertion that "EPA did not take appropriate care in developing parameter estimates for the models that were used." In fact, EPA consulted with local fisheries experts and conducted as thorough a review of the biological literature as possible to obtain the best available life history data. When possible, EPA used life history data recommended by a local technical advisory committee and provided in a current facility study (e.g., EPA used the same life history data used by Salem and by Brayton Point in their recent permit renewal applications).

In regards to EPA's estimates in the Delaware case study presented at proposal of foregone harvest of spot and croaker resulting from I&E at Salem, this analysis was not included in EPA's analysis for the final rule. However, EPA notes that for its final analysis, EPA reviewed the life history data it used to model these species, and revised any values that appeared unreasonable.

Finally, EPA notes that the document referred to by the commenter is not included in EPA's final analysis. For its final analysis, EPA made a good faith effort to document its methods and results as thoroughly as possible, and conducted detailed QA/QC according to a QA/QC plan developed for the study (see DCN #6-1002).

Methods to Evaluate I&E

Author Name Doug Dixon

Organization EPRI (Electric Power Research Inst)

In addition to Dr. Barnthouse's review and comments, EPRI also obtained the services of Dr. Elgin Perry, Statistical Consultant, to evaluate the potential for overestimating losses and benefits because of the multiplicity of conservative choices. Dr. Perry's detailed comments are included in Appendix C. Dr. Perry noted in summary that from his analyses, the EPA methods as presented in the case studies result in an overly protective evaluation of I&E losses. In particular, Dr. Perry notes that EPA has repeatedly made a number of conservative decisions that push estimated benefits off the scale of realism. Examples include:

1. Setting entrainment and impingement survival to zero.

2. Not using models that employ compensatory mechanisms when estimating equivalent adults.

3. Estimating production by life-stage categories using constant mortality and growth within life stage.

4. Summing direct and indirect losses.

5. Estimated use-based benefits on the basis of replacement costs rather than on the basis of increase in value in the resource.

6. Estimating non-use benefits and a multiplier of use-based benefits when quantification of these benefits is very uncertain.

The net result of these conservative assumptions is that I&E losses and the economic benefits from their reduction are unrealistic. Dr. Perry's comments are consistent with those of Dr. Barnthouse and those of Dr. Ivar Strand as subsequently discussed.

EPA Response

EPA disagrees with this characterization of its analysis. Please see response to Comment 316bEFR.074.201, which refutes the assertion that EPA used "multiple conservatisms" in its analysis.

National Benefits

Review of EPA Economic Benefit Analyses Used for Case Study Assessments

Dr. Ivar Strand, Professor Emeritus (Fisheries Economics), University of Maryland, at the request of EPRI, performed a detailed evaluation of the methodology used by EPA to calculate the economic benefits to be derived from reducing CWIS impingement and entrainment losses. Dr. Strand's detailed comments are included in Appendix C. In summary, however, he notes that the analysis could be improved greatly by the elimination of:

-The use of Habitat Replacement Costs (HRC) and forage fish hatchery costs as measures of benefits. As their names indicate, these are simply costs and, only in very unusual circumstances not present here, can they be thought of as benefits. Using costs as benefits obscures the economic content of many of the decisions that EPA must make. In the aggregate benefit category for the preferred option 3 (Table C4-7), the habitat replacement costs represent 100% (or $180 million) of the Ocean and Great Lakes benefits, or about 25% of all national benefits. Forage fish replacement costs represent over 76% of the "benefits" for the Big Bend facility (D6-1), the facility upon which all Gulf of Mexico estuary facilities are based. Although the out-of-scope facilities in the non-Gulf estuary category generally do not rely on replacement costs, one of the in-scope facilities (the Brayton Point facility) has habitat replacement costs representing over 95% of the "benefits". The effect of using costs as benefits is substantial in the computation of benefits;

-The use of unsubstantiated ratios and multipliers when estimating benefits from commercial fishing. For each $1 annual increase in commercial harvest, EPA estimates annual benefits to commercial fisheries producers and consumers will increase between $1.8 and $3.15. In the Salem, Delaware case study, the proposed regulations are projected to increase spot and croaker landings by 5.1 million pounds at a constant price of $0.70/lb and $0.85/lb respectively, even though spot harvests in New Jersey and Delaware are nearly non-existent and croaker harvest is around 2 millions pounds. Benefits from spot and croaker represent about 60% of the benefit estimate at the Salem facility. The Salem facility is used to estimate benefits from all facilities on non-Gulf estuaries. The total value of the non-Gulf estuaries is over 60% of the national aggregate benefits for the preferred option 3 (Table C4-7);

-The inappropriate estimate of nonuse values as 50% of the use value. The Federal government's own best practice (Economic Analysis of Federal Regulations Under Executive Order 12866, OMB, June 11,1996;) does not recognize a 50% rule as measures of nonuse benefits. It states "For many of these goods, particularly goods providing 'nonuse' values, contingent-valuation methods may provide the only analytical approaches currently available for estimating values (OMB, p. 33).";

-Errors and questionable judgment in developing benefit estimates for the case studies. For example, one case study (the Ohio River) presents a benefit estimate implying each additional pound of recreational fish caught on the Ohio River is worth $148 (p. C7-1). This is important because benefits for all facilities on all freshwater rivers in the nation are based on this case study.

-In the aggregation of benefits, EPA selects from the alternative suite of benefit estimates that it has derived (e.g. HRC, RUM, benefit transfers) for each case study. The methods with the highest benefits are usually selected.

All of these comments are relevant even if the EPA chooses to use an economic efficiency criterion (i.e., costs being greater than benefits as the decision criterion to reject a technology). If EPA chooses to use inefficient technologies based on the current criterion of "significantly greater costs than benefits", then it is even more important that correct concepts and methods are applied in the benefit estimation.

EPA Response

EPA does not use the Habitat-based Replacement Cost (HRC) method in the cost benefit analysis for the final Section 316(b) Phase II rule. Please see the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003) for additional discussion of the HRC method. Please also see EPA's response to comment #316bEFR.005.035.

In the cost benefit analyses for the final Section 316(b) Phase II rule, EPA estimated a random utility model (RUM) for each region. The benefits transfer methods that produced the results in question for Ohio are no longer used. For more detail on EPA's recreational benefits methods please see the regional study document (DCN #6-0003), Chapter A11: Estimating Benefits with a Random Utility Model (RUM). Please also see EPA's response to comments on recreational fishing: #316bEFR.075.504 and #316bEFR.041.452.

In the cost-benefit analyses for the NODA and for the final Section 316(b) Phase II rule, EPA did not use the 50% rule-of-thumb to estimate non-use benefits.

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment 316bEFR.005.029.

For EPA's response to comments on the methods used to extrapolate results to the regional level, please see the response to comment 316bEFR.041.041. Please also see Chapter C1 of the EBA on the regional approach used in the analysis for the final rule.

Option 3--Site-specific determination

In 1977, following several years of intensive government and industry research on CWIS impacts and approaches to mitigate them, EPA proposed regulations for implementing Section 316(b)(EPA 1977). Those rules, reflecting the scientific consensus of the time, embraced the site-specific approach for assessing AEI and determining Best Technology Available (BTA) for minimizing AEI where it existed. Although the rules were subsequently remanded due to procedural issues, the rules were informally adopted by state and federal permitting authorities and subsequently followed to present.

In the 25 years that have since elapsed, research and 316(b) compliance activity has further confirmed the validity of the site-specific AEI assessment and BTA determination approach. For the benefit of the regulatory and policy dialog that has developed since the 1995 316(b) Consent Decree, EPRI has consolidated and summarized much of the technical information 1977 through present. Key EPRI reports <FN 1> or EPRI sponsored initiatives documenting the site-specific nature of AEI assessment and BTA determination include:

-Summary of EPRI Cooling Systems Effects Research 1975-1993. EPRI Report TR-104302

-Evaluation of Fish Behavioral Barriers. Prepared for EPRI by Alden Research Laboratory. Palo Alto, CA. TR-109483.

-Proceedings: 1998 EPRI Clean Water Act Section 316(b) Technical Workshop. TR-112613. April 1999.

-Fish Protection at Cooling Water Intakes: Status Report. TR-114013. December 1999.

-Catalog of Assessment Methods for Evaluating the Effects of Power Plant Operations on Aquatic Communities. TR-112013. June 1999.

-Procedural Guideline for Evaluating Alternative Fish Protection Technologies to meet § 316(b) Requirements of the Clean Water Act. EPRI Report 1000551, December 2000.

-Evaluation of Biocriteria as a Concept, Approach and Tool for Assessing Impacts of Entrainment and Impingement under § 316(b) of the Clean Water Act. TR-114007. June 2000.

-Assessment of Spawning and Nursery Habitat: Review and Evaluation of Methods Potentially Applicable to Regulation of Cooling Water Intake Structures. February 2002. Report # 1000732

-Behavioral Technologies for Fish Guidance. August 2001. EPRI Report #1006198

-Power Plants & Aquatic Resources: Issues and Assessment. Journal of Environmental Science & Policy, Volume 3, Supplement, September 2000. EPRI Order #1000767.

-Review of Entrainment Survival Studies: 1970-2000. EPRI Report #1000757, December 2000.

-Technical Evaluation of the Utility of Intake Approach Velocity as an Indicator of Potential Adverse Environmental Impact under CWA § 316(b). EPRI Report #1000731. December 2001.

All the above, including independent research results, have documented that the assessment of AEI and determination of BTA is a site-specific process.

Footnotes

1 All the reports listed have been previously provided to the water docket as part of EPRI comments on the Phase I 316(b) rule and in response to the EPA Phase I NODA.

EPA Response

EPA appreciates the commenter's submittals. EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Review of Methodology Used by EPA to Evaluate Impacts of Entrainment and Impingement Losses on Commercial and Recreational Harvests

Lawrence W. Barnthouse, Ph. D.
LWB Environmental Services, Inc.
Oak Ridge, Tennessee

Prepared for the Electric Power Research Institute under Agreement No. EP-P8210/C4139

August 1, 2002

Summary

I reviewed the methodology used by EPA in its Case Study Analyses for Section 316(b) of the proposed rule for existing facilities. My objective was to evaluate whether the methods used are consistent with the best state-of-the-practice in entrainment/impingement impact assessment, and whether the parameter estimation methods used yield reasonable and unbiased results. My review report includes 1) a summary of EPA's methodology, 2) a general evaluation of the methodology, including equations and assumptions, 3) an evaluation of EPA's rationale for assuming absence of biological compensation, 4) an evaluation of parameter estimates for selected species, and 6) identification of omissions and errors in documentation.

I found that, although generally consistent with methods used in other similar assessments, the methodology as documented contains two significant errors. Without reproducing EPA's calculations I could not confirm whether the calculations are wrong or the documentation is wrong. Even when correctly applied, EPA's methodology is highly sensitive to estimates of natural mortality rates in early life stages of fish, and in particular to assumptions made concerning the temporal distribution of entrainment and impingement mortality within life stages. Because it ignores biological compensation, EPA's methodology should overstate the benefits of alternative intake technologies. Despite EPA's arguments to the contrary, recent advances in understanding of biological compensation appear to provide a basis for developing quantification methods suitable for benefits analysis.

When I examined life history parameter values used in selected case studies, I found that different case studies often used different parameter values for the same species, leading to greatly differing estimates of the impacts of any given level of entrainment or impingement mortality. Some of the values used imply implausibly high or low population growth rates, and for the Delaware Estuary case study EPA's estimates of annual harvest and production foregone due to entrainment and impingement of spot and Atlantic croaker are more than an order of magnitude greater than the commercial harvests of these species over the same period. These results indicate the presence of a

major bias in EPA's calculations, although without a detailed evaluation of the calculations it is not possible to determine the source of the bias.

The documentation provided by EPA, both for the methodology itself and for the individual case studies, is unclear and incomplete. Despite the incompleteness of the documentation, it is evident even from my brief examination of the case studies that EPA did not take appropriate care in developing parameter estimates for the models that were used, and did not perform "reality checks" to ensure that results of the calculations were realistic and reliable.

Although I did not perform an exhaustive evaluation of all species or a statistical sampling of species evaluated by EPA, it appears that most of the assumptions chosen by EPA lead to overestimation of the impacts, not to a balance of overestimates and underestimates as claimed by EPA. A more detailed evaluation of the case studies would be needed to determine the magnitude of the overestimation, but at least in the case of the Delaware Estuary case study the harvest reduction and production foregone estimates appear to be greatly inflated.

Introduction

At the request of EPRI (Electric Power Research Institute), I reviewed the methodology used by EPA in its Case Study Analyses (CSA) for Section 316(b) of the proposed rule for existing facilities. The primary focus of the review is on the methodology itself, not the applications of the methodology in the individual case studies. However, because the validity of the case study results is highly dependent on the methods used to develop parameters for the models, the review includes a "first-level" review of the application of the models to the cases included in the CSA. The objective is to evaluate whether the methods used are consistent with the best state-of-the-practice in entrainment/impingement impact assessment, and whether the parameter estimation methods used yield reasonable and unbiased results.

The review includes the following components:

-Summary of EPA's methodology,
-General evaluation of methodology, including equations and assumptions,
-Evaluation of EPA's rationale for assuming absence of biological compensation,
-Evaluation of parameter estimates for selected species, and
·-dentification of omissions and errors in documentation.

Summary of EPA's Methodology

EPA's methodology for evaluating entrainment and impingement consists of four major components:

1. Estimation of entrainment and impingement losses by life stage
2. Extrapolation of stage-specific losses to losses of age-1 equivalent fish
3. Extrapolation of age-equivalents of exploited fish species to pounds of fish lost to commercial and recreational fisheries
4. Extrapolation of age-1-equivalents of forage fish to losses in production of commercial and recreational fish

This review focuses on steps 2 through 4, extrapolation of age and stage-specific losses to estimates of reductions in recreational and commercial harvests. EPA's methods for making these extrapolations are documented in Chapter A5 of the CSA. One potentially significant aspect of EPA's methodology involves the assumption that no compensatory processes (e.g., density-dependent growth or survival) are operating in the modeled populations. EPA's justification for this assumption, which is documented in Chapter A6 of the CSA, is also included in this review.

Extrapolation of losses to age-1 equivalents

Extrapolation of stage-specific losses to age-1 equivalent fish requires estimates of the probability of survival from the age of entrainment or impingement to age 1 (1-year-old fish). Mortality of early life stages is typically very high, so that only a small fraction of entrained or impinged organisms would survive to age 1, even if there were no entrainment or impingement. Survival rates vary greatly among species and life stages, because of the great diversity of life histories among fish species. A single female striped bass can spawn several million eggs per year over a reproductive life span of ten years or greater, whereas a female salmon may spawn only a few thousand eggs and spawns only once before dying. In both cases, only two of these spawned eggs must, on average, survive to reproductive maturity. The survival probability of each salmon egg must, therefore, be many times higher than the survival probability of each striped bass egg.

Early life stage survival rates are available for relatively few species, and even within species estimated survival rates are highly variable and somewhat unreliable. Where stage-specific rates were unavailable, EPA used the following equation, from Goodyear (1978), to estimate survival:

[see hard copy for equation]
(Equation 1)

where:
Seq = the probability of survival from egg to the expected age of spawning females
fa = expected lifetime total egg production

Given estimates of stage-specific survival rates, EPA calculates survival from the stage of entrainment or impingement to age 1 using the following equation:

[see hard copy for equation]
(Equation 2)

where:
Sj,1=cumulative survival from stage j until age 1
Sj = survival fraction from stage j to stage j+1
[see hard copy for equation] = adjusted Sj
jmax = the stage immediately prior to age 1

The survival adjustment factor, which is documented in Appendix VII, Attachment F-4 to the most recent permit application for Salem Generating Station (PSEG 1999), assumes that fish within a given stage or age class are equally vulnerable to entrainment or impingement throughout that stage or age. The intent of the adjustment is to account for the fact that fish entrained or impinged near the end of any stage would have had a higher probability of surviving and contributing to later stages or ages than would fish entrained or impinged early in that stage or age. Age-1 equivalents are calculated by multiplying the losses at each stage j by the appropriate value of $S_{j,1}$ and then summing over all life stages entrained or impinged.

Extrapolation of age-equivalents of exploited fish species to pounds of fish lost to commercial and recreational fisheries

EPA's equation for calculating foregone harvest due to entrainment and impingement is provided on page A5-4 of the CSA:

[see hard copy for equation]
(Equation 3)

where:
Y_k = foregone yield due to I&E losses in year k
L_{jk} = losses of individual fish of stage j in year k
S_{ja} = cumulative survival fraction from stage j to age a
W_a = average weight of fish at age a
F_a = instantaneous annual fishing mortality rate for fish of age a
Z_a = instantaneous annual total mortality rate for fish of age a

The foregone harvest for fish entrained in any given year is estimated by first calculating the expected future harvest from each stage or age group lost, and then summing over all stages and ages lost during that year.

Estimation of foregone production of forage fish

The method for calculating foregone production of forage fish is documented in section A5-3.3 of the case study report. According to EPA, Rago's (1984) model for calculating foregone at a specific stage, age or size class i (P_i) was used:

[see hard copy for equation]
(Equation 4)

where:

P_i = expected production for an individual during stage i
G_i = instantaneous growth rate for individuals of stage i
N_i = number of individuals of stage i lost to I&E (expressed as equivalent losses at subsequent ages)
W_i = average weight for individuals of stage i
Z_i = instantaneous total mortality rate for individuals of stage i

The term N_i in equation (4) must be interpreted differently depending on whether a cohort of fish was entrained or impinged at stage i or at some earlier stage. For fish lost at age i, N_i would be equal to the total loss at stage i. For fish lost at an earlier stage j, N_i would be equal to the losses at stage i discounted by the fraction of fish expected to survive from stage j to stage i:

[see hard copy for equation]
(Equation 5)

The CSA does not explicitly state that this adjustment was made. However, according to EPA's responses to UWAG questions (EPA 2002, response 5) the adjustment was made as described in Rago's (1984) paper.

Production foregone for fish lost at any stage j is obtained by calculating the production foregone at each future stage or age using equation 8 and then summing over all stages:

[see hard copy for equation]
(Equation 6)

where
Pj = production foregone for all fish lost at stage j
Tmax = oldest age group considered.

The total production foregone from all fish lost during any given year, PT, is obtained by calculating Pj for all stages or ages entrained or impinged during that year:

[see hard copy for equation]
(Equation 7)

where:

PT = total production foregone for all stages
tmin = youngest age group considered.

According to Chapter A5 of the CSA, EPA applied the production foregone approach to forage species, and then used the resulting estimates of PT to translate reduced forage fish production into reduced predator production.

Reduction in harvest related to foregone production of forage fish

EPA used a trophic transfer model to quantify the effect of foregone forage fish production on the biomass production and harvest of exploited RIS. The approach involves using trophic transfer coefficients to convert prey (forage fish) biomass into predator (harvested fish) biomass:

[see hard copy for equation]
(Equation 8)

where:

Pp = biomass production of predator
k = trophic transfer efficiency (typically about 0.1)
Pf = biomass production of forage species

EPA subdivided the overall trophic transfer pathway linking forage fish production and predator production into a "high efficiency" and a "low efficiency" pathway. For the high efficiency pathway, EPA assumed that 20% of forage fish production is consumed directly by predators, at efficiency k1. The remaining 80% of forage fish production was assumed to reach predators indirectly, through intermediate trophic levels. This intermediate step involves an additional transfer efficiency coefficient, k2. The reduction in biomass production of harvested species due to foregone production of forage fish was calculated by EPA as the sum of production losses for the high efficiency and the low efficiency pathways:

[see hard copy for equation]
(Equation 9)

EPA assumed a value of 0.09 for the transfer coefficient k1 and a value of 0.1 for coefficient k2. Thus, the net effect of the dual pathway model is that the biomass of predators available for harvest is assumed to be reduced by an amount equal to 2.5% (weighted fraction of the two transfer coefficients) of forage fish production foregone. EPA provided no rationale for the 20%-80% split or for the values of the coefficients k1 and k2.

Evaluation of methodology

At least in concept, EPA's approach is similar to approaches used in site-specific assessments such as the 1999 permit application for the Salem Generating Station (PSEG 1999). As discussed below, the approach ignores biological compensation and, therefore, provides upper bound estimates on the number of age-1-equivalents, pounds of harvest, and production foregone caused by entrainment and impingement.

At least in two cases, however, EPA may have erroneously interpreted the original source literature, thereby introducing potentially significant errors into the calculations.

EPA's equation for calculating foregone yield due to entrainment and impingement (Equation 3 above) cannot be correct. According to Equation (3), the yield lost at any given age is equal to the number of entrained or impinged fish that would have survived to that age (L multiplied by S) times the average weight of a fish at that age (W) times the fraction of the total mortality rate at that age that is attributable to fishing (F/Z). However, the yield to a fishery depends on the fraction of the population dying at any given age, not just the on ratio of fishing mortality to total mortality. The fraction of fish dying at any age i is given by:

[see hard copy for equation]
Equation (10)

where:

Ma = instantaneous natural mortality rate at age a

The fraction of an age group caught by a fishery cannot be any higher than this fraction, and can be as large as this fraction only if there is no natural mortality (i.e., Ma = 0 so that Fa = Za). If total mortality is very low, then Aa will be very low, the yield to the fishery will be very low, and nearly all fish will survive to the next age class. This is true regardless of the proportion of Za that is attributable to fishing. On the other hand, given the exact same ratio of Fa to Za, if total mortality Za is very high then Aa will be very high. The yield to the fishery from age group a will be very high, but very few fish will survive to the next age class.

Baranov's Catch Equation, as documented in Ricker (1975), correctly accounts for both the ratio of fishing to total mortality and for the fraction fish dying at any age i:

[see hard copy for equation]
(Equation 11)

where:

Na = Initial number of age a fish
Ua = (FaAa)/Za = exploitation rate of fish at age a
= fraction of fish of age a that die at age a

Given this relationship, then the loss in future yield for fish entrained or impinged during year k at life stage j should be:

[see hard copy for equation]
(Equation 12)

The total loss in future yield for all fish entrained or impinged during year k should be

[see hard copy for equation]
(Equation 13)

The literature cited by EPA (Ricker 1975) describes the correct form of the yield model. In its response to UWAG questions (EPA 2002), EPA stated that Equation (3) as printed in the case study report was used, in that form, to estimate foregone fishery yield due to entrainment and impingement. If this is true, then EPA's foregone yield estimates are incorrect and are biased high.

The correct version of the model (i.e., equation 13 above) was used in the Salem Generating Station's latest permit renewal (PSEG 1999, Appendix VII, Attachment 4). Even when correctly applied, the model does not include compensation and therefore is conservative, producing upper bound estimates on the actual reduction in future yield due to entrainment and impingement.

EPA's application of Rago's (1984) production foregone model also contains a significant error. According to Rago (1984) the term Wi refers to the average weight of individuals at the beginning of stage i. However, according to EPA's responses to UWAG questions (EPA 2002, response 3), EPA assumed Wi to be the average weight of all age i individuals. This difference in interpretation is potentially highly significant, because early life stages of fish grow very rapidly. The weight of fish at the end of each stage can be many times higher then the weight at the beginning of that stage. Use of an average weight calculated from weights measured at both the beginning and the end of a life stage would introduce a substantial upward bias into the production foregone estimates. EPA's citation to page 82 of Rago (1984) as support for its approach is incorrect. The correct citation is to page 84, which provides Rago's equation for calculating the average biomass of a cohort of fish over any time interval:

[see hard copy for equation]
Equation (14)

where:
= average biomass
= initial biomass at time 0
= average weight at time 0, i.e., the average weight at the beginning of the interval over which production is being calculated.

Since, in Rago's model, production over a life stage is equal to average biomass multiplied by growth rate, Equation (4) is obtained simply by multiplying both sides of equation (14) by the growth rate, G:

[see hard copy for equation]
Equation (15)

Aside from these errors, several other significant uncertainties and potential sources of bias are inherent in EPA's methodology.

Equation (1), which is used to calculate early life stage survival rates when empirical data are unavailable, assumes 1) that the population being modeled is stable over time, and 2) that survival is constant over the period between the spawning and adulthood. The stability assumption is reasonable as a first approximation because, measured over long time spans, the average sizes of most populations are relatively constant. The assumption of constancy over all stages is clearly an oversimplification, because mortality of all life stages and ages of fish is size-dependent. Survival rates of early life stages are very low; survival rates increase with increasing size and age. It is not clear from Chapter 5 how EPA apportioned Seq among different life stages, when more than one life stages was entrained or impinged.

Moreover, it is not clear how EPA used Equation (1) to calculate survival rates. The variable fa in Equation (1), the expected lifetime total egg production of a female recruit, is not a directly measurable quantity. This variable represents the number of eggs expected to be produced over the life time of a fish that has just reached reproductive age, accounting for both the number of eggs produced by the fish at each subsequent age and the probability that the fish will survive to reach that age:

[see hard copy for equation]
(Equation 16)

where:
Si = fraction of fish surviving from the age at first reproduction to age i
Mi = number of eggs spawned by a female fish at age i
S1 =1

Estimates of age-specific fecundity and survival are unavailable for many species, and even within a species different populations can have substantially different life histories. Age-specific survival rates for all of the modeled species are listed in the individual case study appendices, however, fecundity estimates are not provided. The input data spreadsheets provided in Docket Nos. 4-2035 through 4-2055 contain fecundity data for some, but not all species.

The adjusted survival fraction in Equation 2, S*j, is also a potentially significant source of error. This adjustment is included to account for the fact that typical entrained or impinged organisms will have already spent a certain amount of time in the life stage where they were entrained or impinged, and so will have already have survived some natural mortality. The probability that such fish would have survived to age 1 had they not been entrained or impinged is higher than it would have been had they been entrained or impinged on the first day of that life stage. Because of the adjustment, S*j is always larger than Sj.

The adjustment formula assumes that fish are equally susceptible throughout the entire duration of the life stage, i.e., the daily probability of entrainment or impingement is constant. If fish become progressively less susceptible during the stage (e.g., because of growth or emigration), then the adjustment will produce estimates that are biased high, especially if the stage is long in duration. Juvenile fish, for example, are often susceptible to entrainment immediately after transformation from the larval stage (~20 mm in length for many species). However, juvenile fish grow very rapidly and in many species reach a length of 100 mm or greater by age 1. Beyond a length of ~ 40 mm, they may be too large to be entrained. In this circumstance, the actual average age of entrained juveniles would be much younger than assumed in EPA's model, so that extrapolation of the losses to age-1 equivalents would be inflated.

The importance of the above two sources of uncertainty, early life stage survival rates and the survival rate adjustment factor, is illustrated in Figure 1. As in some of the case studies modeled by EPA, the "juvenile" period, i.e., the period from transformation to the juvenile life stage and the end of the first year of life, is divided into two substages, termed "juvenile 1" (J1) and "juvenile 2" (J2). Figure 1 plots the number of age-1 equivalents lost per 10,000 entrained J1 fish. Figure 1 assumes a survival rate of 40% for J2 fish, similar to values for striped bass and weakfish used in the Delaware Estuary case study. A range of values is used for J1 fish, from about 4% to 12%. These values are consistent with the range of values assumed for various fish species in EPA's case studies.

Survival rates for early juvenile fish are especially difficult to measure because juveniles are too large and mobile to be efficiently sampled by ichthyoplankton nets. Few empirical estimates of early juvenile mortality are available, even for well-studied species. All survival rate estimates for this stage are highly uncertain, and the actual uncertainty in survival rates for many species is probably greater than the range used in this example. For a range of 5-10% J1 survival, application of EPA's methodology produces a range of 381-727 equivalent one-year-olds per 10,000 entrained J1 fish. If, however, juveniles were susceptible to entrainment only at the beginning of the J1 stage, then the same 10,000 losses would equate to only 200-400 age-1 equivalents.

These uncertainties translate directly into uncertainties concerning the magnitude of reduced harvests caused by entrainment and impingement. Because EPA's model is linear, a factor of two uncertainty in the number of age-1-equivalents per lost fish translates into the same factor of two uncertainty in pounds lost and economic value.

The production foregone model used by EPA involves many of the same uncertainties. Rago (1984) performed an extensive sensitivity analysis of this model. He found that model outputs were especially sensitive to 1) survival rate and estimates for post yolk-sac larvae and age 0 (juvenile) fish and 2) mean weight estimates for age 0 fish. He also discussed the influence of density-dependent population regulation (compensation) on production foregone estimates. He noted that the model assumes that compensation does not occur, and therefore should provide upper bound estimates of production foregone. The production foregone model, like the other models used by EPA, is linear so that a factor-of-2 uncertainty in estimates of production foregone per entrained or impinged forage fish translates directly into the same uncertainty in estimates of pounds of harvestable fish lost.

In at least on respect, however, Rago's (1984) model is inconsistent with the approach used by EPA to calculate age-1 equivalent losses and future yield for harvested species: the production foregone model does not include the survival rate adjustment discussed above. In calculating the production foregone at future stages or ages (i.e., stages or ages subsequent to the stage or age at which the loss occurred), the model assumes that the loss occurred at the beginning of the stage. Using the survival rate adjustment (which would have made the production foregone model logically consistent with the age-1-equivalent loss model), would have increased the production foregone estimates.

EPA's approach to estimating secondary and tertiary harvest reductions due to prey production foregone is conservative both in assuming that no compensation occurs and that all of the entrained and impinged prey would ultimately have been consumed (directly or indirectly) by harvested predators. When forage fish are entrained and impinged, predators – in this case the surviving members of the harvested predator populations – can potentially consume alternative prey. Moreover, some of the entrained and impinged forage fish are those that would have been consumed by the entrained and impinged predators, had they survived. However, EPA's "secondary and tertiary" yield loss calculations assume that production foregone translates directly (discounting for transfer efficiencies) into reduced yield of harvested predatory fish, i.e., into reduced numbers or size of the harvested predators. Implicitly, EPA assumes that no consumption of alternative prey occurs and that the forage fish losses consist solely of fish that would have been consumed (directly or indirectly) by the surviving members of harvested species. These assumption, although consistent with EPA's conservative assessment approach, are clearly biologically unrealistic.

Critique of EPA's rationale for assuming no biological compensation

Chapter A6 of the case study report discusses the use of "population models" in assessing long-term consequences of mortality due to entrainment and impingement. In this context, "population models" means the use of classical spawner-recruit models such as the Ricker and Beverton-Holt models to quantify the influence of density-dependent population regulation (compensation) on the abundance of fish populations, and to calculate estimates of long-term effects that include the influence of density-dependence. Specific topics covered in Chapter A6 include:

-The general concept of population regulation and the principal models used by fisheries scientists to quantify compensation,

-The way in which these models can be used to calculate quantities of interest to fisheries managers (e.g., maximum sustainable yield),

-Modifications of the models made to apply them to CWIS impacts,

-Various uncertainties that limit the ability of stock-recruitment models to predict responses of fish populations both to harvesting and to entrainment/impingement losses, and

-EPA's rationale for not quantifying impacts on populations and, instead, using models that assume no compensation.

EPA asserts that stock-recruitment models do not account for impacts on multiple species, do not include impacts of multiple intake structures, do not account for other sources of human-related mortality (e.g., toxic chemicals), do not incorporate inter-species interactions, and do not consider interactions between density-dependent and density-independent processes. Because of the high degree of uncertainty associated with stock-recruitment models, and because many of the fish species that are vulnerable to entrainment and impingement may already be depleted by overfishing, a "precautionary" approach to impact assessment is, according to EPA, appropriate. The precautionary approach, according to EPA, entails (1) use of entrainment and impingement losses as direct measures of potential impacts, analogous to the use of toxicity testing to predict the potential impact of pollutant discharges, and (2) use of density-independent models to project estimates of entrainment and impingement losses to estimates of reduced harvest and production foregone.

The primary concern with EPA's argument is that it inappropriately confuses the phenomenon of biological compensation with the mathematical models that have been used by fisheries biologists to quantify compensation. In addition, EPA oversimplifies the use of compensation in fisheries management.

The operation of density-dependent processes in fish populations has been demonstrated in numerous empirical studies, including statistical analyses of long-term databases and direct manipulative experiments performed in small ponds and lakes (Myers 2001, Rose et al. 2001). Moreover, the existence of compensation is explicitly recognized in fisheries management regulations implemented by the National Marine Fisheries Service, which state that exploitation that reduces the size of populations by greater than 50% below the unexploited stock size are consistent with the long-term sustainability of populations (NMFS 1998a).

In focusing on a few types of simple models, EPA greatly oversimplifies the biological basis for compensation and ignores the fact that compensation is explicitly acknowledged by fisheries management regulations. The Ricker, Beverton-Holt, and other stock-recruitment models are used in fisheries management only when large quantities of high-quality data are available. In other cases, the approach most commonly used for establishing fishing rates that protect the reproductive capacities of fish populations is the "spawning stock biomass per recruit" (SSBPR) approach (Goodyear 1993). The SSBPR approach implicitly considers compensation by quantifying the influence of fishing mortality on the reduction in number of eggs produced per female recruit over her lifetime. To maintain a stable population, the survival rate of each spawned egg must increase in order to offset the reduction in lifetime egg production caused by harvesting. As noted by Goodyear (1993), the SSBPR model was first proposed in 1977 (Goodyear 1977) as a method for indirectly quantifying compensation in power plant impact assessments.

Technical committees of the Atlantic States Marine Fisheries Service have, in fact, developed stock-recruitment models for two fish species that are often entrained and impinged at East Coast power plants: striped bass and weakfish (NMFS 1998b, 2000). These models are used as an input to the management process for these species, although they are not used to calculate numerical harvest limits. Although spawner-recruit models are not widely used in fisheries management, compensation is at least implicitly included.

Many of the uncertainties inherent in EPA's biological assessment method (e.g., estimation of stage-specific natural mortality rates) can at least in principle lead either to overestimates or to underestimates of the potential harvest lost due to entrainment and impingement. However, ignoring compensation leads to an overestimate of harvest reduction and, therefore, an overestimate of the benefits to be gained by implementing additional technologies to reduce entrainment and impingement. The magnitude of the bias introduced by assuming a linear relationship between losses and harvest reduction would be expected to be relatively small for fish stocks that are severely depleted and have a very low compensatory reserve, but relatively large for fish stocks such as striped bass that are currently being exploited at sustainable levels. EPA has made no attempt to quantify the degree of bias, or to evaluate the influence of such bias on the benefits assigned to alternative intake technologies.

It clearly is true that the precision of spawner-recruit models is often too low for use in managing specific fish stocks (Goodyear 1993). However, this degree of precision may not be necessary for a national-scale benefits analysis such as the one performed by EPA. For example, the method developed by Myers et al. (1999) for estimating the compensatory reserve of fish populations based on meta-analysis of hundreds of published stock-recruitment data sets could be used to develop models that are suitable for benefits assessment. Rose et al. (2001) showed that this method produces estimates of compensatory reserve that are consistent with expectations derived from fish life history theory. Although the benefits predictions derived from a model that included compensation would be uncertain, they would, at least, not contain a consistent bias toward overestimation of benefits.

Evaluation of parameter estimates for selected species

Whether or not the uncertainties discussed above compromise the validity of EPA's benefits analysis depends on the validity of the model parameters used by EPA in the various case studies. A detailed evaluation of all parameters used in all case studies would be impossible within the time available for commenting on the proposed rule, however, much can be learned from a limited evaluation of a few model applications, focusing on parameters such as early life stage mortality rates that are known to have especially important influences on model predictions. I selected three specific issues were selected for detailed evaluation:

-The influence of juvenile-stage survival assumptions on estimates of age-1 equivalent losses and yield reductions for Atlantic croaker and spot,

-Inconsistencies between mortality rates used for the same species evaluated in different case studies,

-Checks for unrealistically high or low parameter values and model projections.

These particular issues are representative of the types and potential magnitudes of uncertainties affecting all of the case studies, and of the types of “reality checks” that are needed to ensure that seemingly plausible and well-documented parameter sets do not lead to implausible or impossible model results.

Influence of juvenile-stage survival assumptions on estimates of age-1 equivalent losses and yield reductions for Atlantic croaker and spot

The life history parameters listed in Appendix B2 of the CSA are, for most species, the same values used in PSEG’s 1999 Permit Application (PSEG 1999, Appendix L, Tab 18). Yet, EPA’s estimates of age-1 equivalents lost at Salem are different from the estimates presented in PSEG’s Application, and, in some cases, EPA’s estimates are very much higher. The differences in part are due to EPA’s assumption of 100% entrainment mortality for all species and life stages (see EPRI’s specific comments on EPA’s assumption of 100% mortality), however, for some species the differences are much too large to be accounted for by entrainment mortality alone. For these species, differences in assumptions concerning the age of entrained juvenile fish may account for a substantial fraction of the difference. Examination of the Salem data input spreadsheet (Docket No.4-2051) shows that for Atlantic croaker, spot, and Atlantic menhaden, most of the entrained fish are juveniles rather than eggs or larvae. Early life stages (eggs, yolk-sac larvae, and post yolk-sac larvae) accounted, respectively, for only 7.5%, 0.6%, and 1.2% of total entrainment losses of these species. The juvenile life stages of all three have durations of 9-10 months, during which the fish grow rapidly out of the entrainable size ranges and emigrate from the Delaware Estuary. Because life history considerations and length distributions of juvenile fish collected in entrainment samples at Salem indicate that small, early juveniles account for most of the entrainment of this life stage, PSEG (1999) did not apply the life-stage survival adjustment factor (equation 2) to entrained juveniles. EPA, however, applied the adjustment to all life stages, including juveniles.

Figure 2 compares estimates of the number of age-1 equivalents per 100,000 entrained Atlantic croaker, spot, and Atlantic menhaden, under two alternative assumptions concerning entrainment susceptibility of juveniles: susceptibility only at the beginning of the stage, and equal susceptibility throughout the stage. The values calculated using the EPA assumption range from approximately twice as high (spot) to more than six times as high (Atlantic croaker) as values calculated using the PSEG assumption. These differences in assumed susceptibility translate directly into proportional differences in the estimated lost yields to fisheries and production foregone. Since Salem is used as a model to extrapolate losses calculated for all of the facilities (Salem, Hope Creek, Deepwater, Edge Moor, Delaware City Refinery, Deepwater, Chambers Cogen, General Chemical Corp., SPI Polyols, Sun Refining, Logan Generating Co., and Hay Road) examined in the Delaware Estuary case study, the differences in susceptibility assumptions translate into factor of 2-6 estimates of total yield losses and production foregone for the case study as a whole.

Inconsistent values for life history parameters used in different case studies

Mortality rates for early life stages of fish are notoriously difficult to measure and different estimates for the same species can differ by surprisingly large amounts. Table 1 shows a range of published mortality rates for bay anchovy post yolk-sac larvae. Bay anchovy larvae are abundant and relatively easy to collect, and ages of larvae (in days) can be accurately determined from analysis of otolith increments. Nonetheless, the range of published values for this species and life stage implies a range of stage-specific survival rates from essentially 0 to more than 12%. These large differences, some of which are clearly biologically implausible, are caused by factors such as size-specific gear avoidance and movements of larvae into and out of study areas. Much less information is available concerning early life stage mortality rates for other species and life stages. Under this circumstance, special care is needed to ensure that the values selected for use in impact modeling are biologically realistic and that consistent sets of parameters are used in different components of a study.

There is no indication in the case study documentation that EPA attempted to check the biological realism of literature-derived early life stage mortality rates. For some species, different case studies apparently used different mortality rates. Impacts on Atlantic menhaden and alewife were quantified for the Delaware Estuary, Brayton Point, and Seabrook/Pilgrim, case studies. Gizzard shad and several other species are common to both the Ohio River and Great Lakes (Monroe and J.R. Whiting) case studies. All three Atlantic coastal and both Great Lakes case studies evaluated impacts on alewife. Inspection of the stage-specific mortality rates provided in the life history appendices show that in some cases different values were used in different case studies, producing dramatically different estimates of the number of age-1 equivalents lost per entrained or impinged fish. The stage-specific survival rates used by EPA for the above species are summarized in Table 2. Not all of these values, however, were actually used in the benefits analysis. For example, although early life stage mortality rates for alewife are listed in Appendices G1 (Seabrook/Pilgrim), H1 (J.R. Whiting, and I1 (Monroe), no entrainment or impingement estimates for alewife eggs, larvae, or juveniles were used in those case studies.

Figure 3 shows, for menhaden, alewife, and gizzard shad, the influence of the assumed ELS mortality rates on the estimated numbers of age-1 equivalent fish entrained or impinged. Only mortality rates that were used in the benefits calculations are included in this figure. To facilitate graphical comparisons, the estimates are expressed as numbers of age-1-equivalents per 100 million eggs, per 10 million larvae, and per 100,000 juveniles. The differences are substantial. For Atlantic menhaden, any given number of entrained or impinged fish would translate into 4-20 times more age-1 equivalents using the Delaware Estuary mortality rates as using the Brayton Point mortality rates. On the other hand, for alewife, the Brayton Point mortality rates imply 5-20 times as many age-1 equivalent fish per entrained or impinged fish as do the Delaware Estuary values. For gizzard shad, the Ohio River values translate into twice as many age-one-equivalents per unit entrainment of eggs and larvae as the Great Lakes values, but only into one 20th as many age-1-equivalents per unit entrainment or impingement of juveniles.

These inconsistencies in life table parameter values translate directly into inconsistencies in estimates of yield losses and production foregone used in the different case studies.

Checks for unrealistically high or low parameter values and model projections

CSA Tables B3-16 and B3-17 provide, respectively, EPA's estimates of annual average harvest foregone and production foregone due to entrainment for the Delaware Estuary case study. Figure 4 compares EPA's harvest and production foregone values for Atlantic croaker and spot (all 12 facilities combined) to average annual Delaware and New Jersey landings of these two species from 1990 through 2000. The NMFS data are available on-line at http://www.st.nmfs.gov/st1/commercial/. Figure 4 shows that EPA's estimates of entrainment impacts on these species are 10-100 times the actual landings of these species in the two states bordering the Delaware Estuary. For both species, EPA's production foregone estimates are larger than recent (1990-2000) average landings for the entire Atlantic coast (~15 million pounds of Atlantic croaker and 7 million pounds of spot). Such a result is quite remarkable because the Delaware Estuary is at the northern end of the geographic range of both species, so that only a small fraction of fish spawned each year should be susceptible to entrainment or impingement at Delaware Estuary facilities. The gross disparity between EPA's estimates and the actual landings of these species could be related to a variety of assumptions, including inappropriate application of the survival adjustment factors, the method used to extrapolate from the model facility (Salem) to the other facilities, the assumption of 100% entrainment mortality of all life stages, and the assumption of no compensation. Whatever the combinations of factors, it seems clear that EPA's values probably overestimate the actual impact of these facilities, possibly by a factor of 10 or more. Inspection of the other values in Tables B3-16 and B3-17 suggests that impact estimates for other species entrained at Delaware Estuary facilities may also be unrealistically high. The estimated annual yield loss and production foregone for striped bass and weakfish, for example, are also greater than the 1990-2000 annual average commercial landings for these species in Delaware and New Jersey (~ 400,000 pounds of striped bass and 1.6 million pounds of weakfish).

The plausibility of EPA's model results can also be evaluated by examining the implications of the survival rate parameters with respect to the long-term growth rates of the populations. Considered over the long term, the average growth rates of most populations remain near zero. A decline of 50% within a single generation would be cause for great concern, yet, given the high uncertainty in estimates of early life stage mortality rates, it is easy to develop density-independent population models that predict growth rates far larger or smaller growth rates, e.g., an increase of 10x per generation or a decline of 99% per generation. Calculation of population growth rates per generation from life history data requires, in addition to the age-specific mortality rates documented in the life history appendices attached to the case studies, estimates of age-specific fecundity and % maturity. Fecundity and maturity estimates for alewife were available from PSEG (1999), and estimates for yellow perch were available from Docket 4-2046, the input spreadsheet for the Monroe case study. Values for Atlantic menhaden were not developed by either PSEG or EPA, but were available from a U.S. Fish and Wildlife Service report on Atlantic menhaden (Rogers and Van Den Ayvle, 1989). Age-specific fecundity values for these three species are provided in Table 3. These estimates, together with the stage and age-specific mortality rates used by EPA, were sufficient to estimate per-generation growth rates for each species, measured as the number of eggs produced by each spawned egg, given the probability of survival of each egg to reproductive maturity, the sex ratio (assumed to be 50% for all three species), and the expected lifetime egg production of each newly mature female. The necessary data for several other fish species are available in the 1999 permit application for Salem, however, as discussed below, the mortality rates used for Salem (and adopted in general by EPA) were adjusted to produce a net population growth rate of zero and so do not provide an independent test of EPA's modeling procedure.

The resulting population growth rate estimates are provided in Table 4. The values for Atlantic menhaden and yellow perch are generally within a range of 0.5 to 3.0. These are at least within the plausible range, and could be consistent with observed rates of change in real fish populations. For alewife, however, the Brayton Point values imply a growth rate of more than 6x per generation. This value could substantially overstate the actual impact of entrainment and impingement, depending on which mortality rates are responsible for the high growth rate and which life stages are most vulnerable to entrainment or impingement.

To overcome the problem of biologically unrealistic combinations of life history parameters, PSEG (1999) adjusted literature-derived early life stage mortality rates for all species to produce a net population growth rate of zero. The ratios of daily mortality rates for eggs, larvae, and early juvenile fish were fixed based on recommendations from independent experts, and then an "adjustment factor" was applied to each of the daily rates to reduce the net population growth rate to zero. PSEG's approach is not the only possible approach to reconciling conflicting literature-derived life history parameter estimates, however, it provides an illustrative example of how such adjustments can be performed.

Figure 5 shows results obtained by applying PSEG's procedure to the Atlantic menhaden, alewife, and yellow perch mortality rates used by EPA. The natural mortality rates for eggs, larvae, and juveniles of each species were adjusted by a common multiplier until a growth rate of zero was produced. Figure 5 compares, for each species, numbers of age-1 equivalent fish per unit entrainment or impingement calculated using EPA's values and using values calculated using the adjusted mortality rates. With the exception of Atlantic menhaden at Brayton Point, All of the adjustments reduce the number of age-1-equivalent fish lost per unit entrainment or impingement. In two cases, (alewife at Brayton Point and Atlantic menhaden at Seabrook/Pilgrim), the reductions are greater than 50% for at least one life stage.

Identification of Errors and Omissions in Documentation

As discussed above, the harvest foregone equation (Equation 7, p. A5-4) provided in the CSA report is clearly erroneous. EPA's interpretation of the weight term in Rago's (1984) production foregone model is also erroneous. Neither of these errors is evident in the text of the CSA itself, which is extremely vague and provides few details beyond lists of equations and terms. The nature of the errors was evident only from EPA's responses to UWAG's request for clarification of the methodology (EPA 2002, responses 1 and 3).

The CSA provides no rationale for the biomass transfer functions used to extrapolate foregone production to reduced yield of predators, however, the values themselves are consistent with values used in other similar studies. Similarly, no rationale is provided for the 80%-20% split assumed between direct and indirect trophic transfer pathways, and this choice of values appears to have been arbitrary. In response to a question on this rationale from UWAG (EPA 2002, response 6), EPA stated that the 20% fraction assumed to be directly consumed by predators was "…introduced for illustrative purposes only to present the rationale for using the low net transfer efficiency of 2.5%." In other words, the choice of transfer factors was arbitrary.

The scope of this review did not include a detailed evaluation of the individual case studies; however, spot checks of the case studies indicate that there are some significant omissions in documentation. In particular, all of the appendices contain tables (e.g., Table B3-17 of the Delaware Estuary case study) of production foregone estimates for harvested species. No explanation is provided concerning how or why these tables were developed. According to Chapter A5, the production foregone method was to be applied only to forage species. The sources of early life stage mortality rates for many species are also inadequately documented. Some of the values appear to be biologically unrealistic, however, the most unrealistic values often were not actually used in the benefits analysis.

Conclusions

The models described in Chapter A5 of the CSA are superficially similar to the models used in other assessments of impacts of entrainment and impingement on fish populations, however EPA made at least two significant errors in interpreting the original sources for the models used. In both cases the errors lead to overestimation of the reduction in harvest attributable to entrainment and impingement. Even when correctly applied, these models do not account for biological compensation. Because of this limitation, the CSA methodology should, even using correct formulations, overestimate actual impacts of entrainment and impingement on age-1 abundance, harvests, and production foregone. The calculated benefits associated with reducing entrainment and impingement impacts would, as a consequence, be overestimated.

Aside from the errors and the conservative assumptions, the models used by EPA are highly sensitive to assumptions concerning patterns of vulnerability with any particular life stage and to values chosen for key parameters, especially larval and juvenile mortality rates. Examination of a few examples in the case studies shows that EPA may well have made inappropriate assumptions in some cases, and that inadequate care was taken in the development of life history parameters for many species. Some of the errors would have reduced the projected values of age-1 equivalents, harvest foregone, and production foregone, however, in most of the cases examined the errors appear to have inflated those values.

EPA does not appear to have performed any reality checks on the models or the results. Examination of individual mortality rate parameters (Table 2) and estimation of implied population growth rates for selected species (Table 4) shows that many of the parameter sets are biologically unrealistic. Simple comparisons of the estimated harvest foregone to the known harvest of commercial species should be clues that there are probably errors in the analyses. The huge disparity between the estimated spot and croaker harvest and production foregone estimates developed for the Delaware Estuary case study and the actual New Jersey and Delaware landings of these species indicates that for these species the bias may be as large as a factor of 10 or greater, although without a detailed evaluation of the calculations it is not possible to determine the source of the bias.

EPA has been conservative in assuming 100% mortality of all entrained organisms (see EPRI's separate comments regards this assumption), no compensation, and constant susceptibility to entrainment throughout the juvenile life stage. Although I did not perform an exhaustive evaluation of all species or a statistical sampling of species evaluated by EPA, it appears that most of the assumptions chosen by EPA lead to overestimation of the impacts, not to a balance of overestimates and underestimates as claimed in Section A5-4 of the CSA.

[see hard copy for tables and figures]

EPA Response

Regarding the survival values used by EPA, please see response to Comment 316bEFR.305.003.

In response to comments on compensation, please see EPA's response to Comment 316bEFR.025.015.

Another technical issue noted by the commenter involves the method for adjusting survival rates of entrained juveniles. Several commenters indicated that entrainment of juveniles occurs predominantly to fish that are early in the juvenile stage, because older juvenile individuals are stronger swimmers and are therefore able to avoid entrainment. Commenters noted that it is therefore appropriate to use unmodified survival rate parameters (Sj), rather than using parameters that are modified (S*j) to account for an unknown precise within-stage ages. EPA acknowledges that the commenters have identified a valid improvement to the method, and EPA has discontinued application of S*j for assessing juvenile entrainment.

Regarding EPA's calculation of production foregone, please see response to Comment 316bEFR.305.003.

The commenter notes a problem in the Case Study Document submitted at proposal in EPA's reported equation for calculating foregone yield. The equation in question was misprinted in the document, but has been corrected in subsequent reports. Note that the associated calculations were performed with the proper equation, not the misprinted equation.

The commenter questions the structure and basis of the trophic transfer model. EPA has responded to this question as part of its response to Comment 316bEFR.306.202.

The commenter states that the reporting of citations of the sources of survival rates is inadequate. However, EPA notes that the sources of all life history parameter values used in its I&E analyses are provided in an appendix to each regional report in the Regional Analysis Document (DCN #6-0003).

The commenter questions EPA's identification of survival rates, in particular the use of the equation Seq = 2/fa to estimate survival rates. The commenter has misinterpreted EPA's use of Seq = 2/fa In fact, EPA used the equation only in very few instances, and only in cases where survival rates for particular life stages were unknown. In such cases, EPA used the method in conjunction with known survival rates in other life stages to deduce a survival rate for a single stage. In no cases did EPA use the method to infer survival rates throughout the entire lifespan of a fish. The commenter correctly notes that survival rates vary dramatically between life stages, and the parameter sets used by EPA reflect that.

The commenter asserts that EPA has not done any "reality checks" on the results. This is not true. In fact, EPA conducted rigorous QA/QC as well as "reality checks" on all results. EPA recognized that in some cases its estimates of foregone harvest were larger than actual empirical harvest rates even though all growth and mortality rates appeared reasonable. This issue is complicated by uncertainty about what to assume about the nature of particular fisheries. For example, EPA did not wish to assume that every stock was fully exploited, nor did it wish to make other stock-specific assumptions about how the fishery might respond if the stock changed as a result of reductions in I&E. EPA considered capping estimates of foregone harvest in some relation to current harvest rates, but eventually elected not to alter the basic results by capping loss estimates in this way, given no compelling reason to do so. EPA considers these cases to be more uncertain than its other estimates. However, such cases were few and did not significantly affect EPA's results or lead to any distinct bias in the overall national benefits analysis.

The commenter has concerns about EPA's assumption of 100% mortality of all entrained organisms.

EPA has responded to this issue in its response to Comment 316bEFR.306.506 and in Chapter A7 of the Regional Analysis Document (DNC #6-0003).

At the request of EPRI (Electric Power Research Institute), I performed a technical review of the EPA Case Study Assessment (CSA) methodology (DCN 4-003), a supporting document to the EPA Proposed Phase II Section 316(b) Rule for Existing Facilities (67 Fed. Reg. 17,121-225; April 9, 2002). The following are the results of my review.

EPA has the daunting task "to protect human health and to safeguard the natural environment air, water, and land upon which life depends." The consequences to society of not succeeding to accomplish this task are sufficiently grave that it seems prudent to proceed with a conservative strategy, a strategy that is more likely to err in the direction of being over-protective rather than under-protective. In the last decade experience has illustrated the consequences of relying heavily on models and not being sufficiently conservative. Examples of highly managed fisheries that suffered disastrous consequences include the 1992 collapse of the North Atlantic cod fishery, 1993 collapse of the pacific herring fishery in Prince William Sound and the 2000 collapse of the King Salmon fishery in Yukon River Alaska. In some cases the fisheries models gave warning that collapse was near, but regulating agencies were reluctant to reduce fishing pressure out of short sighted concern for the economic welfare of those in the fishery.

In the CSA, EPA indicates that it intends to take a “precautionary approach” to estimating the CWIS impacts, in light of the “at risk” status of may fish stocks CSA, A6-6. This review does not challenge EPA’s decision to take a conservative position on protection of the environment, but instead it addresses the statistical effects of a multiplicity of conservative decisions. In particular, I consider the likelihood that numerous conservative decisions in a sequential process will result in a final position that is overly conservative. An overly conservative decision will be more costly than is needed to protect a resource.

In this discussion I consider a conservative decision to be one that is protective of the environment in an extreme condition that has a low probability of occurring. A example would be a water policy that insures adequate water supply even in a drought that is expected to occur once in 100 years. An overly conservative decision might be one that is protective of a once in 100 thousand-year event. The geological record indicates that in a period of 100 thousand years, planetary conditions will be sufficiently changed that the conditions under which we formulated this decision would no longer apply. Thus, most would agree that planning on that time scale is folly.

I begin with a simple example that illustrates how conservative steps in a sequential process can result in an overly conservative position. Assume a five-step process. At each step, there is an estimate with some degree of uncertainty. The estimate of each subsequent step is based on the estimate of the previous step. Because of this structure, uncertainty propagates through the process. At issue here is whether it is better to manage this uncertainty by being conservative at each step or by estimating the propagation of error to the final step and being conservative at the final step only. To illustrate the difference between the two, consider a specific case. Let the first step have a mean of 6 and a variance of 1.0. At each subsequent step the process is increased by a random variable with mean = 1.0 and variance = 1.0. Thus at the final step, the process has a mean of 10 and the error has propagated up to a total variance of 5.0.

In this five-step process it is desired to manage risk to protect against a 1 in 100 event. This is consistent with the use of a 99% upper bound. If one were to compute a 99% upper bound at each step and use that as the mean for entering the next step, the upper bound attained in the last step is 21.6. The probability of obtaining a value as extreme as 21.6 in a distribution with a mean of 10 and a variance of 5 is about 1 in 100 million. Clearly, taking even a moderately conservative position at each step in a multi-step process can result in an extremely conservative position. A 99% upper percentile of the step 5 distribution (mean=10, variance=5) is 15.2. This illustrates that taking a conservative position at each step of a multi-step process can result in a final position that protects against events with risk 5 in 100 million when the intention is to manage for risk of 1 in 100.

In what follows, I look specifically at the steps for evaluating impingement and entrainment (I&E) losses as presented in EPA case studies and examine the conservative nature of some steps in the EPA assessment. While the degree of conservatism may seem reasonable at each step (and sometimes not), bear in mind that in a few steps, it will accumulate to a position that is extreme. In most cases, it is impossible to put a probability level on the degree of conservatism used by EPA and thus it is not possible to judge the total degree of conservatism.

The evaluation of I&E as presented by EPA in its summary of case studies is a multiple step process. At a gross level, the steps can be thought of as:

1. Impingement and Entrainment Estimation. Numbers of fish impinged or entrained a estimated based on statistical sampling designs and methods.

2. Equivalent Adult Modeling. Estimating the number of additional age 1 fish that would have entered the population if there had been no losses to I&E.

3. Direct Foregone Production: Forecast of pounds of fish lost to commercial and recreational fishery as a result of I&E of species exploited by commercial and recreational stakeholders.

4. Indirect Foregone Production: Forecast of pounds of fish lost to commercial and recreational fishery as a result of I&E of forage species.

5. Economic evaluation: The translation of production losses into economic value based on Cost of

replacement and perceived non-use benefits.

However, within each of these steps, there is more than one opportunity to be conservative. For example, in the production-forgone model there are four independent variables and each of these is supported by a separate model. For each independent variable, one might first choose a conservative model and then choose a conservative estimate from that model. As a result, there are at least eight opportunities to be conservative in this single calculation as I illustrate:

$$Pji = \frac{Gi\ Nij\ Wi\ (\exp(Gi-Zi) - 1)}{Gi - Zi}$$

The independent variables are:

Gi= instantaneous growth rate for individuals during stage i
Nj= number of individuals loss at stage j expressed as equivalent age stage i fish.
Wi= average weight for individuals of stage i.
Zi = instantaneous total mortality rate for individuals of stage i.

For each of these we might choose between models (a) and (b):

Gi :(a) constant growth rate model
(b) decreasing growth rate model (e.g., von Bertalanffy model)

Nij: (a) equivalent adults model without compensation
(b) equivalent adults model with compensation.

Wi : (a) unweighted average of biomass
(b) weighted average of biomass

Zi : (a) constant mortality rate model (e.g., negative exponential model)
(b) decreasing mortality rate model (e.g., Pareto Model)

Holding all else constant, one of the two models listed for each independent variable will predict higher production lost and is therefore environmentally conservative relative to the other. In addition, there will be uncertainty in the estimate that may be modeled by a statistical formulation. One may choose a value from the environmentally conservative side of the distribution of plausible values. This provides eight opportunities to be conservative. If the initial example of a five-step process is extended to an eight-step process, then the result of making a conservative choice at each of eight opportunities is to arrive at an extreme position that has probability of a little less than 1 in 200 billion. I am not saying that EPA has implemented production calculations with this extreme degree of conservatism, but this illustrates the potential of getting off the scale of realism in a single calculation.

In presenting the case studies, EPA has repeatedly made a number of conservative decisions that push estimated benefits off the scale of realism. Examples include:

1. Setting entrainment and impingement survival to zero.

2. Not using models that employ compensatory mechanisms when estimating equivalent adults.

3. Estimating production by life-stage categories using constant mortality and growth within life stage.

4. Summing direct and indirect losses.

5. Estimated use-based benefits on the basis of replacement costs rather than on the basis of increase in value in the resource.

6. Estimating non-use benefits and a multiplier of use-based benefits when quantification of these benefits is very uncertain.

EPA supports these decisions as follows:

I&E survival: The EPA position on entrainment and impingement survival is: "Although EPA agrees with the conclusion of the EPRI report that an assumption of zero entrainment survival rate for all facilities may be unwarranted for certain species and certain conditions, EPA believes that it remains to be determined whether non zero survival rates are common for cooling water intake structures in general." CSA, p. A7-14 makes it clear that this is one of numerous conservative choices presented in the case studies.

Compensation: EPA again chooses a conservative approach in its treatment of compensation. The agency acknowledges that the concept of density dependence is fundamental to the study of biological populations and to the application of population modeling in fisheries management. EPA, however, chooses to implement several density-independent models to conservatively estimate potential consequences for fishery harvests and ecosystem production. EPA justifies this choice saying "Given that many fish stocks are at risk, EPA has adopted a 'precautionary approach' in evaluating CWIS impacts because of the many uncertainties associated with modeling compensation and stock-recruitment relationships." CSA, p. A6-6. The Agency further states: "EPA believes that the many uncertainties associated with modeling stock-recruitment relationships and potential compensation justify this approach, in keeping with the precautionary approach to environmental decision-making." CSA, p. A6-7.

Estimating production: While EPA acknowledges the conservative nature of the I&E survival and the compensation choices, the conservative nature of the production-forgone calculations are less obvious. The EPA suggests a life-stage model with constant population rates within stage as a tool for evaluating production foregone. Using data from a power station study (Loos and Perry, 1989) where larvae were measured to the nearest mm, I compared the computation of production based on life-stage categories and production based on 1-mm categories. The use of constant rates over broad life-stages results in an estimate of production that is 3 or 4 times greater than the estimate obtained using 1-mm categories. This difference is largely resolved by a within life-stage adjustment (S* of equation 4 , Chapter 5), but is it not clear that EPA recommends this adjustment for production foregone (equation 8, chapter 5). Barnthouse also discusses biases due to this life-stage model (see separate EPRI comments in Appendix A).

Summing direct and indirect losses: In general, it would seem that direct and indirect losses should be combined by a maximum function rather than a sum. The logic supporting use of a maximum rather than a sum is as follows. Suppose an aquatic system had 1000 potential recruits and was balanced such that it had forage to support these 1000 recruits. If a CWIS removed 100 of the 1000 potential recruits and at the same time removed forage that could have supported these 100 recruits, then the cumulative effect remains at 100 which is the maximum of the direct and indirect losses. Summing direct and indirect losses is a conservative choice.

HRC benefits: EPA endorses a Habitat-based Replacement Cost (HRC) for evaluating I&E losses. Many economists believe that evaluation of benefits on the basis of replacement costs rather than on the basis of increase in value in the resource results in a over-estimate of benefits (See comments prepared for EPRI by Dr. Ivar Strand, Appendix C). This is another conservative position in the I&E evaluation process.

Non-use Benefits: Citing Freeman (1977), EPA applies a rule of thumb for national-level passive use benefits of water quality improvements of 50-percent of the estimated recreational fishing benefits. EPA further cites Fisher and Raucher (1984) who "conclude that since nonuse values were likely to be positive, applying the 50 percent "rule of thumb" was preferred over omitting nonuse values from a benefits analysis entirely". EPA goes on to discuss a list of uncertainties related to the 50% number and concludes that it intends to revisit this topic, but will apply the 50% number in the interim. In view of this uncertainty, it is impossible to know if 50% is a liberal or conservative estimate of non-use benefits. However, on the one hand setting non-use benefits to 50% of angling benefits on the assertion that is "must be positive" and on the other hand setting entrainment survival to zero when it has been demonstrated to be positive is inconsistent logic applied in a conservative direction.

Conclusions

In the preceding, I have demonstrated the risk of obtaining an end result that is overly conservative when a reasonable level of conservatism is applied repeatedly in a multi-step process. I have shown that the EPA case studies demonstrate a multi-step approach to evaluating I&E losses and that EPA has made a number of conservative choices in that process. From this I conclude that following the EPA methods as presented in the case studies will result in an overly protective evaluation of I&E losses. Given this general tendency toward environmentally conservative evaluation of I&E losses it is disturbing the find that EPA repeatedly alludes to existing estimates as underestimates with comments such as the following:

"EPA notes that most of these studies were completed by the facilities in the mid-1970's using methods that are now outmoded. A number of the methods used probably resulted in an underestimate of losses." CSA, p. A8-1.

Our experience has shown otherwise. In cases where initial studies showed large I&E losses and additional studies with improved methods were conducted, the improved methods resulted in lower estimates of I&E losses (Bailey et al. 2000). This trend is a natural result of the conservative approach to protecting the environment. Initial studies were performed using methods with a high degree of uncertainty. Because of the uncertainty, conservative choices are made and the resulting estimates are environmentally conservative. If the conservative estimates are not of concern, then no further studies are done. If the conservative estimates seem large, additional studies with improved methods are conducted to reduce uncertainty. The improved precision allows one to estimate a conservative position that is not as extreme as that obtained from the less precise study. Thus in general, improved methods result in lower estimates of I&E losses.

EPA Response

EPA regrets its unfortunate use of the term "precautionary approach," as discussed in EPA's response to Comment 316bEFR.005.026.

EPA disagrees that there are multiple conservative assumptions in its final benefits analysis. First, the analyses referred to in points 5 (replacement costs) and 6 (50% rule) of Dr. Perry's comment are no longer included in EPA's analysis. For a discussion of replacement costs, please see response to Comment 316bEFR.005.035. For a discussion of the 50% rule, please see response to Comment 316nEFR.005.034.

Regarding entrainment survival (point 1), please see response to Comment 316bEFR.306.056. EPA notes that its analysis did consider impingement survival in cases where data on survival were presented in the facility documents that were used.

Regarding compensation (point 2), please see EPA's response to Comment 316bEFR.025.015.

Regarding constant growth and mortality rates (point 3), EPA made a good faith effort to use the best available life history data for its analyses, which seldom included information on variation in growth and mortality rates within life stages.

Regarding production foregone calculations, please see EPA's response to Comment 316bEFR.305.003.

Regarding the summing of direct and indirect losses (point 4), EPA notes that its analysis was not concerned with fishery recruits only; thus it was appropriate to consider the combined losses of both forage and fishery species.

Finally, EPA wishes to note that its analysis was unfortunately limited by the quality of facility-provided I&E data, which often had serious limitations for the purposes of EPA's 316b benefits analysis. Limitations included: (1) the geographic basis of data collections, which were not designed to support a national scale benefits analysis; (2) the set of facilities with available records is not a random or representative sample of all facilities; and (3) there are numerous inter-facility differences in sampling methods, e.g., the frequency of collection (many studies are from the 1970's and include only 1-2 yrs of data or only count losses on a seasonal basis for a subset of species); lack of information on collection efficiency or variance in I&E estimates; lack of taxonomic detail (e.g., many losses not identified to species level); many facilities did not report losses according to size/age classes of fish during first year of life; and many facilities only evaluated a subset of the species impinged and entrained.

All of these limitations resulted in many data uncertainties that were beyond EPA's control, as discussed in Chapter A6, Chapter A10, and the regional reports contained in the Regional Analysis Document (DCN #6-0003)and in response to Comment 316bEFR.041.843.

Benefit Estimation Methodology

The following is a critique of the methods, procedures and case study examples of the economic analysis associated with the benefits and costs of implementing performance standards shown in the EPA Proposed Rule for Phase II Existing facilities. This critique will not consider in detail all eight case studies. It raises questions regarding methods and techniques associated with the benefit estimation and raises questions regarding the application of methods and techniques in three of the case study examples. It does not attempt to assess the biological models associated with the benefit estimates nor with particular estimates associated with the Habitat Replacement Cost (HRC) method. <FN 1>

The Methods of Estimating Benefits from Reduced Entrainment and Impingement

There is a long history of using benefits and costs to assess proposed regulatory actions and a long list of literature associated with methods to assess them. Based on that history and literature, one could conclude that the economic profession as a whole would have substantial disagreement with several of the methods EPA used to assess both use and nonuse benefits of the proposed rule.

Chapter A9 of §316 (b) Existing Facilities Benefits Case Studies, Part A: Evaluation Methods contains EPA's judgments regarding methods to assess four different categories of benefits based on whether the goods arise from: marketed goods, non-market direct use goods, non-market indirect use goods, and non-market non-use goods. I will comment on EPA's choices of methods to be used and, later in this review, on their application of the methods in several of the case studies. Of the methods suggested in Chapter A9 and used by EPA in the case studies, the benefit transfer method, the RUM models and value of foregone production are legitimate concepts for estimating benefits of the proposed rule. Three other methods employed (HRC, forage fish replacement costs and the use of 50% of use value to measure nonuse value) are not.

In most case studies, EPA employs a "benefit transfer" <FN 2> method of analysis to obtain some of the use values used in their analysis. This method, properly applied, has a solid foundation in economic theory. But it is important to note that this approach must be used with much caution and good judgment because it can be grossly inaccurate in natural resource valuation. The goods being valued are based on natural resources, sought in their natural state and location, and that fact must be taken into account. The value of a natural resource-based good is inherently dependent on location (e.g., the value of a bag of sand in the Sahara desert is different from one in New York City). Taking a value produced in one study and applying to another circumstance might introduce substantial error. Applications should be done with care, and there are numerous instances in the case studies where greater care should have been exercised.

In other studies, EPA relies on values derived from Random Utility Models (RUM). Without the data and programs to evaluate the models, it is difficult to check particular benefits estimates. While the model is a perfectly reasonable approach, the devil is in the detail. The two case studies that I examined, the Ohio River and the Salem Nuclear Plant, produced results that cannot be defended in my opinion and require more effort on EPA's part if they are to be used.

Use Benefits from Marketed Goods

The primary marketed goods likely to be affected by the proposed rule are commercially harvested fish. The document transfers benefits based on literature that have little correlation with those EPA seeks to examine here. The proposed regulations state that the producer surplus (short run benefits to fishermen) should be estimated as lying between 40 and 70% of the increase in gross revenues to fishermen. These are presumably estimates of increased short run profits to fishermen. The procedure is based on West Coast studies by Rettig and McCarl (1985) and on Great Lake studies by Holt and Bishop (2002) and Cleland and Bishop(1984). There is no East Coast study cited, which is strange given that the only commercial fisheries that are important in the national aggregates are the non-Gulf estuaries and these estimates are based solely on the Delaware Bay. The Norton et al. (1983) study on the Atlantic coast striped bass estimated a surplus for striped bass of approximately 15% of ex-vessel value but was not used here despite being used later when examining the benefits to consumers. In general, the producer benefits depend greatly on the fishery and on the year considered. Wild fluctuations in fish abundance imply wild fluctuations in producer surplus. A reasonable estimate of the short run benefit might be 15-40 % of the new revenues. <FN 3> Because most fisheries are not limited in the number of fishermen or anglers that can enter, long run adjustments in fishing effort are likely to be important. When a change such as the proposed rule occurs, fishing increases and drives down the stock, reducing the gains to the point that only “normal returns” occur. If this happens, there are no long-run benefits to fishermen from the initial improvements. Most U.S. fisheries are managed as open access systems so that one would expect long run benefits to be eliminated.

In most instances, it would be better for the analyst to understand what is happening in the fisheries and, if necessary, survey the industry to determine the appropriate percentages. Given that EPA does not want to devote this effort to commercial benefit estimation, I suggest that

1) For very small changes in production in open access fisheries, an estimate of 15% of new revenues could represent a lower bound and the 40% of new revenues themselves would provide a realistic upper bound on the economic surplus lost from I&E.
2) For larger changes in open access fisheries that draw new entry and cause increased costs, use 15% of new revenues declining to zero over time for a lower bound and 40% new revenues declining to zero for an upper bound.
3) For large or small changes, when the fishery is managed as an individual transferable quota, take the present value of 15% of the new revenues for a lower bound and the present value of 40% of ex-vessel revenues as an upper bound.

EPA extends the benefits to market agents above the ex-vessel level (e.g., wholesalers, retailers, and the ultimate consumers) based on the producer surplus changes. Citing the Norton et al. (1983) work and personal communication with Bishop and Holt (2002) and Bishop (2002), EPA decides to use an expansion factor of 3.5 to estimate benefits to consumers and all other economic agents. Following the EPA procedures, the process implies that the national benefits will rise between $1.8 and $3.15 for every $1 of increased dockside revenue. This is completely arbitrary.

As an alternative to this procedure, one could estimate an ex-vessel demand curve properly (Just et al., 1983; Thurman and Easley, 1992) and obtain all of these values directly. The ex-vessel data exist and, based on my experience, can be used to identify ex-vessel demands because the supply curves shift dramatically with stock changes. This is neither a difficult nor an expensive procedure and it might provide justifiable short run benefit estimates. It does not distinguish gains to consumers (that are long run) and short run gains to wholesalers and retailers.

In all studies, another factor should also be noted: it takes time to build fish stocks. EPA apparently does not consider time adjustment for the lag between when the rules are implemented, the new structures installed, and the fish stocks rebound. If EPA accounted for the time delay and adjusted the benefits with a social rate of discount, then the annualized returns would be a smaller and a more appropriate estimate.

As it stands, the analysis of the benefits to commercial fisheries has absolutely no economic content. The nation is being asked to make a $15-30 billion investment in part based on commercial benefit estimates; it seems reasonable that the estimates have some economic content.

Direct Use Benefits from Non-Marketed Goods

The primary benefactors of the proposed regulations in many instances are likely to be recreational anglers. The document proposes that the preferred methods of economic analysis for sportfishing are the random utility model (RUM) and the benefits transfer approach. The benefits transfer approach utilizes previous studies to infer values applicable under different circumstances. Typically, a RUM model will yield a benefit measure for a change in historic catch rate. The improved sportfish populations from changes in intake technology are alleged to increase the catch rate, and the benefit measurement will be the value/catch rate times the improvement in catch rate times the number of fishing trips. In some cases, the improvement that may induce an increase in the number of total trips taken must also be considered.

These two approaches are clearly the most desirable of those methods available However, the details of the analysis are critical, and bad study results can arise from use of a good methods. Table A9-2 of the Economic and Benefits Analysis shows the previous research used to develop benefit estimates in the case studies. Given the tremendous advances in methodologies of estimating benefits since the early 1980’s and potential changes in tastes, the early studies referenced in the Table may be of little use.

Indirect Use Benefits from Non-Marketed Goods

EPA assumed that forage fish stocks will be enhanced by the proposed regulations and EPA uses two methods to value the increase:

1.) The replacement cost of improving the stock. This is not a legitimate method from an economic perspective.
2.) The foregone commercial and recreational production. This is conceptually correct but may be difficult to implement.

Let us deal with the general notion of replacement costs first. The “Replacement Cost” (including the Habitat Replacement Costs) approach to benefit estimation is the most critically flawed part of the CWIS proposed regulations because the costs of activities, not the satisfaction of individuals, are used as the basis of estimating benefits. It might be instructive to review how “defensive expenditures” or costs of actions can end up as benefits in any economic analysis. In doing so, hopefully the reason why they should not be used in this instance will become evident.

To begin with, the economic notion of benefits derives from an individual's welfare improvement- that is, individuals obtaining satisfaction from improvements in their surroundings. The use of replacement costs derives from a literature on "defensive expenditures" or "averting behavior". In that literature, individuals are observed to incur costs to avoid or avert an environmental harm. For example, if the effects of groundwater contamination can be avoided by filters and households chooses to incur the filtering costs and the households' welfare from pre-contaminated groundwater is the same as from filtered groundwater, then one can say that the value households' place on clean groundwater is at least as great as the averting costs that they incur. One can also say that the cost to society of the original contamination is no greater than these averting costs. (all costs are assumed to be variable) (Bartik, 1988; Abdalla, Roach and Epp, 1992). These are strong assumptions that must be true for these bounds to hold and the actions must be based on individuals' behavior. The only reason there is a relationship between costs and benefits here is that the individual is comparing the two and only choosing to incur the cost if they are no greater than the benefits.

Now let us consider the cost of replacing forage fish that is necessary to offset the value of the commercial and recreational harvest they provide. First, these costs are not costs incurred by individuals who are comparing their benefits with these costs but costs incurred through a political process. EPA seems to argue that the political process allocates so that benefits are as great as the costs and EPA then chooses a situation, such as San Francisco Bay, to justify its point and obtain costs. The first presumption, political choice reflects value, is hard to believe. Even if it were true, there are probably 10,000 communities and waterbodies (including the ones being considered) that have not incurred forage fish replacement costs. Why choose the communities that have incurred replacement costs instead of the ones that have not? If we were to consider only the replacement/mitigation costs, then we'd have to deduce that the local value for the CWIS is lower than replacement/mitigation costs because the vast majority of communities have chosen not to incur them. <FN 4> Accepting the proposition that a political process reflects benefits greater than costs and then choosing a representative replacement cost (including zeros), one would have to conclude that the value to communities was nearly 0! The forage fish improvements benefits <FN 5> are not necessarily zero but the process of using selected replacement costs to reflect values is not defensible.

To conclude, the alternative that EPA proposed, the use of the "dollar value of foregone commercial and recreational production" is far superior to using replacement costs. In most of the case studies, estimates of lost commercial and recreational value because of decreased forage fish abundance are already provided. These values should be used and the use of replacement costs should be eliminated.

Nonuse Benefits

The improved stock of fish and other organisms not caught by commercial or recreational fishermen may have some value by themselves even after the value used to produce goods and services have been estimated. These are called nonuse values. Some economists do not believe in the concept of nonuse values (e.g., Rosenthal and Nelson, 1992), others believe that nonuse values should not be estimated and not included with use values (e.g. Quiggin, 1998), and others include them as part of cost-benefit analysis and would have them estimated using contingent valuation (e.g., Arrow, et al., 1993; OMB, 1996). The proposed rules go further and suggest four processes: contingent valuation method (CVM), a value proportional to the use values (i.e., 50 % of the use value), a benefits transfer approach, and habitat replacement costs (HRC).

CVM analysis is a common although controversial method of obtaining nonuse values (Arrow et al. 1993). Most economists would consider it the only possible way of determining nonuse values. It is interesting to note that despite the enormous expenses incurred in valuing resources over the last 20 years (including the case studies under consideration), no one in the world has studied the non-use value of changes that occur around cooling water intakes. It seems reasonable that EPA should address this fundamental lack of knowledge. The only feasible way is through the use of a well-designed contingent valuation study. At the same time, they could also examine whether there are negative externalities associated with cooling towers and the plume associated with them. The study would need to be well designed to avoid many of the potential biases associated with its application (Arrow et al., 1993).

Because there is no directly relevant literature, how can one employ a reasonable benefits transfer approach? Because nothing exists related to CWIS technology, the case studies estimate nonuse values as 50% of the use value, citing the work of Fisher and Raucher (1984) as justification. However, the cited literature and all studies that I have reviewed have not addressed the circumstances surrounding the CWIS regulations. The reason that there are no relevant studies with comparable use and nonuse values for CWIS might be that no one ever thought that there were nonuse values here. It is clear that for any of the reasonable approaches to work, some primary research needs to be done on nonuse values associated with effects from CWIS.

The habitat replacement method (HRC) suggested and used by EPA is not a reasonable method, mostly because of the problem of using costs as benefits as discussed above. The rationale for using the costs of habitat replacement probably stems from the literature on marine and estuarine wetlands. Wetlands offer nursery grounds for commercial and recreationally caught species and provide other services such as erosion, wind and wave barriers. The values of services such as erosion control are nearly impossible to deduce from the use of the wetlands by local citizens. Many studies have estimated the wetland benefits by examining the cost of replacing the wetland services with other objects (see Anderson and Rockel, 1991 for a review). The replacement costs have been called "Economic Value of Wetlands" (see Kahn, 1998, p. 383). But they are not necessarily benefits because of the differences in the manner in which the original defensive expenditure argument and the wetland cost approach have been applied. The original defensive expenditure argument laid out all of the assumptions that were necessary for defensive expenditures to reflect benefits and assured that the application conformed to those assumptions. The Abdalla et al. (1992) application provided an excellent example of how to use it properly.

The wetlands argument for using replacement costs of services is not so convincing. In general, the wetlands services that are "valued" have not been lost, so that the knowledge of whether people would make expenditures to replace the services is unknown and the level of needed expenditure is unknown. The estimates of expenditures to offset wetlands loss are usually transferred from other situations. Given that values of natural (i.e., in situ) resources are inherently dependent on location, the cost (or benefits) transfer approach is fraught with potential for error. Also, there is no guarantee that affected individuals' welfare would be the same with the wetland and the alternative. Thirdly, the expenditure estimates (e.g., with erosion, land stabilization structures) are derived from government actions. As argued above, the link dependent on the benefits being at least as great as the costs is no longer established under collective action.

As a final comment, the wetlands alternative services that have been valued with cost estimates are almost exclusively use values, not nonuse value. EPA is attempting to use the defensive expenditure concept in a new context, <FN 6> one in which potential environmental impacts from a cooling-water intake are considered to generate nonuse values of an unseen aquatic habitat. The nonuse values are measured by the potential costs of eliminating the environmental impacts. The extension requires a great leap of faith. First, there is no guarantee that the impacts exist. <FN 7> Numerous other stressors of the environment exist and other organisms may have filled the niche of the forage fish. There is a reasonable chance that eliminating the cooling water flow will have little or no positive impact on the waters adjacent to the intake. Hence there is a degree of uncertainty not present in the original basis of the defensive expenditures approach. Second, in EPA's approach, the nonuse benefits of the reduced impacts are measured. This is a highly unusual application of the defensive expenditure approach that is normally employed to assess use values. Defensive expenditures reflect revealed preferences and are most useful when based on individual choice. Finally, there is no reason to believe that the mitigation/replacement costs that EPA chooses are the least cost way of mitigating/replacing. <FN 8>

Through a political process, the use of defensive expenditures has emerged and is being used to answer questions it was not designed to answer. It is instructive to view the long-term consequences of following the proposed rule and its application. By making costs appear as benefits, the benefits of a project will rise exactly as costs rise. Thus, the most difficult and costly habitat restoration project will have the greatest benefits, irrespective of whether the resource is unique, whether there are numerous individuals near the location or whether there are other factors that might affect benefits. The perverse consequence of using the HRC approach is to require the most restrictive CWIS technology for cases where restoration of the habitat is most difficult (because the costs are benefits). <FN 9> To me, this is clearly nonsensical. As a Nation, we want to use our limited resources in the most productive fashion possible, not to use them to achieve the most costly results possible.

Economic Criteria in Decision Making

If EPA chooses to use economically inefficient performance standards and associated technology based on the current criterion of "significantly greater costs than benefits," it is imposing a cost to the nation. The proposed rule suggests that this is based on a precautionary principle, accounting for uncertain environmental effects that the CWIS might have on the environment. But what are the potential unexpected costs? While by definition we do not know, it seems that some activities are more likely to have more uncertain effects than others. Our experience with the use of cooling water intakes in power production has spanned many decades and unforeseen consequences are doubtful at this time. Using the precautionary principle in this instance appears overly cautious.

It also appears that the EPA is considering the criteria of "wholly disproportionate" to weigh costs against benefits. This is uncommon economic procedure and raises the cost to the society from the "significantly greater" criteria. Again, one should ask what uncertain consequences arise from using cooling water for power plants. Making the rule more stringent is moving in the wrong direction.

Despite using the "significantly greater costs than benefits" criterion, EPA appears to recognize that net benefits (benefits minus costs) should be positive and, facing a number of choices across different benefit estimation methods and case studies, reveals a preference for being “environmentally cautious” by choosing benefits methods that are associated with large values. This is inappropriate. If EPA chooses to use inefficient technologies based on the current criteria of “substantially greater costs than benefits”, then it is even more important that correct and unbiased methods and applications are used in the benefit estimation.

Footnotes

1 In some instances, particular estimates are used to show the absurdity of using replacement costs as benefits. However, the particulars are irrelevant because replacement costs generally do not measure benefits associated with the resource.

2 “Benefit transfer” is a term referring to the practice of taking an economic value derived for one situation and transferring it to another situation.

3 Many fisheries work under contractual agreements whereby 40-60 % of new revenues are a direct payment to labor. Using 40-70 % of new revenues as profits denies almost any other cost of production.

4 EPA uses Breffle and Rowe (2002) to defend the proposition that replacement costs are less than willingness to pay. However, the research was based on restoration associated with PCB contamination in the Fox River, not cooling water intake regulations.

5 Schell et al. (1996) suggest that increase in forage fish on the Ohio River actually reduced recreational harvests.

6 EPA might be considering HRC as benefits in the sense of “avoided costs” as damage assessment analysis often does. The conditions for this interpretation are clearly not evident in the proposed rule.

7 Perry et al. (2002) show that CWIS impingement and entrainment at several Ohio River facilities do not have perceptible impacts on populations of most (16 of 22 species) fish species examined.

8 This does not mean that mitigation such as replacing commercial or forage fish should not be considered as an alternative technology in the options for the plant. It only means that replacement costs should not be used as benefits, except in appropriate cases. None of the case studies to which HRC was applied appear to be appropriate cases.

9 EPA notes “Where restoration costs are very high, or where public values might be much lower than costs, economic studies can be conducted to determine the value of habitat replacement.” However, the case studies reveal that EPA is willing to use HRC instead of a reasonable alternative method even when these conditions are met.

10 Based on the value of $3.56/fish to $8.56/fish and assuming an average rainbow smelt weighs 8 ounces.

11 An actual replacement figure would be higher because the transportation cost of moving the fish is not considered in the $0.34/lb.

12 It is not clear why rainbow smelt was chosen as a forage fish and a commercial and recreational species at the same time. Presumably, all of these species are forage for another species at some point in the life history but rainbow smelt appears to have been selected as a special case.

13 Unpublished data, National Marine Fisheries Service.

14 The same would be true if costs per age 1 equivalent (Tables G6-41 and G6-42) were considered.

15 Additionally, it would be useful to know the names of the non-RIS species so that someone could determine whether $0.96/lb was legitimate.

16 For New England, Norton et al. propose a completely ad hoc adjustment to the value of $2.23/fish derived from the travel cost model. Whereas the $2.23/fish might be low, the addition of $10/fish because some of them are sold is not defensible.

17 There also may be overestimates associated with the usage of benefits transfer.

18 Pending EPA answers to my submitted questions, I am unclear as to whether or not any of the sites in the mainstem of the Ohio River were actually included in the original measurement. The abundances for the Ohio River sites may all have been derived from electrofishing abundance surveysin smaller streams or in the nearshore of the Ohio River.

19 The proposed rule states:

“Assuming that fish abundance is uniform within each pool, changes in relative fish abundance under different policy scenarios can be calculated as follows:

[see hard copy for equation]
(p. C5-10 and p. C5-11).”

EPA Response

EPA agrees that the benefit transfer methods, the RUM models, and the value of foregone production are legitimate concepts for estimating the benefits of the 316(b) rule.

This comment refers to EPA’s proposed rule analysis. For the final rule analysis, EPA has made significant changes in its methods and applications. For the final Phase II 316b analysis, EPA uses regional rather than local case studies, and has reduced its reliance on benefit transfer to estimate recreational fishing benefits. In the recreational fishing analysis, benefit transfer is used for the inland region, and benefit function transfer is used for the North Atlantic region. EPA has estimated RUM models for all other coastal regions (Mid-Atlantic, South Atlantic, Gulf of Mexico, and California), and for the Great Lakes region. Therefore, the comments on benefit transfer presented here are no longer relevant. For EPA’s response to comments on the methods used to estimate recreational fishing benefits for the final Phase II rule, please see the responses to comments 316bEFR.041.452, 316bEFR306.320, and 316bEFR337.010.

The comment recommends the use of species-specific discounting of future benefits. EPA has done so in its final rule analysis. This discounting takes into account both the lag in installation of the technology, and the lag in growth of fish to catchable size.

For EPA’s response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment 316EFR.005.029.

The HRC method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see the response to comment # 316bEFR.005.035.

As stated in the NODA, the rule-of-thumb approach to estimating non-use is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. Given the unavoidable uncertainties in estimating non-use benefits for this rule, the Agency presented a qualitative assessment of the benefits of the environmental protections at issue in the final 316(b) benefit cost analysis.

EPA does not agree that the only acceptable method of estimating non-use benefits would be to conduct an original stated preference study. Many resource economists support the idea that benefits transfer analyses, properly conducted, can be used as an alternative to a primary research survey in order to estimate non-use benefits. While it might be preferable to conduct such research in an ideal world, EPA did not deem it feasible as a matter of cost or timing to conduct such a primary study here. EPA also notes that failing to assess non-use values would only tend to make the qualitative assessment of ecological benefits all the more important.

The comment states that the fact that there have been no relevant studies with comparable use and non-use values for CWIS might indicate “no one ever thought there were nonuse values here.” EPA does not agree. The fact that a study has not been done for a particular issue does not indicate that the issue does not exist. There are many natural resources that people obviously value for which no non-use valuation studies have been done. There are numerous threatened and endangered species and significant habitats that are, by definition, significant. Yet they have not all been studied.

In addition, lack of quantification of CWIS losses with carefully designed and executed monitoring studies by the owners of these CWIS and scientifically and statistically sound annualizing procedures have prevented the public as well as economists from recognizing the full extent of the problem. Another major contributor to the lack of recognition of the issues surrounding CWIS is the fact that impingement and entrainment data, even when collected and appropriately annualized, are rarely evaluated on a watershed-specific basis or on a regional basis. Therefore, the extent of cumulative impact of I&E is typically unknown.

The comment states that a “wholly disproportionate” benefit cost standard is “uncommon economic procedure,” and suggests that EPA has selected valuation methods that produce large values. The Agency recognizes that quantification and monetization of ecological benefits involves unavoidable uncertainties and thus “precise monetization” was not attempted for the final Section 316(b) Phase II rule. For example, in addition to presenting monetized benefits EPA presents a qualitative assessment of ecological benefits. The Agency believes that it undertook reasonable, appropriate analyses and explained its approaches in the Regional Analysis Document for the Proposed Section 316 (b) Phase II Existing Facilities Rule. EPA points out that benefit considerations should not strictly determine policy decisions, and that other factors should also be weighed. For a discussion of benefit cost test in the context of the 316b rulemaking, please see EPA's response to Comment 316bEFR.005.020. For EPA’s response to comments on “wholly disproportionate” criteria please see comment #316bEFR.005.018.

EPA agrees that accurate valuation of benefits is critical when applying the benefit-cost test. However, no methods are available for estimating either costs or benefits with perfect accuracy or without uncertainty. Therefore, informed decisions must be made with the best available information and analysis.

The comment discusses EPA’s case study approach for the proposed rule. As mentioned above, EPA has changed its case study approach to a regional approach. In addition, EPA has changed some of the modeling procedures mentioned in this comment. EPA’s revised RUM models, conducted for the final Phase II 316b analysis, estimate separate values for boat and shore mode anglers. Values for boat anglers are applied to charter boat anglers in calculating total benefits. It is likely that charter boat anglers have higher per-day values than boat anglers, so using boat anglers’ values results in a lower bound estimation of value for charter anglers.

The comment states that the choice sets for RUM models should be larger. For the final Phase II 316b analysis, EPA estimated regional RUM models, thus allowing for the largest possible choice set for each angler. EPA’s specification of choice sets and distance calculations are significantly better than those in the available existing studies, including the Hicks et al. (1999) study that many commenters agree is a valid study to use for the 316b analysis (DCN #4-1603). While existing studies only allow substitution across counties, EPA's models include all possible fishing sites within each region, thus providing a much more realistic total choice set. Also, previous studies calculated straight-line travel distances between county centers. In contrast, EPA calculated a near approximation to actual road travel from the person's town to each specific fishing site, based on the lat/long coordinates of the site.

The comment states that historic catch rates should be used in RUM models. All of EPA's RUM models used in the final 316b Phase II analysis use historic catch rates for the five years including and preceding the year of the survey. For the final 316b Phase II analysis, EPA has estimated catch rates for no target anglers using average catch rates for all species caught by no target anglers at each site. Please see response to comment #316bEFR.306.320 for details.

The comment notes that one of the coefficients in EPA's original Delaware RUM model was negative. The RUM model estimated for the Mid-Atlantic region for the final 316b Phase II analysis has positive and significant coefficients on catch rates for all species and species groups.

The comment states that EPA's recreational fishing analysis for the North Atlantic could overstate values for winter vs. summer flounder. EPA does not agree. The North Atlantic regional case study uses a benefit function transfer based on the Hicks et al. (1999) study (DCN #4-1603). Hicks et al. (1999) estimates a single coefficient for the flounder/flatfish group. This group includes the following species in the flatfish/flounders group: summer flounder, sole, wither flounder, flounders, and southern flounder. See Hicks et al. (1999) p. 8. Fish size variations are significant within one species group and across all groups considered in Hicks' analysis. Thus, the analysis of Hicks et al. is applied to assess an average "flounder" caught in the North Atlantic region. There is no empirical evidence that this value either overstates or understates the value of winter flounder.

EPA has changed its Inland and Great Lakes approaches. For the Great Lakes region, EPA has conducted an original RUM study.

For the Inland region, EPA did a benefit transfer using values from numerous studies. EPA followed its Guidelines for Preparing Economic Analyses for benefits transfer (BT) in developing a benefits transfer approach for the Inland region. The steps were followed as recommended in the Guidelines when using BT: (1) describe the policy case; (2) identify existing, relevant studies; (3) review available studies for quality and applicability; (4) transfer the benefit estimates; and (5) address uncertainty. Further information on the methods EPA used to estimate recreational fishing benefits for the Inland region is provided in the regional study document prepared for the analysis for the final Phase II rule. See Chapter H4: Recreational Fishing (DCN# 6-0003).

Case Study Specific Comments

Case Studies

Because the proposed rule depends in large part on how EPA applies the choices of benefit methods available, it is useful to review the case studies accompanying the rules. Three case studies involving the Delaware River (Salem, Hope Creek, Edge Moor, and Deepwater facilities), the New England coast (Pilgrim and Seabrook facilities), and the Ohio River (nine facilities from southwestern Pennsylvania to mid-Kentucky/Indiana) were chosen. In addition, there is some discussion of information associated with the Brayton Point study, a facility outside of these three case studies.

EPA Response

EPA's notes that its final analysis for the Phase II rule including many more facilities (a total of 46) than were evaluated for proposal. For information on EPA's extrapolation approach for the final rule, please see Chapter A5 of the Regional Analysis Document (DCN # 6-0003) and response to Comment 316bEFR.041.041.

Subject Matter Code 10.03.06

Pilgrim and Seabrook

New England Ocean Facilities (Pilgrim and Seabrook)

The two New England Ocean facilities considered by EPA are nuclear power plants that are on the Gulf of Maine in similar ecologies but have different intake structures. The Pilgrim intake is located in an artificial embayment, whereas Seabrook's intake is located over a mile offshore in deep water. Seabrook is located in Massachusetts, near the New Hampshire border, while the Pilgrim plant is located on Plymouth Bay, 38 miles south of Boston. The information associated with Pilgrim in addition to information from the J.R. Whiting facilities on the Great Lakes, is used to extrapolate the benefits from reduced I&E to all of the nation's relevant facilities on the Ocean and Great Lakes.

According to the data presented by EPA, the entrainment of fish is several orders of magnitude higher than the impingement at both the Pilgrim and Seabrook facilities. The commercially or recreationally harvested fish species that also are impinged at Seabrook include winter flounder, red hake and Atlantic silversides. At Pilgrim, the harvested species that are impinged include Atlantic silversides, Atlantic herring, rainbow smelt, and Atlantic menhaden. Primary harvested species that are entrained at Seabrook include Atlantic mackerel, winter flounder and red hake while Atlantic mackerel and cunner are entrained at the Pilgrim plant. There also are estimated forage fish losses at both facilities, "including fourbeard rockling, lumpfish and rock gunnel at Seabrook and American sand lance, fourbeard rockling and lumpfish at Pilgrim" (EPA, Chapter G3, p. G3-51).

In the proposed rules, the impingement and entrainment losses are valued for the harvest improvements to commercial and recreational fisheries, the replacement cost of forage fish and/or the foregone commercial/recreational harvest from the forage fish. In addition, estimated benefits are computed for the non-use value of the losses to the forage fish. Finally, Habitat Replacement Costs are determined.

To get an idea of the absolute level of the "values per pound" that are assigned toeach lost pound by benefit category, consider the rainbow smelt. The ranges in benefits per pound for recreational catch of this species are $7.50 to $17.12/lb, <FN 10> for commercial harvest $0.20/lb, and "forage fish hatchery costs" $0.34/lb. <FN 11> It is difficult to isolate the "value" for rainbow smelt with HRC because more than one species is affected by the habitat.

Comparison of these rainbow smelt benefits is useful for several reasons:

1.) The misuse of replacement costs as values and the arbitrary nature of the benefit transfer in this study. The reason that one does not want to use replacement costs as values becomes clear in this case. If the people in New England valued the rainbow smelt as forage <FN 12> in the water at $0.34/lb, why would they permit fishermen to harvest them and receive only $0.20/lb?

2.) The gross overstatement of EPA's recreational values. A rainbow smelt, a species that few would even recognize and one that is targeted by few in the recreational sample, is valued at a substantially greater value than striped bass. For example, the 1996 percentage of targeted striped bass trips in the

New England was about 6% (4,923 targeted striped bass trips of 77,465 total trips) whereas for rainbow smelt it was 0.01% (14 of 77,465). <FN 13> Why does this matter in the estimation of benefits? At the Pilgrim plant, the annual entrainment value of rainbow smelt represents around 30% of the recreational and nonuse total (Table G4-10).

Because the recreational values generate about 50% of the economic value (exclusive of HRC costs), it is useful to examine how they were chosen. Three studies were examined, McConnell and Strand (1994), Tudor et al. (2002), and Hicks et al. (1999). The Tudor study was discarded legitimately as it was outside of the area and has other problems (see comments on the Delaware River study). Some combination of the McConnell/Strand and Hicks study was used to determine a high and low value, although the document is vague regarding how these numbers were generated. The EPA apparently believes that the McConnell/Strand values were based on a RUM model. As a co-author of this report, I can say with some authority that they were derived from a contingent valuation experiment. Moreover, they are based on an "expected" catch that does not have a simple correspondence with the historic catch rate. In short, the estimated values that EPA used from this study contains problems that make them suspect for the purpose that EPA wants to use them.

The best scientific information available for the assessment of recreational benefits in this area is the Hicks et al. study, the one that EPA claims "may serve as a lower bound for the values of fish". These are not lower bound but rather best estimates in the sense that they are the only ones cited than have any current validity. In fact, they may overestimate the gains at Pilgrim because the category "flatfish" used by Hicks et al. combines winter and summer flounder. Since summer flounder is the more targeted species (about two to one in New England), it probably has a higher value than winter flounder. When the combined value of flatfish is used, the value of the combination is probably higher than winter flounder would be if considered alone. Because the overall recreational losses at both Seabrook and Pilgrim are comprised of over 50% from winter flounder, the economic value of improvements to recreational harvest for this case study is overstated.

The commercial value estimates have little or no economic content. As mentioned in the general comments, the proposed regulations state that the producer surplus (benefits to fishermen) should be estimated as lying between 40 and 70% of the increase in gross revenues to fishermen. These are estimates of increased profits to fishermen. The procedure is based on West Coast studies by Rettig and McCarl (1985) and on Great Lake studies by Holt and Bishop (2002) and Cleland and Bishop(1984). There is no East Coast study cited and using the approach in New England is questionable. Many New England fisheries take 40-60 % of the (adjusted) revenues as a direct payment to labor. Thus, using 40-70 % denies almost any other cost of production. The Norton et al. (1983) study on the Atlantic coast striped bass estimated a surplus for striped bass of approximately 15% of ex-vessel value but was not used to justify EPA's approach to computing returns to consumers. In general, the producer surplus depends greatly on the fishery and on the year considered. Wild fluctuations in fish abundance imply wild fluctuations in producer surplus. In most instances, it would be better for the analyst to understand what is happening in the fisheries and, if necessary, survey the industry.

I understand in this instance why EPA is unwilling to expend the time and resources to calculate economic surplus correctly because of the small losses involved. However, a more sensible approach would have been simply to take 15 % of the new revenues as the short run level of benefits. Because most fisheries are not limited in the number of fishermen or anglers that can enter, long run adjustments can be important. When a change such as proposed one occurs, fishing increases and drives down the stock, reducing the gains to the point that only normal returns occur. In the long run, there are no commercial resource rents from the improvements created by the closed-cycle cooling system. Most U.S. fisheries are managed under open access so that one would expect resource rents to be eliminated in the long run. If there are abnormally high profits because of the new production, entry will eliminate them over time. Because these will be dissipated by new fishing effort, the long run profits will be zero. Thus, the 15 % should be decreased to zero over a period of years.

Given the New England situation, I would take the 15% of new revenues declining to zero over time to be a good estimate for a lower bound. For an upper bound, I would take the present value of 40% of the new revenues.

EPA goes on to base the benefits to market agents above the ex-vessel level (e.g., wholesalers, retailers, and the ultimate consumers) on the producer surplus changes. Citing the Norton et al. (1983) work and personal communication with Bishop and Holt (2002) and Bishop (2002), EPA decides to use an expansion factor of 3.5 to estimate consumers surplus. Following the EPA procedures, the process implies that the national benefits will rise between $1.8 and $3.15 for every $1 of increased dockside revenue. This is completely arbitrary.

Because winter flounder represents about 90% of the commercial value, an alternative to EPA's procedure would be to estimate an ex-vessel demand curve for winter flounder properly (Just et al., 1983; Thurman and Easley, 1992) and obtain values to consumers directly. The ex-vessel data exist to estimate demand and in my experience, will reveal ex-vessel demands because the supply curves shift dramatically with stock changes. This is neither a difficult nor an expensive procedure and it might provide defensible results.

Another factor also should be noted: it takes time to build fish stocks. I could not find how EPA considers the time adjustment for the lag between when the rules are installed, the new structures built, and the fish stocks rebound. If it did not consider this delay, the benefits should be adjusted with a social rate of discount.

In the Pilgrim and Seabrook facilities, the replacement costs of forage fish do not have a great effect on the final estimated benefits, even though they are provided. Because replacement costs are not a legitimate method to estimate benefits anyway, the time used to compute these figures could have been better spent thinking about and improving estimates in the other benefit categories.

Finally, the figures for the habitat replacement costs are developed for the Pilgrim facility because there was no information on which to base restoration costs at the Seabrook facility. The primary source of information for the Pilgrim facility was "the cost of what knowledgeable resource experts consider to be the minimum amount of restoration necessary to offset I&E losses at the Pilgrim facility"(p. G5-1). While I am not in a position to comment on the realism of the costs of restoration, a quick division of annualized "values" to create artificial reefs (G5-41) suggests a value of about $225/age 1 equivalents. Considering that these species are tautog, cunner, rock gunnel, radiated shanny, and sculpin (spp.), an excessive average "value" per fish is indicative of why one should not have used HRC for valuation in this case study.

One further comment on the estimate for the Pilgrim facility is warranted. Based on a project in

Narragansett and Mount Hope Bays, cost figures to restore eelgrass (SAV) at three 16 m2 sites were developed (Table G5-41). These costs were doubled, based on the fact that private, not public contractors would be used. These were then expanded to provide a figure for 100 m2 of “$1,234 (rounded to the nearest dollar)” and when considering 47 similar projects, costs were estimated to be about $57,000. This action would save about 570 age 1 equivalents (301 of which are cod) at a cost of about $100/age 1 equivalent saved.

The Pilgrim case study goes further by showing HRC on an incremental basis (Table G6-2). Ignoring the fact that they are not benefits, the figures raise other questions. They seem to indicate that incremental percentage reductions in environmental effects come at a constant cost of about $1 million per 10% reduction. This does not make sense in the context of Tables G5-35 and G5-36 that show huge differences in the average costs per acre of habitat restored. <FN 14> When designing activity to meet low performance standards, EPA should use the projects with least average cost first. With increasing performance standards, EPA should choose the next lowest cost projects and the average cost of an acre or age 1 equivalent should rise. Hence the incremental costs should rise. Perhaps there is more substance to what EPA has done but the proposed rule fails to reveal it.

For the Pilgrim facility, the habitat replacement cost is about 15 times larger than the mid-point between EPA’s low and high estimates of economic benefits based on other methods. EPA however considers habitat replacement costs as benefits and goes on to use them to expand to national benefits. As previously explained, HRC are not benefits and should be considered only as costs incurred by the power companies if habitat replacement is a desired alternative to meet performance standards.

EPA Response

For EPA's responses to comments on replacement costs and the HRC method, please refer the document entitled "The Habitat-based Replacement Cost" method (Docket #6-1003) and to EPA's response to Comment 136bEFR.005.035.

Regarding commercial fishing valuation methods, please refer to EPA's response to Comment 316bEFR.005.029.

Regarding recreational fishing benefits, EPA did not use a benefits transfer approach for its final analysis for the 316b Phase II rule. Rather, EPA developed a random utility model to estimate recreational fishing benefits for each region (see DCN # 6-0003).

Regarding discounting, please see Chapter A14 of the Regional Analysis Document (DCN #6-0003).

For further detail on benefits methods used in EPA's final analysis, please see Chapter A9 of Part A of the Phase II Regional Analysis Document (DCN # 6-0003).

Delaware River

EPA has based its economic benefits for the Delaware estuary on the Salem Nuclear Station located on a man-made peninsula named Artificial Island at the end of the transition zone between the Delaware River and the Delaware Bay. The benefits are derived based on the impingement and entrainment at this facility and then extended to the other in-scope facilities in the Delaware River basin. In addition, the national benefits for facilities located on non-Gulf of Mexico estuaries are derived from the Salem and Big Bend (Tampa Bay, FL) estimates.

How representative Salem is of the other facilities is beyond my expertise to evaluate but that question is critical in determining the appropriateness of the benefit estimates. That is, everything for the Delaware Estuary is derived from the benefits associated with the species that are impinged and entrained in the Salem facility.

This case study was better than the Pilgrim/Seabrook case study in two primary ways: 1) EPA does not present habitat replacement costs as benefits and 2) EPA presents primary research (Tudor, 2002) using the RUM model for recreational anglers primarily from Delaware, New Jersey, Maryland and Pennsylvania. While the lack of effort on replacement costs is to be whole-heartedly supported, there are some potentially serious problems with the RUM model. Perhaps because of the problems, the document also uses benefit estimates based on previous studies.

The bulk of the estimated benefits are derived from losses in fish that are caught commercially (over 60% of the total I&E losses). EPA's commercial benefit estimates have no economic content. As mentioned in the general contents, benefits are generated by multiplying a species' dockside price by an arbitrary and excessive percentage of the increase in commercial production. The percentage lies between 40% and 70%. This is based on West Coast studies by Rettig and McCarl (1985) and Huppert (1985) and on Great Lake studies by Holt and Bishop (2002) and Cleland and Bishop (1984). Oddly enough, the Norton et al. (1983) study on the Atlantic coast had surplus at approximately 15% of ex-vessel value but was not used here although it was used later. In most instances, it would be better for the analyst to understand what is happening in the fisheries and, if necessary, survey the industry.

The case study of Salem Nuclear Plant illustrates the potential problems that can arise from following EPA's procedure. The use of unsubstantiated ratios and multipliers when estimating benefits from commercial fishing rests on unrealistic assumptions. The proposed regulations are projected to increase spot and croaker landings by 5.1 million pounds and a constant ex-vessel price of $0.70/lb and $0.85/lb, respectively, is used. Based on this, spot and croaker harvest increase generate about two-thirds of the commercial benefits from reduced entrainment. Along with "Non-RIS species" that are unnamed but valued at $0.96/lb, spot and croaker increases represent 83% of the reduced entrainment benefits (Table B4-9). EPA apparently did not recognize that spot harvests in New Jersey and Delaware are nearly non-existent and croaker harvest average around 2 millions pounds per year. <FN 15>

It is inconceivable to me that the New Jersey and Delaware prices for spot and croaker could remain constant at this level if increased production occurred in the Delaware estuary. In states with moderate production, such as Virginia, the average ex-vessel price of spot and croaker is between $0.35/lb and $0.40/lb. Also, the use of 40-70% of total revenues as an estimate of producers surplus is unreasonable. For this large of a change that draws new entry and causes increased costs, an estimate of 15% of new revenues declining to zero over time could provide a lower bound and 40% new revenues declining to zero for an upper bound.

EPA goes on to base the benefits to consumers (e.g., wholesalers, retailers, and the ultimate buyer) on the producer surplus losses. Citing Norton, Smith and Strand (1983) in addition to a personal communication with Bishop and Holt and Bishop (2002), EPA decides to use an expansion factor of 3.5 to expand the producer surplus to estimate consumer surplus. For every $1 of increased dockside revenue, the national benefits rise between $1.8 and $3.15. Conceptually, there is no necessary association between producer and consumer surplus and no basis upon which to establish this arbitrary expansion factor.

EPA should recognize that spot and croaker represent about two-thirds of the commercial benefits and estimate an ex-vessel demand curve for these species (Just et al., 1983; Thurman and Easley, 1992). Although the long-run benefits to consumers cannot be established directly, upper and lower bounds on the benefits could be determined. The ex-vessel data exist and, in my experience, can be used to reveal ex-vessel demands because the supply curves shift dramatically with stock changes.

The recreational benefits represent about 25% of the I&E losses at Salem (Figure B6-1). The recreational benefits are derived from a RUM model and from benefits transfers. In the final estimates of the RUM model, gain from increases in weakfish and striped bass abundances are prominent. In the benefit transfer estimates, bottom fish and non-RIS species are very important. Because of their importance, I will spend time addressing these four categories (striped bass, weakfish, bottom fish and non-RIS species).

The benefits transfer analysis is presented first and contains the same errors in interpretation as the Pilgrim/Seabrook case study. That is, in addition to the EPA's RUM estimates (Chapter B5), four studies were considered: Norton et al. (1983), Agnello (1989), McConnell and Strand (1994), and Hicks et al. (1999). EPA apparently believes that the McConnell/Strand values were based on a RUM model but they were derived from a contingent valuation experiment. Moreover, these benefits are based on the square root of an "expected" catch that does not correspond directly to the historic catch rate. In short, the McConnell and Strand estimates that EPA uses have problems that make them suspect for EPA's intended purpose. Norton et al. and Agnello (1989) also should not be considered for this analysis because they use an out-of-date (about 1981) and inaccurate database. The Marine Recreational Fisheries Statistics Survey of the National Marine Fisheries Service was in its infancy and the data are not as accurate as more recent information. It is also true that recreation demand analysis was in its infancy. <FN 16>

The best scientific information available for the transfer of recreational benefits in this area is the Hicks et al. study, the one that EPA claims "may serve as a lower bound for the values of fish". These are not lower bound but rather best estimates in the sense that they are the only ones cited than have any current validity. Because the striped bass and weakfish are both in the small game category, using this study to estimate benefits would probably eliminate problems that aggregation of the species group would cause. That is, striped bass is probably more highly prized than the average small game fish whereas weakfish are probably less prized. Using the Hicks et al. benefits for small gamefish would probably produce reliable estimates.

The recreational values assigned to additional blue crab harvest deserve a comment. The average recreational crabber will harvest, on average, many more crabs than a similar angler who is fishing. I know of no reliable estimates for the marginal benefit of a blue crab but I would say that the marginal benefit is smaller than for a small game fish.

Now consider values estimated from EPA's RUM model (Chapter B5, also referred to as Tudor, 2002). As stated before, it is a laudable effort and has some commendable aspects. However, there are several problems that cause, in my opinion, the aggregate values to be too large. Specifically,

1. The boat mode values were expanded to shore-based and party charter boat activities. It is likely that benefits per fish for the shore mode angler are substantially smaller than for a private boat angler. Because benefits per trip are expanded by the number of trips and there are nearly the same number of trips by shore-based anglers as by private boating angler (Table B5-9), the aggregate benefit is probably too high.

2. The definitions of the sample population and their choice set of sites in the RUM model are unusual (B5-1.2) and probably upwardly bias the benefits of greater recreational harvest. EPA chooses its sample on the basis of sites and includes only the sites in Delaware Bay and along the New Jersey and Delaware ocean shoreline. In 1998, 65% of the visitors to Delaware sites were from out of state whereas 45% of New Jersey trips were from out of state. By considering the restricted set of sites, the RUM model forces individuals to take trips to these sites and to have considered only these sites in their choice. This produces parameter estimates that are biased downward and estimates of benefits per fish that are biased upward. These visitors probably considered sites in the Chesapeake as alternatives to the Delaware Bay sites. The point is that the model's choice set should include at least the Chesapeake Bay sites if it is to be realistic and relied upon for benefit estimates.

3. The "historic" catch rates measured by EPA are in fact "future" catch rates. EPA uses a sample of anglers fishing in 1994. The historic catch rate that is used to predict which sites the anglers will choose is based on catch information from 1994 through 1996 ((see B5-1.3). EPA could get the abundance measures that Hicks et al. (1999) used in their analysis.

4. The use of weakfish and flounder abundance to represent the relevant abundance for anglers that are not targeting any species probably biases upward the benefit of changes in weakfish and flounder abundance. Because the abundance of bottom fish such as croaker and spot may be important to non-targeting anglers and may be correlated with weakfish and flounder abundance, excluding them may bias upward the coefficient on weakfish and abundance for non-targeting anglers. Any change in weakfish and flounder abundance is overvalued.

5. The problem just discussed would be partially offset if EPA used the value of bottom fish from their RUM model. However, only some results of the RUM model are used. Because the RUM estimates indicate a negative effect of the abundance of bottom fish on the choice of site, it implies that anglers would place negative value on increases in the abundance of bottom fish. Since croaker

and spot are bottom fish and their abundance increases by nearly 15 million fish under the proposed rule (or about 10 times the amount of striped bass and weakfish, Table B6-1), the benefits to anglers might be negative if all estimates were based on EPA's RUM model. The loss of benefits to anglers seeking bottom fish is not included in the value estimates, to the best of my knowledge. Including this effect in the shore mode might even cause the shore anglers to lose value from fishing in the Delaware Bay.

These problems cause the estimated benefits from EPA's RUM model to be unreliable and overstated. Unless the problems are corrected and a new, reasonable model estimated, it should be removed from the document and the results of Hicks et al. (1999) substituted.

It is nearly impossible to tell what benefit estimates go into the final benefit evaluation for Salem (Tables B6-3 and B6-4). However, for such a high estimate of benefits to be presented, the replacement costs of forage fish must have been included. As discussed previously, replacement costs are not a useful measure of benefits in the context of the EPA proposed 316(b) regulation.

EPA Response

This comment refers to case studies presented at proposal that were not included in EPA's final analysis for the Phase II rule. However, EPA notes that its extrapolations were adjusted for technologies in place as necessary. See response to Comment 316bEFR.041.041.

For a discussion of EPA's commercial fishing benefits analysis, please see response to Comment 316bEFR.005.029.

For a discussion of EPA's recreational fishing benefits analyses, please see response to Comment 316bEFR.075.504 and Comment 316bEFR.041.452.

Ohio Watershed

Ohio River

The Ohio River case study considers the effects of nine facilities (Sammis, Cardinal, Kammer, Philip Sporn, Kyger Creek, Beckjord, Miami Fort, Tanners Creek and Clifty Creek) on populations of fish in the Ohio River. Many of these plants use less than 5 % of the mean annual river flow and therefore are not subject to the performance standards to control entrainment. These facilities are required to reduce impingement mortality of all life stage of fish and shellfish by 80-95% from the baseline calculation.

Because there are no commercial fisheries of consequence that would be affected by the proposed regulation, the estimated benefits are shown for recreational harvest improvements, nonuse values, replacement cost of forage fish and the value of production generated from forage fish increases. In addition, the analysis is provided for the nine facilities separately, an entire segment of the Ohio River (29 facilities) and the entire Ohio River (48 facilities).

Over 60% of the total benefit estimate for the twenty-nine plants that is used in the national estimate are comprised of recreational benefits based on a RUM model developed by EPA. In-scope facility impingement and entrainment reduced annual recreational catch by 54,000 pounds in the segment of Ohio River and these lost pounds of fish are estimated to be worth about $8.1 million/year or $150/lb to anglers. To put the benefits in perspective, EPA used two approaches to develop values for the estimated fish lost from impingement and entrainment, a benefits transfer and RUM approach. The benefits transfer values range from $2-4 per fish <FN 17> (Table C4-3). The $150/lb for species such as black crappie, channel catfish, smallmouth bass and walleye is unrealistic and a closer examination of the RUM model on which it is based is appropriate.

As an overview to the recreational benefits, we should put the estimate of 54,000 pounds of fish in perspective. A thorough analysis of the same segment of the Ohio River by the State of Ohio in 1992 and 1993 (Schell et al. 1996) produced an estimate of over 2,500,000 fish caught. If we were to use a conservative estimate that these fish weighed one pound on average, then the harvest gains to anglers from the proposed rule to fishing in the Ohio River segment would be about 2% of total harvest. This is probably imperceptible to the fishing public. In fact, the results of Perry et al. (2002) indicate that if power plant impingement and entrainment mortality were completely eliminated there would be perceptible changes in fish populations for only 6 of the 22 Ohio River sites studied.

Let me explain what I believe is the fundamental mistake in EPA's gross overestimate of benefits. Many of the coefficients of the model are reasonable and indicate the usual response to time and travel cost that a RUM model of recreational demand will produce. The problems arise in the estimation of benefits because EPA uses an index of relative abundance developed by the Ohio EPA <FN 18> and does not apparently account for this when developing benefit estimates. Because the abundance is a relative measure, it is not the actual population- it must be scaled in order to convert it to population. EPA apparently adds the relative abundance to the increase in the absolute level of harvest from the proposed rule. This makes no sense without some conversion of the relative abundance to an absolute abundance AND a conversion of the harvest to an abundance measure. This is my interpretation of what EPA did. <FN 19> If the interpretation is correct, then EPA needs to estimate benefits properly.

Even if EPA were to scale their relative abundance measure and to convert the harvest into abundance, another issue must be confronted. The relative abundance measure is along a straight line and therefore EPA's measure of abundance is for one dimension of the river, the length. It must be expanded to consider the width and depth of the Ohio River. I do not know specifically what EPA did but it appears that they assumed that the new fish would be uniformly distributed down a line, rather than throughout the river. That is, the dimensions of river depth and river width are not considered. Based on the information given on page C1-5, Ohio River is on average about 400 m wide and 4.5 m deep. Because the square root of the relative index was used in the model, I would estimate that the assumed change in abundance from the proposed rule was or 42 times what is should be.

If the above argument is not the reason for the excessively large value per pound, then one must closely look at the model and its extrapolations to determine how these large values could be obtained. I will suggest some additional factors within the RUM model and the extrapolations that could cause an overstatement of benefits.

Specifically, the remaining problems that are apparent at this time are:

1. The water quality variables are used in an inefficient manner. That is, the way EPA employs water quality in their model affects the value of a site but not the value of changes in the abundance of fish at the site. One would prefer that new fish at a site with low water quality would be worth less than new fish at a site with high water quality. The way to achieve this result is to interact the site water quality with the fishery abundance. This was not done and should be considered.

2. There is substantial literature on the overstatement of the number of trips either recalled over an extended past period or predicted to be taken in a future period. In Bockstael et al. (1988) for example, people took only about 70% of beach trips that they predicted they would take from their interview date to the end of the season. There are similar results for recall of past usage. Although EPA notes this ((C5-5.4a), it would have been better to reduce the number of trips by a percentage based on the literature. Reliance on previous literature was followed on using 50% of the use values for the nonuse value, even though it is a far more questionable extrapolation than the one suggested above. Shell et al. (1996) estimate 209,385 as the total number of trips during 1992 for the same segment of the Ohio River. If each trip's benefit from reduced I&E was EPA's estimated $0.12/trip, then if would take about 66,666,666 trips by adult residents in your fishing boundary (Figure C5-1) to produce EPA's total benefit estimate of $8,059,275. If one used the total trips of Shell et al. and EPA's total benefit of $8,059,275, then the benefits per trip would have to be $38. This benefit would arise from a miniscule increase in catch per trip of 0.25 pounds.

3. The procedure used by EPA to obtain fish abundance indexes at sites not sampled by the State of Ohio may bias the economic value of fish upward, although there is not enough information to be certain. If the EPA computes a weighted average of nearby monitored sites, then the procedure may be reasonable. If the EPA diminishes each nearby site's abundance by a factor based on the inverse of distance but does not take a weighted average over the sites, then there would likely be a downward bias in the fish abundance measure for non-monitored sites. Since these sites are probably not visited

as often as monitored sites, the RUM coefficient on fish abundance and the value of improved abundance are biased upward. The description of the data generation is insufficient to tell what the EPA did.

4. The use of 74 individuals from Ohio to estimate behavioral response of all freshwater anglers using the interior waters of the U.S. is obviously precarious. However, it was not clear why only 65 of the 74 individuals were used to make the assessment of the economic value from the proposed regulations. This needs to be explained.

5. Of the 74 or less individuals (66 observations are recorded in the LIMDEP results) used in the analysis, how many individuals actually chose sites associated with the six Ohio River pools? My unofficial count is 5.

6. Given the small numbers of fish involved, it seems highly unlikely that anglers would increase their number of trips because the "value" per trip went up after the reduction in I&E. In addition, the coefficient of the inclusive value in the participation model is not statistically significant. This part of the model should be abandoned (Table C5-4).

7. The estimate of the benefit per trip is $0.12/trip with a standard deviation in the sample of $.0.37/trip. Have you used Monte Carlo techniques to estimate whether or not the benefit per trip estimate is statistically significant? Researchers of ten prefer the median as a measure of central tendency because it has a smaller variance than the mean. What is the median for your sample?

It is completely unclear as to how the total benefits of the reduced I&E reduction are computed "in a manner to avoid double counting" (p. C7-1). This should be clarified. My calculations imply that benefits from nonuse and forage fish generate $1.3 million to $2.4 million dollars annually from impingement reduction and $3.3 million to $4.1 million annually from entrainment losses. These are the differences between benefits shown in Tables C6-2 and C6-3 and the benefits in 7th paragraph of page C7-1.

Because the process by which the nonuse and forage fish benefits are generated is unclear, my comments can only be general in nature. The use of 50% of use value to compute nonuse value is unjustified. My guess is that the nonuse values are extrapolated from the RUM model estimates. Because the RUM model estimates are so unbelievably large, the nonuse values must be also. After correcting for the apparent mistakes in the RUM model, EPA could use 0 as the lower bound estimate of nonuse values and 50% of the use value as the upper bound. Alternatively, they could assess the preferences of residents near the Ohio River with a contingent valuation study of forage fish abundance in the Ohio River.

Some of the total benefits may be associated with replacement costs of forage fish. As previously noted, this approach is not a valid method in this case study.

It is also important to note that EPA's analysis is based on the presumption that improvements in forage fish increase the abundance of recreational fish and those improvements in abundance benefit anglers. Schell et al. (1996) suggest that the abundance of forage fish actually reduces the catch rate of anglers on the Ohio River in 1993;
"One reason for this decline in catch from 1992 to 1993 may also be due to an inverse relationship

between forage abundance and angler success."
(Schell et al. p. 23)

EPA might wish to consider this phenomenon when developing their benefit estimates.

EPA Response

This comment is made regarding EPA's recreational fishing analysis developed for the Ohio Case study presented at proposal. The commenter states that recreational fishing benefits estimated for the Ohio River (48 facilities) are grossly overstated. The commenter further states that the RUM model used in the analysis is appropriate and the coefficients of the model are reasonable and "indicate the usual response to time and travel cost that a RUM model will produce". The commenter, however, argues that the index of relative fish abundance was used incorrectly, which resulted in incorrect benefits estimation. The commenter also raises additional concerns regarding the Ohio case study analysis.

For the final Phase II 316b analysis, EPA no longer uses case studies of individual water bodies or facilities. Instead, EPA has estimated regional models. Therefore, many of the points made are no longer relevant to EPA's analysis.

EPA agrees that the RUM model estimated for the Ohio case study shows the usual response to time and travel cost and other site characteristics. EPA re-iterates that its RUM results are consistent with the results reported in peer-reviewed literature.

The Agency disagrees that the relative fish abundance measure is used incorrectly in the analysis. As shown in Equation C5-6 and Table C5-6, Estimated Changes in Fishery Yield from Eliminating all I&E in the Ohio River, the Agency did convert the estimated changes in recreational fishing harvest into the relative abundance measure. EPA's use of the relative fish abundance index is consistent with the index definition developed by the Ohio Department of Natural Resources. The relative abundance index is defined as fish weight in lbs per 300 meters at a given site. It does not explicitly account for river width or depth. EPA believes that the commenter incorrectly interpreted this measure. See Chapter C5 of the Case Study Analysis Document for the Proposed Section 316 (b) Phase II Existing Facilities Rule for detail (see DCN # 4-0003).

For additional information on the relative abundance index please see the following publication:

Ohio EPA. 1988. Biological Criteria for the Protection of Aquatic Life: Volume II: Users Manual for Biological Field Assessment of Ohio Surface Waters. State of Ohio Environmental Protection Agency, Ecological Assessment Section Division of Water Quality Planning and Assessment, Columbus, Ohio. (DCN #4-1872}

EPA disagrees that the water quality variable is used inefficiently in the model. The RUM model used in the Ohio case study was selected based on the overall model performance, including signs and magnitude of the estimated coefficients, the statistical fit, and consistency with the RUM models from peer-reviewed literature. The model correctly predicts that the value of a site is affected by water quality. The commenter presents no empirical evidence that the value of changes in the abundance of fish at the site is affected by water quality.

EPA believes that its approach to estimating the number anglers expected to benefit from improved fish abundance in the Ohio River is reasonable and consistent with the standard RUM assumptions. The Agency points out that the RUM model estimates the value of an improvement in site quality (i.e., fish abundance) to all anglers whose individual choice sets include a given site. Some of these anglers may not actually visit the affected site, however, the total value of their choice set would increase. Thus, using just the total number of trips to the affected segment of the Ohio River in estimating benefits from reduced I&E is inconsistent with the standard RUM assumptions. For detail, see Chapter A11, Estimating Benefits with Random Utility Model (RUM) of the regional study document (DCN #6-0003)

The Agency disagrees that it used a flawed procedure to obtain fish abundance indexes at sites not sampled by the State of Ohio. EPA used a standard procedure, that is available in the ArcView 3.2 GIS software package with the Spatial Analyst 2.0 extension (Environmental Systems Research Institute, Inc., 2000).

EPA agrees that the data sample is used in the Ohio case study is relatively small. All 74 observations were used in the trip participation model. However, only 65 observations were included in the site choice model because some anglers did not provide sufficient information on the visited site.

The number of anglers who actually chose the affected segment of the Ohio River is irrelevant to the analysis. The RUM travel cost model includes the effects of substitute sites on site values. An angler choosing to fish on a particular day chooses a site based on site attributes. The angler weighs the attributes for various “choice set” sites against the travel costs to each site. These travel costs include both the cost of operating a vehicle and the opportunity costs of time spent traveling. The angler then weighs the value given to the site’s attributes against the cost of getting to the site when making a site selection. If site quality improves more anglers would choose to visit the site. Moreover, based on standard RUM assumptions, anglers are assumed to value all sites included in their choice sets and not only a site that they actually visit on a given day. For detail, see Chapter A11, Estimating Benefits with Random Utility Model (RUM) of the regional study document (DCN #6-0003).

The Agency agrees that the expected increase in the number of trips is negligible given a small increase in the value per trip resulting from improved fish abundance due to reduced I&E in the Ohio River. As shown in Table C5-7, the estimated percent increase in the number of trips is 0.04%. See Chapter C5 of the Case Study Analysis Document for the Proposed Section 316 (b) Phase II Existing Facilities Rule for detail (DCN #4-0003). The Agency also points out that some researchers argue that insignificant variables should be left in the model in the predictive portion of the analysis. For example see: R. Florax, P. Nijkamp, K. Willis, 2002, Comparative Environmental Economic Assessment, Edward Elgar Publishing, p. 148 (DCN #6-3254).

In the analyses for the NODA and the final rule, EPA no longer uses hatchery costs to estimate impacts on forage species. Instead EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule. See Chapter A5:

Methods Used to Evaluate I&E (DCN # 6-0003)

For the final 316b rule analysis, EPA has not included quantitative measures of nonuse values due to unavoidable uncertainty in monetizing non-use values. The Agency, however, has explored several measures that indicate the potential magnitude of non-use values, including meta-analysis, the benefit transfer method, and break-even analysis. For detail see Chapters A12, Non-use Meta-Analysis Methodology, and Chapters C6, D6, and G6 of the final Phase II Regional Studies Document (DCN # 6-0003) and Chapter D1 (break-even analysis) of the final Phase II EBA document (DCN # 6-0002).

APPENDIX E - 1
EFFECTS OF WITHDRAWAL RATE ON RESERVOIR FISH POPULATIONS

Under an October 1995 Consent Decree, the U.S. EPA is revisiting Clean Water Act Section 316(b) and how it applies to cooling water intake structures (CWIS). As part of that effort, EPA is developing new rules for both new and existing facilities. On November 9, 2001, EPA established location, design, construction and capacity standards for cooling water intake structures at new facilities. On February 28, 2002, the EPA Administrator approved a proposed regulation that will establish similar standards for existing facilities. The proposed regulations will, in part, address approaches for assessing the potential for "adverse environmental impact" (AEI) and measures for minimizing AEI. These measures may include requirements affecting the design, construction, location, and capacity of CWIS. Potentially impacted are all power plants and industrial facilities that withdraw cooling water. One component of EPA's proposed rule for existing plants establishes standards that regulate the volume of water that can be withdrawn for cooling purposes.

The recent regulatory focus on water withdrawal rate or volume as an indicator of likely biological damages from cooling-water intakes begs the following questions:

-What percentage of a source water body can be withdrawn (circulated) without significant adverse environmental impact?
-Is there a single maximum withdrawal rate that can be specified for specific cooling-water uses on all types of waters?
-Is there a single minimum withdrawal rate (intake-to-volume ratio) that can be categorically judged acceptable in any circumstance?

In this analysis we try to address these questions in a unique way by looking at potential biological effects of water releases and withdrawals from reservoirs as a surrogate for CWIS withdrawals. It is our working premise that water withdrawals from reservoirs, often for hydropower but also for municipal and other water uses, can result in an irretrievable loss of fish from the upstream waterbody that might be reflected in the status of fish populations in that waterbody. This irretrievable loss for that waterbody occurs regardless of whether the fish are killed or injured in dam passage, which is another issue not considered here. This chapter presents analyses we performed to determine if there is a relationship between the amount of water withdrawn from a reservoir system (via normal reservoir discharge and/or CWIS withdrawal) and some measure of a fish population or community health, such as total standing stock, sportfish density, forage fish density, etc. Our analyses were performed on two sets of reservoir data where we were able to find records of fish abundance, reservoir discharge (i.e., river flow), and CWIS withdrawal if present. Throughout this chapter we will refer to releases from the reservoir either through hydropower turbines or as spill at the dam as "reservoir withdrawals". Other types of withdrawal will be differentiated by purpose such as "CWIS withdrawals". "Total withdrawal" refers to the combination of releases and withdrawal for all purposes.

As part of our investigation into the contribution of water withdrawal as a factor affecting fish populations, we performed original analyses and revisited past studies of reservoir fish populations. Although these studies had different objectives, they each address fish removal and population response in one form or another. In this section of the report, we present the results of five analyses, which in various forms evaluated the relationship between fish withdrawal from reservoirs and population-level effects. The five analyses include:

-An original analysis of population effects of water withdrawal/discharge for reservoirs in Texas and tributary reservoirs in the Tennessee River system,
-A review of findings of the U.S. National Reservoir Research Program that intensively studied fish populations in reservoirs in relation to numerous environmental factors between the late 1960s and the mid 1980s,
-A review of findings of international efforts to develop simple indexes for predicting the fish productivity of water bodies, particularly the Morphoedaphic Index (MEI), that were hotly debated in the late 1970s and early 1980s,
-A summary of withdrawal rate effects at systems with high discharge rates and reported high entrainment rates, and
-A review fish control programs, in which certain species are targeted for reduction or elimination as a fisheries management tool.

3.1 Reservoir Withdrawal: Population Effects Analysis

The objective of this study was to compile reservoir and fisheries data with which we could evaluate possible relationships between the rate at which water is removed from the reservoir and fish abundance. In particular, we were interested in a relationship that includes the withdrawal (or intake) rate as a function of reservoir volume as we do not think withdrawal rate by itself is a very useful indicator of possible effect. Our working hypothesis is that we expect to find little or no population-level impacts at low intake-to-volume ratios, but at high intake-to-volume ratios, effects might start to become evident. In addition, we expect the greatest impact to be on those species or life stages that reside nearest the intake. For most dam release points (i.e., turbine intakes and spillways), the affected fish are those that reside in the offshore, pelagic zone of the reservoir.

3.1.1 Methods

Fish abundance - To investigate the possible effect of reservoir discharge rate on fish abundance, we first had to identify large data sets of fish abundance information that were collected in a similar manner for many reservoirs. Although estimates of actual abundance in large reservoir systems are not common, we found two data sets with measures (biomass per acre and catch per unit effort, CPUE) that are reasonable surrogates of actual fish abundance. These data sets are described below.

Texas Reservoirs: Fish populations in 111 reservoirs throughout Texas were sampled from 1974 to 1982 to assess the status of reservoir fish communities (Miranda 1984). Fish were sampled using standard cove rotenone techniques, and results reported as fish biomass per acre for each species collected. Many reservoirs were sampled during more than one year. For the analysis presented here, we selected fish abundance data from 36 of the 111 reservoirs for which we could readily find corresponding information on reservoir release rate and other water withdrawal information (Figure 3-1; Table 3-1). Measures of fish abundance used in this analysis included:

-Total fish biomass (lb/ac) of all species collected. Although it is unlikely that release of water from the system affects all species equally, there are likely some species that might be entrained and others that could be affected indirectly by the loss of a food resource.
-Shad species biomass (lb/ac). The shad species (gizzard shad Dorosoma cepedianum and threadfin shad D. petenense) are representative of fish that frequent the pelagic zone of a reservoir and are therefore in close proximity to most dam intakes. The biomass of shad comprised 27% of the total fish biomass across all years and lakes.
-Black bass species biomass (lb/ac). Adult and juvenile black basses (Micropterus spp.) represent species that are structure-oriented and usually found near the bottom or in the littoral zone and less likely to be impacted by dam intakes. Larval black basses, however, may go through a period of pelagic existence at which time they could be more susceptible to open water intakes. The biomass of black basses comprised 8% of the total fish biomass across all years and lakes.
-Ratio of shad to total biomass. Because shad and other clupeids are commonly entrained at dams (as well as CWIS), we might expect to see a decline in the shad biomass relative to other species if population-level effects are present.
-Ratio of shad to black bass biomass. Because adult and sub-adult black bass populations are not expected to be directly affected by reservoir releases, expressing shad abundance relative to black bass abundance may show changes in shad population that would not otherwise be apparent.

[see hard copy for table]
Table 01
Texas reservoirs included in the analysis of the effects of dam release rates on fish abundance. The six reservoirs with the primary withdrawal being for CWIS and with minor reservoir release were not included in statistical analyses, but were included in the figures for comparison.

Tennessee Valley Reservoirs: Fish populations in 31 reservoirs throughout the Tennessee River system were sampled from 1990 to 1999 to assess the status of reservoir fish communities (Dycus and Baker 2000). Fish were sampled using gillnets and electrofishing techniques at three general areas in the reservoirs including the forebay near the dam. Because we were interested in the potential effect of entrainment at dam intakes, we only used those results from sampling at the reservoir forebays that were reported as catch-per-unit-effort (CPUE) for each species. Reservoirs were sampled once a year for 4 to 8 years. For the analysis presented here, we used fish abundance data from 20 Tennessee River tributary reservoirs (Figure 3-2; Table 3-2). Measures of fish abundance used in this analysis included:

-Reservoir Fish Assemblage Index (RFAI) score. The RFAI is a metric developed by TVA biologists to assess the health of a reservoir fish community similar to the Index of Biotic Integrity (IBI) for stream fish communities (Karr 1981). The RFAI uses 12 fish community metrics that describe species richness and composition, trophic composition, reproductive composition, abundance, and fish health (Hickman and McDonough 1996). This measure was used both as yearly values and as site averages (i.e., years combined).
-Average electrofishing CPUE of all species collected. The unit of effort for electrofishing was 300 m of shoreline sampled. A yearly sample for any one reservoir consisted of 15 300-m runs completed on the same night. Electrofishing results from 1991 were not included in the analysis because the unit of effort that year was in minutes and not comparable to subsequent sampling.
-Average gillnetting CPUE of all species collected. The unit of effort for gillnetting was net-nights. Yearly sampling at each reservoir consisted of a single overnight set of 12 30-m long nets.
-Shad species CPUE for gillnetting. The gillnet CPUE of shad comprised 22% of the total gillnet CPUE across all years and lakes.
-Black bass CPUE for electrofishing. Shoreline electrofishing provides a better estimate of black basses abundance than does offshore gillnetting. The CPUE of black basses comprised 9% of the total electrofishing CPUE across all years and lakes.
-Ratio of shad gillnet CPUE to black bass electrofishing CPUE. Because we do not expect adult and sub-adult black bass populations to be directly affected by reservoir releases, expressing shad abundance relative to black bass abundance may show changes in shad population that would not otherwise be apparent.

When sampling fish that school, such as clupeids and many minnow species, it is not uncommon to occasionally collect an abnormally high number of individuals in a single sample. If enough sampling is performed, these unusually high samples do not inordinately affect the final estimate. However, because of the limited amount of sampling during the TVA studies, these outliers have a dramatic impact on the final estimate of CPUE. Therefore, we used Grubbs test (also known as the extreme studentized deviate method) to identify samples that were outliers compared to the other three to six estimates of CPUE for a particular lake. Because the groups within which the outlier test was performed contained only 4 to 7 samples, only extreme outliers were identified, which resulted in 8 out of 585 measures being removed from the analysis.

[see hard copy for table]
Table 02
Tennessee Valley reservoirs included in the analysis of the effects of dam release rates on fish abundance.

Reservoir Withdrawal—The most basic measure of reservoir withdrawal is simply the average rate of release (e.g., cfs or m3/s) over some defined time (e.g., annually). Although we are skeptical of discovering any relationship between the rate of withdrawal (without reference to water body volume) and fish abundance, we include it here to make sure our assumption is correct.

We believe an effect of reservoir withdrawal on fish abundance is more likely to be found if the reservoir withdrawal is presented in terms of reservoir volume, such as storage ratio or residence time. Storage ratio can be defined as the ratio of the daily intake volume to the water body volume. A reservoir's residence time is, in theory, the time that it takes for a complete turnover of the reservoir's water volume. In actuality, because of irregular mixing, the entire volume of water is not replaced molecule for molecule as new water enters the reservoir, however, this metric can provide valuable insight into other physical and biological characteristics of the reservoir. Residence time can be estimated as the time it takes for the volume of either the inflow or the outflow to equal the total reservoir volume. We estimated residence time in days as the reservoir volume divided by the daily outflow (or inflow if outflow was not available). If units are consistent the storage ratio and residence time are simply reciprocals of each other.

Several different estimates of residence time were calculated as follows:

-Long-term annual residence time (days): Average lake storage volume (ft3) divided by the average release/withdrawal (cfs converted to ft3/d) during past 40 years.
-Short-term annual residence time (days): Average lake storage volume (ft3) divided by the average release/withdrawal (cfs converted to ft3/d) during the 2 years prior to the year that fish sampling occurred. These flow data did not exist for some fish sampling events.
-Short-term Spring residence time (days): Average lake storage volume (ft3) divided by the average release/withdrawal (cfs converted to ft3/d) during the months of April, May, and June of the 2 years prior to the year that fish sampling occurred. This time period was chosen based on the possibility that short residence time in Spring when flows are high might flush large numbers of larval and juvenile fish from the system because their small size and/or choice of pelagic habitat makes them most susceptible. These specific flow data did not exist for some fish sampling events.
-Short-term June-July residence time (days): Average lake storage volume (ft3) divided by the average release/withdrawal (cfs converted to ft3/d) during the months of June and July of the 2 years prior to the year that fish sampling occurred. Similar to spring months, June and July are times when juvenile fish might be highly susceptible to high flows. In addition, flows during these months were found to significantly affect year-class strength in largemouth bass (Maceina and Betolli 1998). These flow data did not exist for some fish sampling events.

Texas Reservoirs: Several databases were used to derive the necessary information to calculate residence time for Texas reservoirs. We used the National Inventory of Dams database (NID) managed by the US Army Corps of Engineers (available on the internet at http://crunch.tec.army.mil/nid/webpages/nid.cfm) to find information on the precise location of each dam (latitude and longitude), the average storage volume (acre-feet), and the name of the receiving stream.

The average reservoir releases, both long-term and short-term, were derived from data collected at USGS gage stations and available at the USGS internet site (http://water.usgs.gov/nwis/sw). A site map that shows the location of each gage station was used to ensure that the location was representative of flows below the dam. Long-term annual and seasonal averages were calculated using monthly averages from 1960 to present when available. In a few cases, it was necessary to use pre-1960 data.

In addition to reservoir releases, we also included CWIS withdrawals when present on the reservoir. Intake rates at CWIS were obtained from the Entrainment and Impingement Database (EIDB), which is maintained at Alden Research Laboratory, Inc. (S. Amaral, personal communication). The values for CWIS intake rate in the EIDB are intake capacities and might overestimate the actual withdrawal, which may not always be at the maximum rate. Not having ready access to the actual withdrawal rates for the particular years of interest, we used the intake capacities as the average intake rate throughout the year.

Tennessee Valley Reservoirs: Much of the information necessary to calculate residence times for the Tennessee Valley reservoirs was obtained directly from the TVA (G. Hauser, personal communication). Because some of these reservoirs undergo a significant drawdown each winter, reservoir volume was estimated as the average of the volumes at full pool and at the average winter pool. Daily flow data obtained from TVA was used to estimate long-term and short-term reservoir releases. Flow data for four of the 20 reservoirs were not readily available and these reservoirs were only included in the comparisons that included the long-term annual residence time that was provided by TVA. There are no CWIS on the tributary reservoirs used in this analysis.

Water Withdrawal versus Fish Abundance Comparisons—Because the precise mechanism by which the magnitude and timing of reservoir withdrawals (and CWIS withdrawals) affect fish populations and communities is poorly understood, we made comparisons of several measures of both reservoir withdrawal and fish populations in search of any possible relationships. Regression coefficients (R2) were calculated for each comparison as a preliminary indicator of a possible relationship. For a few select comparisons we performed a linear regression analysis to determine if the relationship was statistically significant (i.e., whether or not the slope of the relationship is different from zero).

Most of the comparisons include fish abundance data collected over several years at several sites, but for a few cases, we also averaged data across years to create a single average value for each site. We present the results below in a progression from broad scale (i.e., long-term annual withdrawal measures and site averages of fish community measures) to fine scale (i.e., recent seasonal withdrawal measures and yearly abundance estimates of specific species), with the feeling that perhaps as the resolution of the analysis gets finer the chance of finding a relationship would increase.

3.1.2 Results

Texas Reservoirs: The results of multiple comparisons of various measures of reservoir withdrawal and fish abundance in Texas reservoirs are presented in Table 3-3 and Figures 3-3 to 3-6. Table 3-3 summarizes the sample sizes and R2 values for the linear regression for the various combinations of two-variable comparisons. These analyses included two types of reservoirs: (1) those where the major source of water withdrawal is release at the dam to a receiving stream and (2) those where water withdrawal includes both substantial release at the dam and withdrawal at a CWIS (see Table 3-1). Some reservoirs in Texas that provide water for CWIS have negligible releases at the dam and, in most cases, do not have corresponding USGS flow gages by which flows can be estimated. These “cooling” reservoirs typically have very small drainage areas and receive additional water to maintain elevations by pumping from nearby rivers and other sources. Although these reservoirs were not included in our analysis of water withdrawal effects, 6 of them are included in the figures for comparison.

[see hard copy for table]
Table 03

Water withdrawal versus fish population comparisons for Texas reservoir data.

At the broadest scale, there does appear to be a slight relationship between reservoir withdrawals (expressed either as mean annual discharge or long-term residence time) and total fish biomass (Figure 3-3A, B, C, D). A statistical analysis of the mean annual discharge versus total fish biomass determined that there is a statistically significant relationship (Table 3-4), though not in the direction expected. These data suggest that higher discharge rates are beneficial to fish production (Figure 3-3C).

[see hard copy for table]
Table 04
Results of select linear regression analyses on various measures of reservoir withdrawal versus fish abundance for Texas reservoirs.

Viewing just the plots of long-term residence time versus various measures of fish abundance (Figure 3-4A, B, C, D), we see little evidence of any relationship except with the ratio of shad to black bass biomass (Figure 3-4D). Regression analysis reveals that this is a significant relationship though the slope of the curve is small (Table 3-4). This relationship suggests that as reservoir withdrawal decreases (and residence time increases) the biomass of shad increases relative to black bass, the species that is less likely to be entrained in reservoir releases.

When the short-term residence time, which is based on flows during the two years prior to fish collection, is used as the measure of reservoir withdrawal, there is little evidence of any affect on fish abundance (Figure 3-5A, B, C, D).

When the short-term Spring residence time (based on recent flows during April-June) is used as the measure of reservoir withdrawal, a slight relationship exists with the shad:black bass ratio (Figure 3-6D). The linear relationship between short-term Spring residence time and shad:black bass ratio is a significant one (at the a=0.05 level) even though the corresponding relationship with shad biomass is not (Table 3-4).

Using flows in June and July during the two years prior to sample collection did not uncover any stronger relationships than those using the Spring flows (Table 3-3).

Although not included in the regression analyses or R2 calculations, fish abundance data collected at reservoirs with CWIS withdrawals but little other withdrawals or releases suggests that fish abundance can be quite high even when the water turnover rate is high (i.e., residence time is low) (Figures 3-4 to 3-6).

Tennessee Valley Reservoirs: The results of multiple comparisons of various measures of reservoir withdrawal and fish abundance in Tennessee Valley tributary reservoirs are presented in Table 3-5 and Figures 3-7 to 3-10. Table 3-5 summarizes the sample sizes and R2 values for the linear regression for the various combinations of two-variable comparisons. The major source of water withdrawal from these reservoirs is release at the dam to a receiving stream; none has any associated CWIS.

[see hard copy for table]

Table 05
Water withdrawal versus fish population comparisons for Tennessee Valley reservoir data.

At the broadest scale, a review of the plots of reservoir withdrawal (expressed either as mean annual discharge or long-term residence time) versus RFAI, the fish community index, indicates no apparent relationship (Figure 3-7A, B, C, D). However, the regression analysis of these two relationships determined that there is a statistically significant relationship between mean annual discharge and RFAI but not between long-term residence time and RFAI (Table 3-6). As one might expect, as discharge increases the measure of community health decreases. However, the slope of the relationship is so small that the statistical significance has little practical meaning.

[see hard copy for table]
Table 06
Results of select linear regression analyses on various measures of reservoir withdrawal versus fish abundance for Tennessee Valley reservoirs.

Viewing just the plots of long-term residence time versus various measures of fish abundance (Figure 3-8A, B, C, D, E, F), we see little evidence of any relationship. Regression analysis of long-term residence versus RFAI corroborated this observation (Table 3-6).

Likewise, when short-term annual residence time was used as the measure of reservoir withdrawal, there was little evidence of any effect on fish abundance (Figure 3-9A, B, C, D,E, F).

When the short-term Spring residence time was used as the measure of reservoir withdrawal (Figure 3-10A, B, C, D, E, F), a slight relationship is apparent with the RFAI score (Figure 3-10A). The linear relationship between short-term Spring residence time and RFAI was a significant one (at the a=0.05 level) (Table 3-6) and in the expected direction based on the operating hypothesis. That is, fish community health increased as reservoir withdrawal as a function of volume decreased. In addition, the relationship between short-term Spring residence time and shad CPUE was also significant, though the slope of the relationship, albeit very small, is contrary to that expected (Figure 3-10D). That is, shad abundance decreased as residence time increased.

Using flows in June and July only during the two years prior to sample collection produced relationships that were generally the same as those using the Spring flows (Figure 3-11A, B, C, D, E, F). Because Maceina and Bettoli (1998) found a relationship between black bass year class strength and residence times based on June-July flows in Tennessee River mainstream reservoirs, we were most interested looking for a similar relationship in the tributary reservoirs. Regression analysis, however, indicates that there was not a significant relationship between short-term June-July residence times and black bass abundance (Table 3-6).

In addition to the RFAI, an additional index, the Sport Fish Index (SFI), was calculated to quantify the status of the sportfish community and selected sportfish species in TVA reservoirs (Hickman 2000). Values of SFI were obtained from TVA for the reservoirs in the analysis from 1997 to 2000. Similar to the analysis presented above, we also investigated possible relationships between reservoir withdrawal and SFI. Except for a moderate correlation between discharge (cfs) and LMB SFI (Figure 3-12A), we found no indication that increased withdrawal resulted in poorer sportfish populations. Instead, we found just the opposite. The relationship between discharge and LMB SFI is counter to that expected from the dose-response analogy; that is, as discharge increases, the SFI for LMB improves.

3.1.3 Discussion

The analysis performed here was not able to identify conclusive evidence for a relationship between population- or community-level effects and rate of water withdrawal, either as a direct measure (i.e., mean annual discharge) or as a function of water body volume (i.e., residence time). A few significant relationships were found (Tables 3-4 and 3-6), but even some of those (e.g., mean annual discharge versus total fish biomass in the Texas reservoirs) were counter to our expectation of a negative effect on fish populations as discharge increased. Of the various measures of withdrawal rate we tested, the residence time based on spring flows for the two years prior to the collection of the fish data seems to be the most useful for explaining variation in fish abundance.

Maceina and Bettoli (1998) compared variation in recruitment of largemouth bass in four mainstem Tennessee River reservoirs (with mean residence times < 20 days) to various types of hydrologic and aquatic plant abundance data to explain factors related to the formation of strong and weak year classes. They found that a majority of the variation was explained by June-July discharge rates when fish were age 0. They found that weak year classes were produced during wet years when reservoir releases were high (and residence times were low) and, conversely, strong year classes occurred during dry years. This study suggests that largemouth bass year class strength is directly related to the effects of early summer flows on young-of-year fish, though it is not clear whether that effect is entrainment (i.e., removal from the system) or whether it is a result of some other mechanism associated with high flows, such as primary production. Slipke et al. (1998) and Buynak et al. (1991) also found that black bass recruitment was higher in Tennessee River impoundments during years when spring and early summer flows were lower than average. Although, Maceina and Bettoli (1998) found that June-July flows predicted largemouth bass year class strength in Tennessee mainstem reservoirs, we found that April-June flows provided better relationships than June-July.

In addition to water release, there are a variety of factors that can affect fish abundance and that may have impaired our ability to find a relationship between withdrawal and abundance. These include supplemental stocking, the effects of water level variation on reproduction, and compensatory mechanisms that might result in the loss of significant numbers of larval or juvenile fish having little effect on the total population of adult fish. Consideration for which life stage is entrained is an important one. There is good evidence that the entrainment of adult and sub-adult fish can have a significant effect on the population as indicated by the kokanee examples above described in Section 3.4 (Cichosz et al. 1999; Skaar et al. 1996).

Other confounding factors in our analysis include unknown diversions (e.g., those for municipal water supply, irrigation, etc.) for which we did not account. This is not likely a significant problem for the Tennessee Valley reservoirs, but might be in Texas where irrigation is more prevalent and where some of the reservoirs were located near large cities that may use the reservoirs for public water supply.

Although we included in our analysis the species that we thought most susceptible to dam entrainment (i.e., gizzard shad and threadfin shad), it is possible that we overlooked a species that might have had a more pronounced interaction with among-reservoir and among-site variations in residence times.

Differences in behavior and life history among fish species have a significant impact on their susceptibility to entrainment and the potential for entrainment to have population-level effects. The entrainment of kokanee in western reservoirs is a function not only of their preference for open water habitat which puts them in close proximity to dam intakes, but also a function of innate migratory behavior that draws them to the outflowing currents at the intakes. The relatively low rate of fecundity of kokanee, which is typical of salmonids, likely contributes to the observed population-level effects resulting from high levels of entrainment. On the other hand, we know that shad are commonly entrained at dam intakes, and given their relative abundance in most southern reservoirs probably at a high rate, but population effects were not observed in our analysis, likely due to their high rate of reproduction.

3.2 U. S. Reservoir Research Program Synthesis

The question of whether water withdrawal rate has a major influence on the status of fish populations was investigated in the 1963-1980 U.S. Reservoir Research Program, along with the broader question of the relative roles of other factors in controlling fish productivity. Freshwater reservoirs were the focus. This program produced a large literature, which presents the results of extensive statistical correlations among potential environmental factors and different measures of fish populations of many species.

As nearly every major river system in the U.S. was being dammed for navigation, hydropower, flood control, and (as an added benefit) recreation, the U.S. Congress in 1963 established the National Reservoir Research Program (NRRP) to be administered by the U.S. Fish and Wildlife Service. The major goal of this program was to determine the factors affecting the development and sustainability of fish populations (particularly those populations that provided recreational fisheries). The Program inventoried trends in both reservoir construction and the development of recreational fisheries in new and maturing reservoirs. Disbanded formally in 1980, but continued by participants for a few years thereafter, the program's published literature forms a valuable resource for those interested in understanding the factors that regulate fish populations.

Between 1960 and 1980, the former NRRP made four inventories of U.S. reservoirs with a surface area larger than 500 acres. These did not include natural lakes that were regulated by outlet dams unless the lake area or volume was doubled by the dam. By 1985 (the last inventory), there were 1,687 reservoirs with a total surface area of 10,063,000 acres, and the rate of increase in new reservoirs had dwindled (Jenkins et al. 1985). Jenkins et al. estimated that fishing on reservoirs 500 acres or larger accounted for approximately 25% of all freshwater angling in the U.S.

Estimates of annual sport-fish yield were obtained (largely from state fishery agencies) for 294 reservoirs (Jenkins 1982). The database included 18% of the number and 35% of the total area of U.S. reservoirs. The reservoirs are located in 39 states, but half are in 8 states (Oklahoma, 50; Kansas, 20; California, 16; Tennessee, 14; Colorado, 13; Kentucky, 13; Michigan, 11; and Wyoming, 10). Mean age was 22 years (1-118 years). Most data were collected between 1940 and 1979. Other characteristics of the data set are described by Jenkins (1982). Regrettably, the publications do not list all of the relevant physical data for each of the 294 reservoirs (such as withdrawal rate), but instead focus on presenting results of the correlation analyses. The original data files are no longer accessible. We have been able to deduce some of the withdrawal data, such as that used by Ploskey et al. (1984) for their analyses of 11 reservoirs selected to represent a range of reservoir types. These reservoirs had annual average discharges ranging from 1 m3/s (24 MGD) to 821 m3/s (18,744 MGD), with most in the range of 40-225 m3/s (900-5,000 MGD). For comparison, a 1,000-MWe nuclear electricity generating station uses cooling water at a withdrawal rate of about 130 m3/s (3,000 MGD).

The Program focused on several fish-production issues that were important at the time. A large literature was generated; a few key findings and summary papers are cited below. The relevance of a finding for current CWIS issues is indicated.

-Reservoir fish production was not constant over the life of any reservoir, which complicated making correlations with other physical and environmental factors. Reservoirs typically experienced a “boom and bust” cycle of fisheries, in which there was an initial pulse of productivity and high fish catches, followed by a gradual decline. The NRRP established that this cycle was related to nutrients in soils and vegetation that were released on flooding, yielding especially high initial fish populations that could not later be sustained by annual input of nutrients from the watershed. Jenkins (1977) observed that Lake Keowee, a hydropower storage reservoir in South Carolina used also as a cooling lake for a nuclear power plant, exhibited a gradual and typical decline in standing crop of fishes over a 10-year period after impoundment. Recommendations for managing flooded lands during construction to maximize retention of nutrients and fish habitat values were developed (Ploskey 1981, 1985).

The relevance of this finding for CWIS is that long-term monitoring of reservoirs used for cooling may show declines in fish populations unrelated to cooling-water use, but reflecting a normal aging process for the reservoir.

-Water level fluctuations strongly influenced fish populations. Such fluctuations are typical of many reservoirs (particularly those used for seasonal water storage) but atypical for natural lakes and cooling reservoirs. Fish productivity was affected especially by influences on spawning and nursery habitats in spring. The fluctuations in elevation and water surface area caused major disruptive effects, particularly on littoral-zone predators such as largemouth and smallmouth bass. Recommendations for minimizing the detrimental effects of water operations on fish populations and for using selected water fluctuations to beneficially manage certain fish populations were provided (Ploskey 1986).

The relevance of this finding for CWIS is that waters used for cooling are likely to have more productive fish populations than reservoirs not used for cooling, regardless of the volume of water withdrawal, largely because water elevations need to be maintained stable for operation of intake pumps.

-The vagaries of weather (wind, temperature, precipitation) affected fish populations of reservoirs in many ways (Aggus 1979). The effects were often related to disruptive storm events affecting nest survival of shoreline spawning fishes, rapid temperature changes (often declines) at critical times for spawning fish, and differing precipitation regimes that influenced flow of nutrients from watersheds. Reservoir statistics on variations in water through-put relative to reservoir volume (calculated as retention time, storage ratio, or flushing rate) often reflected changes in precipitation and nutrient dynamics (higher flows usually equated to higher ecosystem and fish productivity). Although meteorological events are not controllable, an understanding of their effects aided in understanding cause-effect relationships for other factors that were more manageable.

The relevance of this finding for CWIS is that effects of fairly consistent water withdrawals (characteristic of most cooling-water uses), if any, are likely to be masked by more prominent effects of weather events.

-The ratio of predatory fish to prey fish was found to be an important attribute of reservoirs, which influenced perspectives on stocking of game fish and the importance of forage fish populations. The quantitative relationships between numbers of predators and prey, and the “balance” in fish assemblages, had preoccupied fish managers since the early days of managing fish ponds. Studies in New York reservoirs in the 1930s, TVA studies in their new reservoirs in the 1930s and 1940s, and Swingle’s theoretical and field studies of fish ponds contributed to theories of fish community structure that were tested by the NRRP (Jenkins 1979). There were concerns that popular stocking of predators was ineffective, largely because of an imbalance that was created with abundance of available prey. The NRRP focused on determining desirable ratios of available prey to predators (AP/P ratios) for large southern reservoirs (Jenkins 1979). Prey-predator ratios fluctuated greatly, largely due to environmental perturbations, with food for predators usually determining predator abundance after lags of several years. Jenkins (1977) observed that the predator/prey ratio was not disrupted by the CWIS of the Oconee Nuclear Plant on Lake Keowee, South Carolina (CWIS capacity 129m3/s or 2,945 MGD), although there were year-to-year changes.

The relevance of this finding for CWIS is that maintenance of prey populations, ones often entrained, is important for maintaining strong populations of predators, which are usually the game fish of most direct interest to anglers and fishery managers. Prey populations may be some of those most affected by CWIS because many forage fish have pelagic (drifting) larvae and juveniles susceptible to entrainment. Monitoring of prey populations may be important in CWIS monitoring programs. However, the wide fluctuations caused by natural environmental perturbations makes separation of CWIS effects difficult.

-Total Dissolved Solids (TDS) and average depth were the principal correlates with fish standing crop. Predictors of fish standing crop were sought among the many variables recorded for reservoirs (Jenkins 1977). Of the 166 mostly southern reservoirs included in this analysis, 97 were hydropower reservoirs (52 mainstem and 45 storage; the rest served various purposes). Total dissolved solids (TDS) was the most important independent variable in partial correlation analyses of fish crop vs. 11 environmental variables. When combined with average depth as the morphoedaphic index (see separate discussion), the TDS correlations were highly predictive (Figure 3-13). Jenkins (1977) specifically tested correlations for clupeids (shads), which are the fishes most frequently impinged and entrained at southern power plants, and make up 40 to 55% of the biomass in reservoir cove samples. He reasoned that if mortalities induced by power plants were profoundly affecting the fish populations in reservoirs, the effect should be detected first in clupeids. Nonetheless, he found that TDS was the predominant factor affecting clupeid populations, although with a lower coefficient of determination than for total crop regressions.

The relevance of this finding for CWIS is that factors unrelated to CWIS (TDS and water depth) are the dominant correlates with fish populations, outweighing any dose-response relationship with water withdrawal.

-Factors associated with water withdrawal, e.g., flushing rate, were not clearly related to fish productivity (Jenkins 1970, Ploskey et al. 1984, Ploskey 1993) or the relationship was positive (reservoirs with high inherent water exchange rates supported larger standing crops; Aggus and Lewis 1976). Jenkins (1977) analyzed the effects of selected environmental variables on the standing crop of fishes in 140 large reservoirs and found some significant correlations between standing crop and storage ratio (volume/water flow). Lower rates of water exchange (high storage ratios) increased crops of bullheads, channel catfish, largemouth bass, smallmouth bass and crappie, but decreased crops of flathead catfish, bluegill, and longear sunfish. Physical flushing of young-of-the-year probably contributed to lowered catches of young fish in two run-of-the-river reservoirs (Walburg 1971) but in three large reservoirs studied by Ploskey (1993), predicted catches were positively related to flushing rate at normal-pool elevations. Only when pool elevations were especially low (flushing rate high because of decreased reservoir volume) were there negative relationships. Aggus and Lewis (1976) analyzed 26 reservoirs from 9 states in the Southeast for correlations between environmental variables and standing crops of fish for the simultaneous study years 1972 and 1973. Storage ratios were calculated (annual volume/annual discharge, which is the inverse of flushing rate) and ranged from 0.015 to 5, average 0.87). In multiple regression analyses, storage ratio was negatively correlated with sunfish and black bass crops, positively correlated with carp and catostomids, but not correlated with crops of clupeids, crappie, small fish (less than 4.5 in.) or total standing crop. When the focus is on providing harvestable fish such as sunfish and bass, a low annual storage ratio (high annual flushing rate) was found to be better.

The relevance of these findings for CWIS is that factors associated with water withdrawal rates are generally not as important for determining fish population strength as other features such as TDS and water depth. The importance of withdrawal varies among species and is more of a determinant under peculiar circumstances such as drastic reservoir drawdown. For some game species, high withdrawal rates were beneficial, and by analogy, a high rate of cooling water withdrawal at a CWIS could also be better for the populations than a low rate. The general lack or inconsistency of correlations with withdrawal is perhaps the main point for CWIS applications.

-Seasonal hydrological events had more impact on fish populations than annual average statistics (Ploskey et al. 1984). Summer drawdowns tended to flush young fish from the reservoirs, with negative effects on subsequent populations. Seasonal changes in reservoir area were more important than spring or fall storage ratio. For hydropower storage reservoirs (usually at the upper part of river basins and thus apt to withdraw more fish than are received from upstream), the percent of positive or negative correlations were: spring area (+93), annual change in area (+96), summer area (+89), spring change in area (+95), winter-spring area (+92), fall change in area (+79), summer change in area or drawdown (-89), spring storage ratio (-82), and surface area in the previous fall (-91). Whereas fall storage ratio affected fish populations in mainstem and flood-control reservoirs, it did not do so in upstream storage reservoirs. Overall fish productivity seemed to depend on the balance between positive effects (such as shoreline flooding in spring) and the negative effects of fish losses, such as through summer drawdowns.

The relevance of these findings for CWIS is, as observed above, that the relative consistency in elevation of water bodies used for cooling tend to stabilize and enhance fish populations. Seasonal changes in hydrology (e.g., high flow events) are likely more important for flushing fish from a reservoir system than is a recirculating CWIS.

In summary, the results of the NRRP may not be conclusive for establishing the effects of water withdrawal at CWIS, possible threshold limits on withdrawal for fish protection, or on dose-response relationships between withdrawal and fish population status, but they are valuable in establishing perspective with other (more dominant) effects on fish populations. The NRRP considered numerous reservoirs that varied in many design, operational, and environmental factors. The diversity of potentially causative factors for fish standing crops or yield may have obscured those that could be important when others such as water level are maintained more constant (for example, water level is often nearly constant in water bodies used for power plant cooling). Whether a subset of the about 1,600 reservoirs in the NRRP would provide a good sample of reservoirs having no significant water-level fluctuations but having a wide range of withdrawal rates and storage ratios (and still have good fish production data) is not known. The concluding point made by Jenkins (1977) is important, however: the baseline information and indices (such as normal predator-prey ratios and normal fish standing crop at a given TDS level) provided by the Reservoir Research Program can be used as reference points for CWIS monitoring systems.

The Reservoir Research Program data files still exist and might be mined for additional information. They reside with Dr. L. E. (Steve) Miranda, Mississippi State University (smiranda@cfr.msstate.edu).

3.3 Morphoedaphic Index Synthesis

In the 1960s, fisheries professionals examined potential relationships between the volume of water withdrawn from fresh water bodies and fish production in those waters as part of efforts to develop relatively simple indices for estimating fish production. Water withdrawal (in the sense we are using it in this report) was evaluated as the “flushing rate” of the water body, that is, the ratio of outflow to the volume of the waterbody. Correlation analyses among many parameters indicated that there are standard morphometric dimensions (measurements of size and shape) and water-quality parameters that are of major importance to fish production (Hutchinson 1957; Ryder 1982). These parameters were separated into primary and secondary factors. Primary factors were found to be area, volume, mean depth, and total dissolved solids. Secondary factors were considered to be the extent of the littoral zone, flushing rate, and shoreline or volume development. Flushing rate was considered to be of such low importance generally that it was not considered further for use in a predictive index. From these correlations, a school of thinking arose to explain the basis of fish production using what was called the “morphoedaphic index” or MEI (Ryder 1965). The MEI has been widely (and generally successfully) used to estimate fish production and yield in both lakes (Ryder 1982) and reservoirs (Jenkins 1982). The index is the ratio of the average total dissolved solids in the water and the average depth of the water body. As the index increases, fish production and yield increase (Figure 3-14). What the index seems to encapsulate is that overall ecosystem productivity is higher when there is a high level of nutrients and other mineral matter in the water and the water body is shallow enough to allow that productivity to be expressed in the productive photic zone (where light penetrates). The MEI concept merges Rawson’s (1952) thoughts about the relationships of fish production to water body depth with the analyses of the National Reservoir Research Program (above) and the Canadian Comparative Lakes Study (Schindler 1971) indicating the importance of nutrients and other dissolved substances. Nonetheless, after more than 100 publications and demonstration that it has good predictive power, the underlying mechanisms remain unclear (O’Brien 1990).

Successful use of the MEI depends on meeting a fairly stringent set of assumptions or criteria (Ryder 1982). Water bodies need to be in similar latitudes and have other major similarities. Climatic variability (e.g., wide differences in mean annual air temperature) will cause the MEI to be less predictive than climate (Schindler and Regier 1982, who analyzed 43 intensively fished lakes worldwide). The index works better for comparisons among lakes in the same region. Major limnological anomalies disrupt the MEI correlations. The authors readily admit that the MEI is an attempt to simplify among the many environmental factors that influence the productivity of natural lakes (and reservoirs, by extension), and ultimately the yield of fish. The MEI is an attempt to bridge the gap between ecological theory and management application, in a way that may seem overly simplistic. It is a reasonable compromise between "unimaginable complexity" and "ecological oversimplification" (Ryder 1982). It is intended as " a rapid, first-approximation answer to fisheries yield problems."

When applied to reservoirs by the National Reservoir Research Program (Jenkins 1982; see separate section), the relationship of the index to sport fish harvest was curvilinear, with maximum yields expected at index values of 50 to 100. Fish standing crop in 290 reservoirs was also significantly correlated with MEI (curvilinear), with maximum crops expected at values of 50 to 200. The relationships differed by reservoir type, predicted crops were higher in mainstem reservoirs and lowest in non-hydropower reservoirs where sulfate-chloride ions were dominant (Figure 3-13).

We used data from one of the publications on MEI to further examine the effects of reservoir retention time on fish production. One apparent underlying assumption of the mechanisms behind the success of the MEI is that phytoplankton production is greater in lakes with high TDS (and thereby high nutrients). Adams et al. (1983) set out to test this assumption by examining the trophic dynamics of fish production in 17 southeastern reservoirs. The reservoirs chosen for analysis were those in the U.S. Reservoir Research Program that had physical reservoir data, fish production data, and primary production data. We used their data and extensive analysis of trophic energy and carbon transfer to fish populations to examine the effects of reservoir water retention time. Retention time would be a surrogate for water withdrawal rate from a CWIS, assuming that all organisms were killed by the CWIS (longer retention times would correspond to low amounts of cooling water withdrawal per volume of water body). The trophic analysis of Adams et al. was detailed, and mostly related to testing the hypothesis of dependence of fish production on phytoplankton production (which it wasn't). We found fish production in the 17 reservoirs they analyzed to be inversely related to retention time (the longer the retention time, the lower the fish production), although the relationship was weak, especially when one highly productive reservoir was removed from the data set (Figure 3-15). Retention times were as low as 3 days (Nickajack Reservoir, Tennessee) and as high as 489 days (Moss Reservoir, Texas).

The relevance to cooling water use of the MEI and the historical attempts to find simple indices for predicting fish production in freshwater bodies lies in (1) the apparent low ranking of withdrawal rates (as flushing times) in determining fish production in lakes and reservoirs, (2) the apparent success of the simple MEI (without considering withdrawal rates, but concentrating on TDS and water depth) for making such predictions, and (3) the apparent relationship we found from one set of reservoirs that a higher rate of withdrawal actually may result in higher fish production. From the MEI experience and evidence, we can conclude that an hypothesis for a high importance of water withdrawal for determining fish production is not supported, and that factors other than water withdrawal predominate. A dose-response relationship between fish productivity and water turnover rate does not appear to hold, or the effects are below an effects threshold.

3.4 Reservoirs with High Entrainment and Observed Effects

An essential element of a dose-response model is demonstration that effects do occur at some levels of the stressor that can be quantified (Bliss 1937; Suter 1993). Bioassays are always conducted across a range of exposures from those where effects are clear to those where the effect is not detectable.

Demonstration of effects at high levels may allow definition of the dose-response relationship (that is, the quantity of response associated with a quantity of the exposure) and, with adequate data, indicate a threshold level below which there is no effect. If all data were from exposure quantities below the threshold (i.e., no effects could be demonstrated), then there would be little basis for understanding any quantitative relationships between exposure dose and biological effects. Thus, we sought examples of demonstrated effects of entrainment on fish populations. This was not to suggest that these situations would be typical but that they indicate the high end of dose and effect in our "bioassay" compiled from many water bodies and intake systems, including hydropower. From these examples, the mechanisms that create effective doses can be made clearer for application to CWIS. This context is vital for understanding what follows.

Entrainment losses of fish through large hydroelectric facilities is a familiar problem that is stimulating research and development to find solutions (Maiolie et al. 2001). Some reservoirs, such as that behind Grand Coulee Dam on the Columbia River (Lake Roosevelt, Washington, discussed in more detail below) have flushing rates sufficiently high that populations of reservoir fish (in that case, kokanee and rainbow trout) are severely impacted. Such reservoirs are able to maintain fish populations large enough to provide a fishery only after continual stocking from hatcheries and rearing net-pens to make up for the entrainment losses. Effects of entrainment on reservoir fish populations and communities at other dams are presumed to grade to lesser degrees from extreme situations such as at Grand Coulee, with a potential for identifying threshold withdrawal rates for inducing impacts on reservoir fish populations and communities.

In large western reservoirs, kokanee (landlocked sockeye salmon) seem particularly susceptible to entrainment. High losses of kokanee have been reported not only at Grand Coulee Dam (Lake Roosevelt) in Washington (Spotts et al. 2000) but at Libby Dam in Montana (Skaar et al. 1996), Banks Lake in Washington (Stober et al. 1979) and Dworshak Reservoir in Idaho (Maiolie and Elam 1998). High vulnerability to entrainment is likely a characteristic of this species, as discussed further below. Rainbow trout are also entrained in large numbers by dam discharges, and have been augmented by hatchery operations at Lake Roosevelt in order to maintain a fishery (Underwood et al. 1996). Summaries follow of these situations in which entrainment is known to affect reservoir populations.

Grand Coulee Dam (Lake Roosevelt) - Lake Roosevelt, formed by impoundment of the Columbia River by Grand Coulee Dam in north central Washington state, is unique among large impoundments due to its size, seasonal variation in flow, and the magnitude of annual manipulation of the water level (Wilson et al. 1996). The reservoir inundates 335 square kilometers, is approximately 112 m deep at the dam, and has a full-pool volume of just under 12 billion cubic meters. Lake Roosevelt is characterized by intense annual drawdowns to supply water for hydropower operations at downstream dams and for flows to support salmon migrations. Reservoir water level is reduced an average of 24 m each year, with the mean depth lowered by an average of 7 m. Surface area and lake volume typically drop to 55% and 45% of their full pool values, respectively. Water residence times vary greatly through the year, approximately 70 days in stable full-pool situations to as low as 10 days during the late winter and spring drawdowns. Water volumes released during drawdowns are large, often above 150,000 cfs (97,000 MGD). Despite its large size, this reservoir more closely resembles what one would expect from a regulated reach of a large river than a reservoir or lake. For contrast, Pace et al. (1992) states that water residence times in large lakes typically exceed 1,000 days, in large impoundments just above 500 days, and in regulated reaches of large rivers an average of 18 days.

It is apparent that entrainment of fish through Grand Coulee Dam occurs to a significant degree, depending on species and water year (LeCaire 1999). Based on relative abundance, it is suspected that entrainment of kokanee exceeds that of rainbow trout, although both are entrained (sampling difficulties make species identification difficult). Evaluation of the additional third powerhouse by Stober et al. (1979) indicated that the penstocks were positioned to coincide with the depth distribution of kokanee and thus cause significant entrainment. Reservoir entrainment rates have been indirectly estimated from tag returns of rainbow trout by the Spokane Tribal Fisheries, hydroacoustical estimates at the dam's penstock intakes conducted by the Colville Confederated Tribes, and hydroacoustical pelagic estimates in the reservoir conducted by the Washington Department of Fish and Wildlife. These data are reported to the Bonneville Power Administration (Portland, Oregon) in a series of annual reports and project proposals by each agency (from which this summary is derived). Use of hydroacoustical techniques from 1996 to 1999 yielded estimates of 1.5 million fish lost (smolt size or larger). Monthly entrainment totals ranged between 2 and 16% of the reservoir-wide offshore abundance estimate for the month. When totaled, this amounts to 22-88% of the fish stocked to the reservoir each year (uncertainties of estimation are large). Abundance in the reservoir was strongly correlated with the entrainment rate the month before. Few 3-year-old kokanee remain in the reservoir.

Entrainment of kokanee is aggravated by a tendency of this species to migrate in the spring. There is evidence that the landlocked fish still go through a "smolting event" that replicates the physiological changes experienced by sea-run sockeye salmon. One to 3 year-old juvenile fish apparently seek the outflows and will pass through the turbines at the time of short water retention times produced by large spring draw-downs. More 3-year-old kokanee derived from Lake Roosevelt have been recovered downstream of Grand Coulee Dam in years with major drawdown than in years with minor drawdown.

Current research by the Lake Roosevelt Fisheries Evaluation Program (BPA Project 1994044300; Cichosz et al. 1999) is evaluating alternative reasons why the kokanee population in Lake Roosevelt is not self-sustaining and must be continually augmented by hatchery-raised fish. Although several factors have been considered, entrainment of kokanee is believed to be the primary reason. As a result, a program to deter entrainment using strobe lights at the penstock entrances is underway (funded proposals by BPA Project 199501100).

A comparable pattern exists for rainbow trout, which occur in Lake Roosevelt as both wild and hatchery-derived fish. Wild fish appear to more successfully maintain a sustaining population than introduced fish, constituting about half of the combined abundance in the reservoir but less than 10% of the catch. In 1998, all rainbow trout contributed 64% of the fish catch of all species in the reservoir and 98% of those harvested were from hatchery fish reared in net pens (Spotts et al. 2000). Most net-pen fish are caught in the same year as they are released.

The percentage of net-pen-raised rainbow trout that are entrained appears to be strongly related to reservoir retention time and the drawdown-refill scenarios at the time when fish are released into Lake Roosevelt (Cichosz et al. 1998). Historically, fish were released in spring or early summer, at a time of strong drawdown (March-April) followed by refill (May-June). Experimental releases at other times suggested that high entrainment rates can be expected whenever water retention times are less than 20 days, regardless of time of release. When retention times shorter than 20 days are predicted, there is an advantage to releasing fish later in the year (e.g., June). Interannual comparisons also show distinct relationships of fish populations with water retention time. Spring drawdowns in 1990-1991 and 1996-1997 resulted in low reservoir water levels, water retention times below 30 days, and a poor fishery (based on creel census data). In contrast, 1992 through 1995 had higher mean reservoir elevations, longer retention times, and a better fishery.

The situation at Grand Coulee Dam and Lake Roosevelt has clear site-specific and species-specific attributes that make generalizations to a dose-response model among water intakes difficult. However, the case study shows clearly that entrainment of some fish species can occur at rates that are detrimental to maintaining sustaining populations, even with hatchery augmentation. The situation clearly illustrates the seasonality of entrainment and its effects. Annual average water retention times are a less fruitful statistic for evaluating entrainment effects than are monthly retention times as affected by seasonal water drawdown-refill patterns and the seasonal life-history characteristics of the species affected. The emphasis on site-specific factors affecting entrainment and its effects is perhaps the main lesson from this high-end case.

Libby Dam (Lake Koocanusa) - Another high-end case with demonstrable biological effects of entrainment is Libby Dam, Montana. Libby Dam is located on the Kootenai River, a tributary of the Columbia River, near Libby, Montana. The reservoir, Lake Koocanusa, is 154 km long and 100m deep at the dam at full pool. The normal storage is about 5.8 million acre-feet. All outflow is passed through turbines after entering a selective withdrawal system. Unregulated inflow from the Rocky Mountains of Canada and the U.S. peaks in mid-May through late July (30,000 to 65,000 cfs in 1991-1994) whereas outflow is minimized at that time, resulting in reservoir filling (4,000 to 25,000 cfs) (Skaar et al. 1996). Regulated outflows (4,000 to 28,000 cfs; 2,585 to 18,100 MGD) occur in fall and winter with a spring pulse to aid white sturgeon spawning in the downstream reach. Inflows at that time of year were about 3,000 to 5,000 cfs in 1991-1994, resulting in reservoir lowering. Water retention time in the reservoir would thus vary in a complex, seasonal manner related to drawdown and filling cycles. The entrainment study (Skaar et al. 1996) did not calculate water retention times for the reservoir. However, we estimated the retention times to vary from about 780 days at low outflow rates (4,000 cfs) to 125 days at high outflow rates (25,000 cfs), assuming nearly full pool.

Fish entrainment is significant. Kokanee is the predominant species entrained (97.5%), although 13 other resident species were captured in nets placed over the turbine discharges. Young-of-the-year kokanee predominated (74%) while ages one and two comprised about 13% each. Diel patterns of entrainment were identified by hydroacoustic measurements. Fewer fish were entrained in daylight (22%) than between sunset and sunrise (78%). Entrainment increased immediately after sunset and peaked in the 2-3 hours before midnight, followed by steady numbers until sunrise. Extrapolation of periodic hydroacoustics and netting provided estimates of annual entrainment ranging from 1.15 million fish to 4.47 million fish, depending on assumptions (the higher figure was deemed more reliable, for it used extrapolations between adjacent temporal entrainment data points rather than an annual average entrainment rate for unsampled times). These numbers compared to an estimated 4.78 million fish in the reservoir, as estimated by hydroacoustic sampling (23 to 92% of the total kokanee population was estimated to be entrained, respectively). Entrainment rate was most closely correlated with forebay fish density at 10-20 m depth, although there were significantly more kokanee entrained at high volumes of withdrawal than at lower volumes. There were seasonal trends in entrainment, with spring and fall having the highest rates. In spring, fish densities in the forebay are high and located at depths close to the penstock intakes. In fall, entrainment was high largely because of the high rates of discharge.

Population effects on kokanee were shown largely by density-dependent growth and sizes attained. Larger fish resulted when entrainment was high, presumably due to fewer fish preying on the zooplankton food base. Although large fish are desirable for angler interest, too few can cause population collapse. Management use of entrainment rates to regulate fish size for anglers was suggested.

Although the study by Skaar et al. (1996) did not analyze entrainment in terms of water retention time, as had studies of Grand Coulee Dam, there are several points of agreement between them. First, entrainment can affect fish populations in the reservoir, at least to the extent that density-dependent processes such as growth rates are affected. In the Libby case, population sustainability limits were not reached, however. Second, entrainment is a complex matter, varying daily and seasonally. The reservoir management cycles of drawdown and filling, and their necessary effect of varying retention times, have a strong influence on entrainment losses from the reservoir. From the perspective of a dose-response model, the Libby Dan situation is less severe than Grand Coulee. However, quantifying that "dose" is difficult.

Banks Lake (Washington) - We did not examine the study of Banks Lake by Stober et al. (1979 cited in Skaar et al. 1996). However, Skaar et al. (1996) noted that primarily kokanee of ages 2, 3, and 4+ were entrained. An estimated 60 and 75% of the kokanee population was entrained in 1975 and 1976, respectively. Weekly entrainment sampling over a 4-year period showed kokanee entrainment to be erratic. Entrainment appeared to be related to the volume of water withdrawn (which changed markedly due to irrigation demands), maturation state of the kokanee (tendency of smolt sizes to migrate downstream), and feeding movements that brought fish near the lake's outlet.

The relevance for 316(b) is that the biological effects of entrainment can be viewed as a dose-response problem, with definable effects at the high end of the scale for flushing or turnover rates. Turnover rates are applicable to CWIS on lakes and reservoirs although those for CWIS are generally much lower than seen in these examples. These examples illustrate the importance of seasonal site-specific factors, both reservoir filling-drawdown schedules and the vulnerability fish species of concern for determining the amount of entrainment and its biological effects.

3.5 Fish Control Programs

In principle, fish control programs, i.e., programs in which certain species are targeted for reduction or elimination (or are unintentionally reduced by adverse environmental episodes), could be seen as analogues of CWIS that irretrievably withdraw fish from a water body. In such a hypothesized analogy, the population-level effects of reductions in fish numbers through control programs could shed light on population-level effects of cropping by power stations. In both cases, the biological remains (dead fish) often persist in the waterbody. The responses of fish populations to control measures may also fit a dose-response model, in which the population effects are proportional to the quantitative losses due to eradication measures, with some threshold of eradication effort necessary for any population effects to be seen. The suggested analogy with CWIS and a dose-response model is not perfect, for control programs often occur over broader areas than in the localized zone of a power station intake, and usually have been tested for one-time or a few controlled kills rather than the chronic fish removals at CWIS. They also do not necessarily discriminate among life stages, as do entrainment and impingement at a CWIS. Nonetheless, we felt that the analogy was worth exploring for whatever could be learned.

Manipulation of forage fish populations to enhance sport fisheries is a common fisheries management practice, with introductions outnumbering removals. Some of the fish species targeted for reduction are also known to be particularly vulnerable to power plant impingement and entrainment. Gizzard shad and threadfin shad are two such species. We examined recent summaries of fish control programs to see if their experiences could be instructive for evaluating CWIS impacts.

Three reviews and one recent field study suggest that the analogy with CWIS and the proposed dose-response model is difficult to pursue to a useful conclusion for assessing the effects of CWIS (Lennon et al. 1970; DeVries and Stein 1990; Meronek et al. 1996; Kim and DeVries 2000). The status of chemical control efforts up to 1970 were reviewed by Lennon et al. (1970). They reviewed many successful and unsuccessful fish-removal projects, but did not quantify success rates. In a second review, removals of shad (partial removals, in practice) were concluded to be far less powerful for eliciting a response in the fish community than were additions (stocking) of shad to previously shad-free environments (DeVries and Stein 1990). Even so, 65% of the removal studies reviewed believed that they had successfully documented lowered shad populations. There was little longevity to the effects, however. Because shad are extremely fecund, DeVries and Stein (1990) concluded that effects of a 50% reduction in the adult shad population may only be measurable over a single season. By the following year, a large forage-fish year-class could return the population to its original size. Any trends in secondary effects of shad removal (e.g., on game species) were even more difficult to discern from the 14 removal studies reviewed by DeVries and Stein. Target game species experienced a mixture of positive, neutral and negative effects from shad removal. Strong, sustained fish removals are required to detect system responses. Part of the difficulty in discerning effects is the poor quality of the studies, a point made strongly by DeVries and Stein. Few fish manipulations that are undertaken as fish management strategies include a reference water body, adequately monitor before and after the manipulation, use statistical approaches to data analysis, adequately consider the trophic dynamics of altering a part of the food web, or consider how spatial heterogeneity affects community interactions. From the perspective of applying these data for CWIS analyses, we note that they also did not adequately relate the fish-removal effort to physical attributes of the water body, such as volume and rate of water turnover, which we could relate to cooling-water use, entrainment and impingement.

A broader range of species removals was analyzed by Meronek et al. (1996). They reviewed 250 fish control projects from 131 papers, including chemical applications, physical removal (nets, traps), reservoir drawdowns, stocking of predator fish, and combinations. Species included 13 game fish species, 15 panfish species, and 31 rough or forage species. Success was judged by changes in standing stock, growth, proportional stock density (PSD), relative weight values, catch or harvest rates, and other benefits such as angler satisfaction. Reduction in standing stock was the most common determinant of success. Perhaps the most germane result for CWIS considerations was that less than half of the control programs were viewed as successful (43%). Combined chemical and physical methods made for success in 66% of the projects. Waterbody size (0.2 to >400 ha) made no difference in the results of chemical treatments but there was greater success for physical treatments in larger water bodies. The focus of the Meronek et al. review was, as for DeVries and Stein (1990), on how to improve control procedures, not on the resilience of fish species' populations. Nevertheless, their review highlighted the differences in susceptibility of species groups to different control measures. Somewhat surprisingly, there was more success at reducing rough fish populations than either of the more valued panfish or game fish (panfish and game fish are often removed to reduce stunting and increase individual growth and size when numbers are too high for the food base).

A recent study (Kim and DeVries 2000) highlighted the rapidity with which fecund forage species, which are often impinged and entrained at CWIS, can rebound from removal. Within 2 years of a reduction in a population of gizzard shad in a 66-ha Alabama lake, their abundance rapidly returned to high levels. When density was low after population reduction, larvae and juveniles experienced rapid growth. When density was higher in a later year, growth rates slowed. We note that this density dependence is an excellent example of compensatory mechanisms operating to offset higher mortality (an argument commonly used in 316(b) demonstrations). However, slower growth rates of shad when populations were high favored transfer of energy to largemouth bass; the bass had a longer time period when the juvenile shad were of a size vulnerable to predation. The authors stress the importance of the secondary trophic interactions. The rapid population rebound and trophic consequences of the reduction were paralleled in threadfin shad, which repopulated rapidly after a massive winter kill in Watts Bar Reservoir, Tennessee (McLean et al. 1985).

About the most that can be concluded from the literature on fish control projects with reference to CWIS is that it takes a lot of fish removal to successfully reduce most fish populations and that a strong and persistent removal is necessary or the populations will quickly rebound. In other words, a very high and persistent “dose” of removal is needed to obtain much response. Both situations may occur with some CWIS, and have certainly occurred for commercial species that have been over harvested. Responses differ among species. The trophic responses in the fish community to reductions of forage fish like shad species need to be carefully considered as well as the populations primarily affected. These can be only general conclusions, because available fish-control experiences are not well quantified as research experiments. Also, the focus on population control for sports fish management has not created an incentive to relate the control procedures or the results to physical features of the waterbody of interest to CWIS analyses (waterbody volume, rate of water turnover, etc.). Quantitative criteria for successful fish control (a dose-response relationship) are lacking for transfer to CWIS regulations. Nevertheless, the similarities between intentional fish reduction practices and unintentional losses through entrainment and impingement are potent for understanding how fish populations and communities function. A closer collaboration between these two activities might yield more quantitative information on how much loss can be sustained without population decline (for CWIS regulations) or must be inflicted in order to cause persistent population reductions (for control purposes).

The available summaries of fish control programs indicate that a large-scale, continuous removal is necessary in order to have an impact on many of the controlled fish species. In other words, the threshold dose for fish removal is high. Populations of fecund species like gizzard shad rebound quickly from major losses in numbers. Episodic losses, such as those that often occur through CWIS impingement, are most similar to intermittent fish control programs and are unlikely to have lasting effects on populations. Episodic events at CWIS usually involve species with high abundance and with high reproductive potential (e.g., Clupeid species). It is these characteristics that have limited the success of many fish control programs. The belief that high losses at CWIS create long-lasting and ecologically significant effects on fish populations is not supported by the evidence from fish-control programs.

3.5 Summary

One objective of this study was to identify an intake rate or intake-to-volume ratio (or residence time) that might serve as a threshold above or below which, respectively, an impact would be unlikely. Obviously, such a threshold would be species specific, but given the range of residence times in our analysis we were hopeful of some indication of a threshold for the systems and species we included. Above a residence time threshold we might expect other factors (e.g., habitat, food availability, presence of predators, etc.) to be more important in dictating abundance. Entrainment rates of rainbow trout in Lake Roosevelt were low or non-existent at residence times greater than 35 days, moderate at residence times between 20 and 35 days, and high at residence times less than 20 days (Cichosz et al. 1998; Figure 3-16). Similarly, largemouth bass year class strength as measured by catch curve residuals in Tennessee River reservoirs was fairly constant when residence times exceeded 25 days, declined gradually from 25 to 10 days residence time, and declined more sharply at residence times below 10 days (Maceina and Bettoli 1998; Figure 3-17). With a little imagination, a similar pattern can be seen in the relationship between the short-term Spring residence time and the community index (RFAI) for the Tennessee Valley reservoirs presented in this study. The decline in RFAI begins at a residence time of 45 to 50 days (Figure 3-18). Perhaps a residence time of 25 to 50 days would emerge as a valid threshold if further analyses were directed toward reservoirs in this range of residence times.

Although an effects threshold would be useful as a preliminary screening tool, it is important to note that exceedance of the threshold does not necessarily mean population-level impacts. Data collected during the course of this study indicate that high intake rates and high fish abundance are not necessarily mutually exclusive. Figures 3-4 to 3-6 include data from six Texas lakes that are used to provide cooling water to power plants, release only negligible amounts into receiving streams, and have annual residence times (based on CWIS intake rates only) as short as 8 days. Some of these lakes support fish populations that are among the highest observed in the data set (see Figure 3-5A).

Although the analysis presented here failed to produce clear generalizations regarding the relationship between volume of withdrawal and population- or community-level effects, we believe the evidence from this and other studies suggest that such a relationship often exists, but is dependent on a variety of other factors. These factors include species-specific (and life-stage specific) susceptibility, intake design and location, population-level compensatory mechanisms, and water body type. Likewise, the selection of a threshold that could be used as a screening tool to identify those facilities that might cause impacts versus those that are unlikely to cause impacts would also likely be specific to water body type, species (or species type), and other considerations.

Lastly, we believe that using reservoir releases as a surrogate for CWIS intakes to investigate the relationship between withdrawal volume and population effects is a useful approach. Future studies along these lines should investigate which set of flows (i.e., which months and how many years in the past) is most related to the abundance of the population being sampled. Being able to more precisely identify which life stages are affected by increased flow and what ecological mechanisms are operating will make identification of threshold flows more possible.

Overview of I & E effects on organisms

APPENDIX E-2:
VOLUME-RELATED CASE STUDIES

As we investigated the contribution of water withdrawal as a factor affecting fish populations, we revisited several past studies for insight. Although the five studies presented below all had different objectives, they each address fish removal and population response in one form or another. The six studies presented in this section include:

-findings from about 25 years of study of Hudson River fish populations affected by several power plants with large volumes of water withdrawal.
-findings of a Nuclear Regulatory Commission analysis of entrainment and impingement at CWIS as two of the potential biological problems being faced by power plants.
-findings of a team of researchers in The Netherlands on entrainment and impingement at several power stations using once-through cooling located on the extensive river and reservoir system in that country (Hadderingh 1978; van Densen and Hadderingh 1982; Hadderingh et al. 1983).
-a summary of fish population trends in Lake Wheeler, Alabama, pre- and post-operation of the Browns Ferry Nuclear plant.
-findings from a comparative ecological study of an Illinois lake used for cooling and similar non-cooling lakes.

5.1 Hudson River

Several power plants and other water intakes are located on the 243-km-long (151 mile) Hudson River Estuary between Albany, NY and New York City. They include major electricity generating power plants (Bowline Point, Indian Point, and Roseton) as well as smaller power plants (Lovett, Albany Steam Plant, Danskammer, 59th Street Station) and other cooling-water intakes (Empire State Plaza in Albany and the Westchester Resource Recovery Plant). Table 5.1 shows the locations, start-up date, and permitted cooling-water flows for each facility (Hutchinson 1988; CHE&G 1999). We calculated that, in aggregate, these power plants are permitted to recirculate 24.35 x106 m3 of Hudson Estuary water per day (6,433 MGD), or 1.024% of the 2,378.8 x106 m3 volume of the estuary per day (data from CHG&E et al. 1999). At this withdrawal rate, the entire estuary would be turned over by the power plants in 98 days (which is the residence time, assuming a static volume unaffected by tidal or freshwater flows). In comparison, the average daily freshwater inflow at the upper end of the estuary is 35.9 x106 m3 (9,485 MGD), the average daily tidal flow is near 600 x106 m3 (158,000 MGD), and the net outflow (total outflow minus tidal excursions) is 49.9 x106 m3 (13,200 MGD)(Cooper et al. 1988). Thus, the cooling-water facilities daily recirculate slightly less than the average primary daily freshwater inflow, about 4% of the average daily tidal exchange, and about half of the daily net outflow of the estuary.

Due to the large length of the Hudson River Estuary, it is informative to examine the withdrawal statistics for one particular segment (RKM 56-93) that contains three plants in close proximity (Bowline Point, Indian Point and Lovett). These three facilities are permitted to withdraw 15.9 x106 m3 per day (4,200 MGD), which amounts to about 2.5% of the volume of the segment (647.2 x106 m3).

[see hard copy for table]
Table 01
Power plants on the Hudson River, with location (river miles from the Battery in New York City) and water withdrawal rates (CHG&E et al. 1999).

There was intense controversy over the initial permitting of the largest of these plants in the 1970s, because their CWIS were located in zones of the estuary where large numbers of fish eggs and larvae would be entrained and juveniles impinged, especially striped bass (Barnthouse et al. 1988). Modeling of fish populations was the main technique used to estimate long-term effects of losing eggs, larvae, and juveniles during entrainment and impingement. The parties disagreed on the models to be used and the numerical values to be used for model elements. A settlement agreement among the plant developers and regulatory agencies (primarily the USEPA and the New York Department of Environmental Conservation) allowed the proposed plants to be built and operated with flow restrictions to minimize entrainment and impingement. Extensive monitoring of key species in the estuary was required.

As a result of the monitoring requirements, the Hudson River now has one of the most complete data sets in the country on the stock status of key species and on the composition (species richness and diversity) of the aquatic community, extending for over approximately 25 years. Empirical data on fish population performance during decades of entrainment and impingement provide the main evidence for any effects (or lack thereof). In addition, there are multiple data sets for many key system attributes (e.g., juvenile abundance indices from independent sampling programs by the utilities and the NYDEC) that provide mutual confirmation of results. The results to 1998 are summarized in CHG&E et al. (1999). Population modeling has improved, as well, allowing this analytical approach to supplement the empirical data.

The empirical data can be evaluated using explicit “risk hypotheses,” in accordance with guidance from EPA for conducting ecological risk assessments (EPA 1998). These hypotheses recognize that an estuary is a variable and complex environment, with many changes occurring over the 25 or so years of monitoring besides presence of CWIS. Testing of the explicit risk hypotheses helps separate changes in fish population abundances that are due to cooling water withdrawals from those that result from other causes. The evidence for testing these hypotheses is presented in CHG&E et al. (1999) and is confirmed for economically important species by stock assessments by the Atlantic States Marine Fisheries Commission (ASMFC), which follows stocks in order to regulate harvest. These hypotheses are:

1. Populations of species that are vulnerable to entrainment and impingement will show a general decline in abundance over the period of record since cooling water has been withdrawn;
2. Populations of the most vulnerable species will have declined more than populations of species that are less or not vulnerable to entrainment and impingement;
3. Loss of vulnerable species will be reflected in altered community composition as measured by species richness and diversity; Abundance of predators and prey will reflect secondary effects of entrainment and impingement, with loss of prey species (e.g., bay anchovy) from entrainment and impingement being reflected in fewer predators (e.g., striped bass) or declines in predators due to

entrainment and impingement effects being reflected in more abundant (non-eaten) prey.

Differences in population effects as a result of differences in vulnerability to entrainment and impingement among species would constitute a test of a dose-response model. Vulnerable species would be receiving a higher dose of entrainment and impingement relative to their population sizes than would less vulnerable species.

The evidence indicates that none of the risk hypotheses is supported by the long-term data, although some data sets are ambiguous. The major species of concern, striped bass, has exhibited an increase in adults and post yolk-sac larvae (PYSL) since the mid 1970s, and a fluctuating but overall trendless abundance of juveniles. The increase in adults is generally attributed by biologists to reduced harvest since the 1980s, allowing more reproductive-age fish to remain in the river. Despite entrainment, PYSL have increased in proportion to abundance of adults. The lack of trend in juvenile striped bass suggests that the increase in cooling-water use during the period is masked by underlying limits to the carrying capacity of the system for rearing PYSL to the juvenile stage. White perch are less vulnerable to entrainment because they reproduce farther up the estuary than the zone with most entrainment, yet they have little trend in abundance (perhaps a slight decline). They do not show less of a decline than that of striped bass, as the second risk hypothesis would suggest.

Atlantic tomcod, a species with a short life cycle (generation times of 1-2 years) and having vulnerable life stages in the vicinity of major CWIS, has declined, but only since about 1990. This decline correlates better with other changes in the ecosystem than with commencement of operation of the CWIS in the 1970s. American shad spawn in the uppermost parts of the estuary and are vulnerable to most CWIS withdrawal during fall out-migrations. There is some slight decline in stock abundance since 1990 that is not correlated with CWIS (abundance increased during onset of most cooling-water use). The river herrings (alewife and blueback herring) show some decline, similar to American shad. Stocks were depleted by overfishing in the 1960s and 1970s according to the ASMFC, resulting in low coast-wide stocks. Tributary access for spawning has been restricted by dams, especially for blueback herring. There is no evidence that the declines in these species are correlated with CWIS use. The main prey species, bay anchovy and spottail shiner show no trends in abundance and remain stable.

Species richness and diversity show little trend. Ichthyoplankton shows a general increase whereas young-of-the-year and older show slight decreases. The slight reduction shows little relationship to CWIS use, being mostly caused by decline in freshwater species in the upper, less saline estuary (attributed by some analysts to increase in abundance of invasive water chestnut and zebra mussel). The species that dominate the ichthyoplankton (a segment of the community showing increasing richness and diversity) are those most vulnerable to entrainment, thus exhibiting a response opposite to that hypothesized for CWIS influence. Both predator and prey species in the estuary have largely stable populations, and do not show the reciprocal increases and decreases hypothesized under the influence of CWIS.

Thus, the lack of support for the risk hypotheses from the exceptionally complete 25-year data set is persuasive evidence for biologists that CWIS on the Hudson River Estuary are not causing adverse effects to the key species or the aquatic community. Despite the large volumes of cooling water used, and the large numbers of individual fish eggs, larvae, and juveniles entrained or impinged, the amounts of water and organisms affected relative to the entire waterbody (or one segment where most influence occurs) are small and the biological effects undetectable at the population and community scales. Viewed in the perspective of a dose-response model, the losses to entrainment and impingement appear to be below the effect threshold for effects for either the whole Hudson River estuary or for the segment nearest the largest power plants.

In principle, the empirical data set also might be useful for comparative purposes among CWIS on the Hudson. Different-sized CWIS might give an indication of the relative influence of intake volumes on several parameters of fish effects (e.g., numbers of fish withdrawn, conditional entrainment mortality, and conditional impingement mortality). In effect, we might be able to see a dose-response pattern among the several Hudson River estuary CWIS. The data in CHE&G (1999) were not very useful for that sort of analysis. This is because the CWIS are distributed over a long distance of the estuary and the vulnerable fish species and life stages occupy distinct zones along this large geographic gradient. For example, striped bass spawning, eggs, and larvae occur near Indian Point but not near the Albany Steam Station. Thus, the several CWIS are not comparable in many biological respects. The smaller CWIS (Albany Steam Station at Albany, NY and the 59th Street Station in NYC) are located at the geographic extremes, with more similar and larger CWIS clumped midway. Also, the CWIS for the Bowline Point plant is located on an embayment off the main Hudson River channel, which contains biological populations and hydraulic characteristics quite different from those near the CWIS of the other plants. We concluded that the value of these CWIS for conducting comparative, dose-response analyses of the influence of water withdrawal volumes is highly compromised by these other variables. A more detailed analysis for this purpose was not conducted.

The Hudson River situation has, however, spawned a novel way to ameliorate the entrainment and impingement of fish by modifying the volume of water withdrawn by several power stations on the same water body during the species' time of most vulnerability (CHG&E et al. 1999). The approach is generally analogous to the concept of "effluent trading" in application of the Clean Air Act, as discussed further below. Although each of the power stations has some form of structural reduction of entrainment and impingement mortalities (e.g., Ristroff screens at Indian Point, barrier net at Bowline Point), the stations together have proposed implementing a river-wide system of Fish Protection Points (FPPs) to guide cooling-water volume reductions and potentially the scheduling of plant outages for maintenance.

Fish Protection points are an evolution of the Settlement Agreement between utilities and the Environmental Protection Agency in the early 1980s. In the Settlement Agreement, the power stations agreed to cease or reduce generation and its cooling-water withdrawal between certain dates when entrainable fish eggs, larvae and juveniles were in the River (primarily spring and early summer). This volume reduction was deemed the best way to minimize fish losses and still maintain generation through much of the year. In effect, a dose-response model was being applied, and the "dose" (volume of water and its contents of entrainable organisms) reduced during critical time periods. The on-off cycle was entirely dependent on the calendar and knowledge of when the concentrations of entrainable fish life stages were usually highest. The concept of FPPs takes this approach further toward technical accuracy by controlling the on-off cycle of plant operation according to the actual abundance of these organisms in real-time. Fish abundance and numbers projected to be saved by outages are calculated as accounting "points." Further, it allows a trading of "off" times among power stations according to calculations of the value of the "off" time for saving fish based on numbers of entrainable organisms present (FPPs). Further, and controversially, the current generators propose to allow the FPPs to be averaged over a 10-year period so that the average level of protection equals or exceeds that of the original Settlement Agreement. A system based on FPPs would allow more operational flexibility than date-specific outages or flow reductions.

Aside from the 10-year averaging, the concept of riverwide FPPs to be appropriated both volumetrically and temporally by the several power stations is akin to regional trading of air-emissions. The generators can negotiate among themselves which facility or facilities will have an outage or targeted flow reduction at any one time in order to meet the river-wide FPP requirement. Permitting with FPPs would dictate the overall outcome, while leaving the implementation more flexible among facilities. With several fish species involved, each having somewhat different seasonal timing and spatial distribution, the allocation of outages among facilities (having different locations and different withdrawal volumes) can, at least in principle, accommodate the many differences in a way most beneficial to the biology and to power generation.

The down-side of attempting to match cooling-water use to actual spatial and temporal differences in species' abundance is that the control system might become overly complicated and too cumbersome to be effective. The Draft Environmental Impact Statement prepared for re-permitting under the NY discharge permitting system (CHG&E et al. 1999) recognizes this difficulty. Several workshops have been held under the auspices of the NY Department of Environmental Conservation (DEC) and the generators to expand understanding and to work out details of proposed implementation. The DEC has hired an independent consulting firm to thoroughly evaluate the proposal. The outcome of acceptance by the regulators is still unclear.

Relevance for Section 316(b)—The Hudson River Estuary is instructive for questions of using CWIS volume as a regulatory tool. Undeniably large CWIS in terms of water volume withdrawn (and numbers of eggs and larvae entrained) can have little cumulative impact on long-term trends in fish populations or community composition when long-term records are available for examination. The essential functional feature of the CWIS scenario appears to be the percentage of the source water withdrawn, which was low, resulting in biological effects that were, therefore, undetectable. In the words of a dose-response relationship, the doses were below threshold for population effects.

5.2 Nuclear Regulatory Commission Synthesis

In 1996, the U.S. Nuclear Regulatory Commission (NRC) judged entrainment and impingement at CWIS to be of sufficient concern to resource agencies that these potential impacts should be included in site-specific environmental impact statements for the relicensing of nuclear power plants. The NRC, with assistance from Oak Ridge National Laboratory, prepared a generic environmental impact statement for license renewal of nuclear power plants in the United States (GEIS; NRC 1996). This GEIS included an analysis of entrainment and impingement at CWIS as two of the potential biological problems being faced by such power plants. Natural resource agencies and power station operators nationwide were questioned about their concerns. A rich published literature was surveyed. Five case studies of individual operating power stations representing the diversity of cooling-water sources were reviewed by the NRC study (Arkansas One, McGuire, Cook, San Onofre, and Crystal River), and two that were aggregates of several plants on a single water body (Hudson River, Lake Michigan). The flow data are tabulated in Table 5-2. The EIS recognized that entrainment and impingement are not unique to nuclear power plants, but instead are typical of potential impacts from any large steam-electric power plant using once-through cooling, whatever the fuel type. The intent of the EIS was to identify industry-wide issues and approaches to their solution rather than in-depth, site-specific analyses of any particular situations. The main purpose was to identify aquatic ecology issues that generally would not need to be considered in detail in the license renewal process as opposed to those that may or do need to be considered on a site-specific basis.

[see hard copy for table]
Table 02
Water withdrawal rates for nuclear power plants examined in case studies for the Nuclear Regulatory Commission's Generic Environmental Impact Statement (NRC 1996).

The EIS cautioned that power plant impacts cannot be measured simply; for example, by comparing pre-operational data with post-operational data. Environments are in constant flux even without a power plant, for reasons that often are poorly understood. For example, reservoirs change as they age affecting productivity and species composition, and fish standing crops change from year to year and decade to decade (see separate discussion of the U.S. Reservoir Research Program). Power plants superimpose their effects on a mosaic of background influences. The NRC study identified concerns that CWIS issues may increase as fish population status improves in many water bodies as a result of water quality regulations resulting in more fish being available for entrainment and impingement. On the positive side, most nuclear power plants reviewed had been operating for several years, so effects, both local and system-wide, could be evaluated on the basis of monitoring data as well as predictions.

The results of the NRC analyses "indicates that many of the aquatic resources issues evaluated in the licensing stage [of the nuclear power stations] have not materialized as significant problems." However, "entrainment and impingement of fish … from once-through power plants continue to concern some regulatory and resource agencies. …and will need to be considered in the license renewal application." The concerns and the NRC's results are described further below.

5.2.1 Entrainment

Agencies consulted by the NRC for the generic impact statement expressed concerns about large losses of organisms by entrainment at several power stations (Zion, Salem, Oyster Creek, Indian Point, Calvert Cliffs, Millstone, Yankee Rowe, and Surry). Some of these had unresolved 316(b) determinations at the time (Indian Point, Oyster Creek, Comanche Peak, Salem, and Zion). At other nuclear power plants (Beaver Valley, Susquehanna, Three Mile Island, and Peach Bottom), the U.S. Fish and Wildlife Service expressed concern about future losses of organisms by entrainment as restoration efforts, particularly of anadromous fishes, increase fish populations. In such cases, entrainment analyses conducted at the time of the original licensing would not be valid.

The NRC report concluded that entrainment effects on phytoplankton and zooplankton were minor or nonexistent -- "Because of large numbers and short generation times, impacts of entrainment on phytoplankton and zooplankton have rarely been documented outside the immediate vicinity of the plant and are considered to be of little consequence." No special mitigation has been required for these components of the ecosystem.

The NRC recognized entrainment effects on fish and shellfish as one of the important issues examined in initial licensing of the plants and one that is periodically revisited by permitting agencies for NPDES permits and 316(b) demonstrations under the Clean Water Act. The NRC concluded, "Although significant adverse entrainment effects have not been demonstrated at most facilities, the entrainment of fish and shellfish in early life stages remains an issue at some nuclear plants with once-through cooling."

In a discussion of the combined effects of power plant entrainment and impingement on fisheries resources of Lake Michigan, the NRC GEIS cites regression equations developed by Kelso and Milburn (1979) for annual entrainment and impingement as functions of power plant size (Figures 1-7 and 1-8). The larger power stations, with their larger volumes of water withdrawal for cooling, appear to entrain more fish larvae. The relationship of entrainment to population status is hotly debated, however (Scott-Wasilk et al. 1981). A critical question is whether compensation in the fish populations occurs before or after mortalities incurred during entrainment (if compensating mechanisms operate after entrainment mortalities occur, then the losses are less likely to be significant for the population; if compensating mechanisms occur before the life stage at which organisms are killed, then the results are more likely to be significant). Generally, compensation occurs after entrainment of early life stages.

Among the seven case studies presented in the review, the site-specific circumstances overweighed any clear relationship between entrainment and effects on populations. The degree of concerns expressed by resource agencies, although subjective, did not appear to be proportional to water volumes withdrawn, but to other environmental factors. Thus, there did not seem to be any dose-response relationship demonstrated between entrainment and fish population decline. No-effect thresholds may not have been exceeded and other site-specific characteristics dominated.

5.2.2 Impingement

Impingement was recognized by the NRC EIS as one of the unresolved issues in power station licensing. The NRC concluded, "[O]perational monitoring and mitigative measures have allayed concerns about population effects at most plants, but impingement mortality continues to be an issue at others." Concern is especially high where restoration of anadromous fishes may be affected. The NRC cites cases where significant modifications had to be made to the intake structure to substantially reduce impingement once the plant was operating (Oyster Creek, Salem, Surry, and Prairie Island). Of the case studies presented, only San Onofre appears to have scientifically demonstrated a relationship between impingement and population declines of certain species in the vicinity of the plant (a dose-response threshold seems to have been exceeded).

The NRC GEIS cites Kelso and Milburn (1979) for their development of a relationship between numbers of fish impinged and power plant size (as an index of cooling-water volume) for the Great Lakes. There does appear to be a relationship, particularly for clupeids (Figure 1-8). Kelso and Milburn attempted to relate the total number of impinged fish to population size by using commercial catches as an index (losses amounted to about 25% of the commercial catch by weight). This index was disputed by Scott-Wasilk et al. 1981, who noted that the fishery caught only 2.9 to 23.5 percent of the estimated standing stock, depending on species and year. Thus, the commercial catch was an unreliable, and demonstrably low, estimate of the population sizes with which to compare impingement rates. Commercial catches of 2.9 to 23.5 percent would translate to impingement of 0.7% to 5.9% of a population rather than the 25% estimated by Kelso and Milburn.

Among the other case studies presented, the analysis found no clear relationship between volume of water withdrawal and the occurrence and severity of fish impingement. Other factors, such as water temperature and sharp temperature changes, were believed most responsible. Impingement was recognized by the NRC study as a visible problem that still needed to be addressed, but also that waterbodies on which nuclear power plants were located generally had highly productive fisheries even with the plants operating.

Relevance for Section 316(b)—The NRC study demonstrates the subjective opinions of resource agencies that entrainment and impingement are problems at large nuclear power stations. The hard, quantitative evidence for such concerns is lacking in most cases. No general relationship between volume of water withdrawn and effects on fish populations could be shown (no general dose-response relationship). The NRC report concludes that site-specific analyses are essential because it was site-specific circumstances (often unique) that caused the episodic occurrence of high levels of fish losses.

5.3 Dutch Studies

To test the hypothesis of a dose-response relationship, i.e., show that larger water withdrawals for CWIS cause larger biological effects, one needs a comparative study of several power stations of different sizes. Researchers in The Netherlands examined entrainment and impingement at several power stations using once-through cooling from the extensive river and reservoir system in that country (Hadderingh 1978; van Densen and Hadderingh 1982; Hadderingh et al. 1983). Studies included estimates of numbers of fish and species entrained and impinged, mortality rates by species, differences in entrainment and impingement among six power stations located on different river and reservoir systems, and a detailed examination over a 4-year period of the effects of entrainment and impingement on the first-year fish populations of one reservoir used for cooling. Taken together, these studies illustrate the difficulty in defining a dose-response relationship and in selecting regulatory standards for CWIS from the multi-plant comparisons.

At the Bergum Power Station, Hadderingh (1978) found most fish affected by entrainment and impingement were larvae or juveniles. Numbers of individuals were highest after spawning in spring. Many species were affected, the most abundant being smelt (Osmerus eperlanus), pike-perch (Stizostedion lucioperca), and perch (Perca fluviatalis). There were five other species represented. Nearly all fish entering the cooling system in April and May were entrained, while a shift to impingement was seen as fish increased in size in June. Entrainment numbers dropped markedly in June as natural mortality and growth reduced numbers of entrainable fish. Immediate mortality of smelt ranged 54-90%, averaging 74% for the whole period, with an additional 50% mortality of survivors after 24 hours. For Percidae species, mortality was 18-61%, average 34%, with an additional 5% mortality after 24 hours. Impingement mortality was also species dependent, ranging from 95% mortality for smelt to only 3% for three-spined stickleback (Gasterosteus aculeatus), and Percidae of about 65% (little delayed mortality). It was clear that substantial numbers of fish were entrained and impinged. Because fish numbers at the intake were highest at night when power station load was least, it was suggested that cooling-water flow be reduced commensurate with load to minimize the number of fish entrained and impinged.

A comparative study of six power stations on different Dutch rivers (and compared to other studies of the Bergum station on a reservoir) illustrated strong differences in impingement rates among stations (Hadderingh et al. 1983). Each power station had a unique site plan, although intakes often were located on canals diverging from the main river flow. Flow volumes ranged from 6 to 44 m3/s (137 to 1,005 MGD). The numbers of fish impinged differed greatly, with annual numbers ranging from an estimated 14,000 at the Maas station to 1,400,000 at the Amer power station. Normalized to volume of cooling-water flow, there were similar impingement rates per unit volume at four stations (1-2.5/1,000 m3) but highly divergent rates at two (0.2-0.6/1,000 m3). There was no general relationship between flow volume and numbers impinged among all six power stations but there was a relationship for four of them that was apparent whether the volume of cooling water or the percentage of river flow withdrawn was considered (Figure 5-1). The river sites generally had less impingement than the reservoir site. The number of species ranged from 12 to 25, and was strongly affected by the intensity of sampling at each site. The species differed among stations, with permanently fresh water species dominating (some migratory species were seen). The two stations with especially low impingement rates were both located on the same river (Meuse), which may have had low fish populations. These stations had the next-to-lowest and highest cooling water flow rates among the 7 studied indicating that flow rate was not the controlling factor. However, both stations also had deep intakes, which withdrew water from depths at which few of the surface-oriented fish were present. Most impingement in summer was due to mass appearances of juvenile fish. Such appearances diminished as fish grew in capability to avoid the intakes and the numbers available for impingement dropped due to natural mortality. Thus, it appears that the intake type and the waterbody type are more important to impingement than the volume of water withdrawn, although relationships with flow volume are apparent for some otherwise similar plants (Figure 5-1).

The difficulties inherent in translating entrainment and impingement numbers (and their mortalities) to effects on populations of fish in the water body were apparent in a 4-year study of the Bergum Power Station on a small reservoir, the Bergumermeer. The shallow reservoir (average depth 1.3 m, 4.64 km2, 6.0 x 106 m3) lies at an intersection of several canals in the Frisian lake district of The Netherlands. The study included detailed examination of both entrainment and impingement at the power station and of first-year fish distribution, abundance, and sizes throughout the reservoir and in its in- and out-flows. Because the water intake (27.8 m3/s; 635 MGD) is large in relation to lake volume (about 40% of the lake volume is circulated by the power station each day), entrainment mortality in May and June was large and believed to be of the same magnitude as natural mortality. However, the in-flowing canals provided large numbers of fish larvae, immigrating passively with in-flowing currents. Year-to-year variations in fish numbers and entrainment rates were large. There was an exponentially decreasing vulnerability to the intake with increasing size of fish, as shown by ratios of the concentrations of fish in the cooling water and in the lake across a broad range of fish sizes during the spring an summer growth period. Impingement later in the season was considerable, but insignificant compared to natural mortality. The heated effluents from the power station influenced the distribution of 0+ fish in the reservoir (largely by influence of fish temperature preferences in relation to water temperatures; both attraction and repulsion were identified in different species and at different times; there were no lethal temperatures). Faster growth of pikeperch due to the warmer water seemed to have improved both fish sizes and year-class strength compared to a reference reservoir not used for cooling, in spite of the high level of mortalities of larvae early in the season from entrainment.   This result is somewhat counter-intuitive and shows that the influences of power stations on fish populations must be treated comprehensively, and not just as mortalities from entrainment and impingement. Natural mortality rates in the reservoir far exceeded any influences of the power station. The most effective action for having the power station aid fish populations was believed to be reduction in cooling-water flow volume in May and June, when fish larvae are most abundant.

Relevance for Section 316(b)—The revelance for the Dutch studies show that there is a dose-response relationship between the estimated numbers of fish entrained or impinged and both cooling-water flow rate and percent of the river withdrawn, at least for some power stations. The relationship breaks down when a waterbody generally has few fish and the intake is at a depth where few fish reside. Population effects do not necessarily follow the same trend, for a population was better where the water was used for cooling than in a reference site. Thermal and CWIS effects combine to affect fish populations, such that the power station influence must be viewed in its totality, not just as intake effects. The importance of the site-specific situation for each power station is clearly apparent.

5.4 Lake Wheeler

Wheeler Reservoir, Alabama, is a 45,450-acre mainstem reservoir on the Tennessee River. Average annual flow through the reservoir is about 50,000 cfs, and the reservoir has an average retention time of about 7 days. Browns Ferry Nuclear plant (BFN), located on the reservoir about 20 miles upstream of the dam, began operating in 1974. BFN withdraws water for cooling at a rate of roughly 4,400 cfs (2,840 MGD) or about 1% of the reservoir volume per day. Between the water released at the dam and that withdrawn at BFN, about 14% of the reservoir volume is removed from the system on an average day. Water removed from the system is for the most part replaced instantaneously from upstream and tributary inflow and return water from the BFN cooling system. However, organisms that were entrained with the withdrawn water are for the most part lost from the system.

From 1969 through 1997, Tennessee Valley Authority biologists monitored fish abundance in the reservoir by annual cove rotenone surveys (Baxter and Buchanan 1998) to determine if operations of the BFN had any effect on reservoir fish populations. The three sites sampled were about 8, 13, and 19 miles downstream of BFN and about 1, 12, and 13 miles upstream of the dam (note: one of the sites was located 2.7 miles into a tributary embayment). These surveys provide ample data with which to evaluate the effects of long-term withdrawal from a system on its fish community.

A follow-up report to Baxter and Buchanan (1998) presented a regression analysis on the cove rotenone data to identify significant trends in the abundances of species that had been characterized as either important or of special interest from 1969-1997 (TVA 1998). Regression analyses were performed on abundance data (number per hectare) for three size classes (young-of-year, intermediate, and adult) for each of nineteen species. The nineteen species represented three categories of fish – games species (10), rough species (7), and forage species (2) (Table 5-3).

[see hard copy for table]
Table 03
Summary of trends analysis of population dynamics (1969-1997) of 19 fish species in Wheeler Reservoir (TVA 1998).

For ten of the species, no significant increasing or decreasing trends were observed for any of the three age classes (Table 5-3). For the other nine species, there were 6 instances of significant decline and 5 of significant increase. No species experienced a significant decline for all three age classes, and only the spotted sucker showed a decrease for two of the three age classes. There is no indication that any of the declines are a result of entrainment at BFN or at the Wheeler Dam.

In addition to the species-specific analysis, a similar analysis was performed for total standing stock, both numbers and biomass. Although standing stock estimates commonly exhibited extreme fluctuations, the regression analysis found neither a significant increasing nor decreasing trend over the coarse of the study.

Relevance for Section 316(b)—This extensive study of a large CWIS showed no significant trends for many fish species, declines for certain age classes of some species and increases in others. Thus, these is strong species and age specificity for the sum of all of the power plant effects, including the CWIS.

5.5 Illinois Cooling Ponds

Illinois Reservoirs

In the 1970s, EPRI and the Illinois Natural History Survey (a natural resources research arm of the State of Illinois) teamed to conduct a detailed, 4-year, ecological study comparing a lake used for power plant cooling (Lake Sangchris) with lakes not used for cooling, particularly Lake Shelbyville (EPRI 1980). Lake Sangchris is the site of the 1,232-megawatt Kincaid Power Plant (then owned by Commonwealth Edison Company). Other reservoirs studied less intensively were Lake Taylorville, Otter Lake, Lake Lou Yaeger, Evergreen Lake, and Lake Coffeen (another cooling lake). There were three major objectives: (1) acquire data on the functioning of the systems sufficient to represent the systems in the form of a mathematical model, (2) understand the dynamics of the fishery, and (3) understand the quality and distribution of fish food resources. Whereas all impacts of the use of Lake Sangchris for power plant cooling were of interest, the primary concern was for ecosystem effects of the added heat. However, because Lake Sangchris was a nearly closed system, intake effects of entrainment and impingement were necessarily part of the overall power station influence.

Major factors used in selecting lakes Sangchris and Shelbyville for detailed study were physical and biological attributes, background data available, access, and proximity (Table 5-4; Figure 5-2). Although Lake Shelbyville was larger than Lake Sangchris, many of the parameters used to compare the morphometry of the lakes were similar. A major difference between the reservoirs was that Lake Shelbyville functioned as a flood control reservoir and thus had added effects of water level fluctuations.

[see hard copy for table]
Table 04
Morphometric comparisons of Lake Sangchris (cooling lake) and Lake Shelbyville, Illinois (from EPRI 1980).

Lake Sangchris was constructed in 1964-1966 by construction of an earthen dam across a small creek. The shallow, 876-ha (2,165-acre) reservoir consisted of three 8-km-long, narrow (300 m average width) arms extending generally southward with irregular shorelines (Table 5-3; Figure 5-2). The reservoir was created to supply condenser cooling water for the 2-unit, coal-fired Kincaid Power Plant, which was cooled by one to four 160,000-gpm pumps to maintain a temperature rise of between 7 and 10° C between the intake and the discharge. Normally, 480,000 gpm (691.2 MGD) was used when both units were operating at full capacity in summer. Water was withdrawn from the west arm by an intake canal and discharged by a canal to the middle arm. The power plant was a load-following plant, so operation varied considerably during the study (recorded in EPRI 1980).

Lake Shelbyville was constructed in 1970 by the U.S. Army Corps of Engineers using an earthen dam. The Kaskaskia and Okaw rivers were impounded, creating a Y-shaped, 4,490-ha reservoir approximately 30 km long with irregular shorelines (Table 5-3; Figure 5-2). The main purpose of the reservoir is to provide flood control and navigation flows in the Kaskaskia and Mississippi rivers, but it is a multipurpose reservoir serving water quality, water supply, fish and wildlife, and recreational uses. Water inflow and outflow varied greatly (0.28 to 127.42 m3/s; 6.4 to 2,915 MGD) with a typical annual pool fluctuation of about 7 m (20 ft).

The study identified physical and water quality differences between lakes Sangchris and Shelbyville that were related largely to the cooling circuit in Lake Sangchris and the stable water level maintained in it for power plant cooling. Lake Shelbyville exhibited summer thermal stratification, which was largely lacking in Lake Sangchris. Lake Sangchris was horizontally segmented between the warm thermal discharge arm and the more ambient east and west arms. Lake Shelbyville fluctuated in elevation much more than did Lake Sangchris, as noted above. Nutrient fluxes also differed between the nearly closed Lake Sangchris and Lake Shelbyville with its higher flow-through. These characteristics likely dominated any overall effect on fisheries (including entrainment and impingement).

Fish populations differed between lakes Sangchris and Shelbyville in ways that reflected thermal patterns and reservoir-elevation changes (Shelbyville) more than other factors. The average catch of fish was lower in Lake Sangchris (59.1 kg/ha) than in Lake Shelbyville (85.7 kg/ha). Lake Shelbyville had a more diverse fish fauna with higher abundance of carp and gizzard shad making up most of the difference in catches. The biomass of sport fishes was high in both lakes, comprising 26.6% (Sangchris) and 28.3% (Shelbyville) of the total fish catch. Lake Sangchris had not experienced a decline in productivity of largemouth bass with reservoir aging, commonly observed in unheated Illinois reservoirs. There were clear behavioral responses by fish to the thermal discharge: spawning concentrations of white bass appeared in the discharge area of Lake Sangchris whereas in Lake Shelbyville these concentrations occurred in tributaries. Yellow bass, gizzard shad and largemouth bass exhibited seasonal shifts in abundance in Lake Sangchris, moving away from the warmest thermal-discharge areas in summer and toward them in cold months. Gizzard shad, a species often entrained and impinged elsewhere, were smaller and less abundant in Lake Sangchris than in Lake Shelbyville, a fact that was attributed to more rapid maturation and shortened life span due to warmer water. Standing crop biomass of fish was estimated to be somewhat less in Lake Sangchris than in Lake Shelbyville (360.9 and 449.6 kg/ha, respectively), due primarily to lower biomasses of carp and gizzard shad in heated Lake Sangchris. Lake Sangchris' biomass was within normal bounds (intermediate between typical biomasses for reservoirs in the midsouth and midwest). Studies of growth rates, reproduction, movements (telemetry), and food habits indicated either no differences between reservoirs or differences attributable primarily to the differences in thermal regimes. Relative growth rates of fish between Sangchris and Shelbyville reservoirs differed among species: e.g., growth rates were faster in Lake Sangchris for channel catfish, freshwater drum, and largemouth bass whereas bluegill growth was faster in Lake Shelbyville; growth rates were similar in both lakes for white bass, white crappie, and carp. Annual growth of largemouth bass was greater in Lake Sangchris than in other lakes, reflecting the longer growing season due to heated water.

Entrainment and impingement at the power plant's intakes were not purposely studied, but their effects were integrated with other power plant effects on the fish populations of Lake Sangchris. Thus, their influence should have been shown in the comparative studies with non-cooling lakes. The differences in fish populations and their dynamics between the cooling lake (Sangchris) and non-cooling lake (Shelbyville) were largely attributed to the heat load in Lake Sangchris and the periodic drawdowns of Lake Shelbyville for flood control.

Relevance for Section 316 (b)—The overall result of the comparative study was that Lake Sangchris was shown to maintain a highly productive fish community in spite of (or perhaps because of) power plant cooling. There was ample abundance of fish food organisms for maintaining a highly productive sports fishery. Entrainment and impingement, while not measured but certainly occurring, was of minor importance for the dynamics of fish populations when compared to other reservoirs.

Summary

These case studies provide strong empirical evidence that large water withdrawals do not imply large effects on fish populations. The Hudson River power plants have withdrawn over 6,400 MGD for over 25 years (4,200 of that in a sensitive segment for entrainable fish), yet extensive monitoring has shown little impact. When change has occurred to some populations it is in conflict with power-plant-related mechanisms and likely has other causes. The Nuclear Regulatory Commission found little empirical evidence for actual damage from entrainment and impingement in its review of five nuclear plants with withdrawal rates ranging between 486 and 2,785 MGD. Despite this information, it found that natural resource agencies subjectively considered entrainment and impingement to be a problem. It therefore recommended including case-by-case analyses in its nuclear plant relicensing actions. Studies by TVA of Wheeler Reservoir (Browns Ferry Nuclear Plant) showed no significant changes in fish populations beyond the normal increases and decreases in a small percentage of species. Dutch studies found that whereas cooling-water flow rate and numbers entrained or impinged varied proportionately in most plants, the effect on fish populations was the reverse—populations were in better shape with power plant cooling because of the combined effects of thermal (stimulatory) and intake effects. Intake type and water body type dominated over cooling-water volumes in determining numbers of organisms entrained and impinged. Viewing the cooling system effects in totality and on a case-by-case basis was stressed by the Dutch researchers. A detailed study of the fisheries of a reservoir used for cooling in Illinois (691 MGD) and reference reservoirs showed that the combined effect of heating and water circulation in the cooling lake did not yield fish populations greatly different from those in reservoirs not used for cooling. The available studies in the literature provide a poor scientific basis in empirical data for regulating power plant intake systems on the basis of the volume of cooling-water use.

RFC: Entrainment vs. entrainment mortality

APPENDIX F – EVALUATION AND COMMENT ON EPA'S ASSESSMENT OF ENTRAINMENT SURVIAL – CASE STUDY METHODOLOGY, CHAPTER A7 OF THE PROPOSED §316(B) RULE

SUMMARY

EPRI has reviewed, from a scientific and risk management point of view, EPA's decision to base the proposed §316(b) performance standard on entrainment, rather than entrainment survival. Detailed comments resulting from review of sections VI.A.7 and VI.A.8.b of the rule and the support document on entrainment survival, Ch A7, are provided below. The major findings and recommendations resulting from the review include:

-The proposed rule's exclusion of entrainment survival from the BTA performance standard is scientifically flawed;

-The proposed rule's exclusion of entrainment survival from the BTA performance standard can be ecologically unprotective and would not provide comparability in quantifying resource impacts among facilities and waterbodies;

-To provide a solid scientific and resource management foundation for BTA determination, the performance standard should be based on realistic estimates of entrainment losses (i.e. entrainment mortality) and be linked to protection of higher biological levels of organization.

-EPA's evaluation does not reflect consideration of the evolution of entrainment survival study methods—methods have matured and later methods do allow for valid estimates of entrainment survival with appropriate levels of precision.

-EPA's assumption of 100% entrainment mortality is not supported by the overwhelming evidence of substantial entrainment survival of many species that has been found in studies conducted to date, and is not justified by the concerns EPA presented in Ch A7.

1. THE PERFORMANCE STANDARD FOR BTA SHOULD BE BASED ON REDUCING ENTRAINMENT LOSS, AS IT CURRENTLY IS FOR IMPINGEMENT

EPA correctly states that:

Assessment of ecological and economic consequences of entrainment is based on estimates of the number of fish and shellfish killed as a result of entrainment" (p. A7-1) (Emphasis added.)

Despite the above statements, EPA, instead, proposes a performance standard that requires reducing numbers entrained rather than reducing numbers killed (VI.A.7 of the proposed rule). Their decision was based the belief that appropriate entrainment mortality data for existing and potential intake technologies used as the basis for the rule was either absent or insufficient. However, EPA, in reality, is not excluding entrainment mortality from consideration in choosing this approach, but rather assuming all entrained organisms die (100 percent mortality) as a result of passage through cooling water intake system (CWIS) for all of the baseline and benefits evaluations. EPA notes in Chapter A7 (e.g. Section A7-5), that they believe this assumption of 100 percent entrainment mortality is consistent with a precautionary approach, is protective of biological resources, and implies consistency in quantifying resource impacts at different facilities and waterbodies.

It is of utmost importance that EPA reevaluate this position, which fundamentally influences the soundness of the decision-making process for 316(b). A performance standard that is scientifically sound, consistent with risk assessment and management frameworks currently in use by EPA, and environmentally protective should be based on numbers killed, as EPA currently proposes for impingement, to provide better measures of potential risks at population and community levels. Our comments are elaborated in more detail below.

1.1 The proposed rule should clarify terms dealing with entrainment mortality and distinguish between entrainment loss as a performance standard and estimates of entrainment mortality rate that may be used in benefits assessment

A reading of the proposed rule and Chapter A7 together makes it apparent that EPA is using the terms "entrainment mortality" to refer both to the loss of organisms as a result of entrainment and to the rate as which entrained organisms die. However, it is important to recognize that these two concepts are not the same and that by combining the two concepts considerable confusion can result. Consequently, we recommend the following clarifications:

-The term "entrainment loss" should be used to refer to the number of organisms of each species killed by entrainment. Entrainment loss is a function of both the exposure (entrainment) and sensitivity (death rate as a result of entrainment) of the organisms. Measures of entrainment loss can be either qualitative estimates of susceptibility, or quantitative estimates of direct, equivalent, or fractional losses (EPRI 2002a, EPRI 2002b).

-The term "entrainment mortality rate", then, is a measure of the sensitivity of the organisms to entrainment exposure (i.e. probability of dying as a result of entrainment). Estimates of entrainment mortality rate can be based either on entrainment survival measured under specific CWIS conditions of interest, or estimated using process models that combine independent estimates of sensitivity to mechanical, thermal, and chemical stresses of entrainment.

The distinction between these two concepts (by using different terms) is applied to these comments.

However, using entrainment loss as the performance requirement for benefits assessment does necessarily impose the requirement for field-study measurement of through plant survival or measurement of survival under all exposure conditions. In fact, benefits assessments for proposed alternatives will inherently involve projection of effects for conditions not-yet studied at a facility. Benefit assessments will, in practice, be accomplished only by combining information available from site-specific studies and from the general literature into process models, using professional judgment.

1.2 The protection requirements should be consistently based on actual risks to the ecological entities of concern for both entrainment and impingement.

As acknowledged by EPA, the ecological risks posed by CWIS operation depend on loss of organisms from entrainment and impingement. As illustrated in Figure 1, CWIS risks at all levels of biological organization depend on susceptibility of species to entrainment and impingement, which is a function of both exposure (number entrained or impinged) and sensitivity (mortality rate from entrainment or impingement). EPA has appropriately recognized this conceptual model in setting a performance requirement based on reducing impingement loss, but chose not to do so for entrainment. To provide sound scientific and risk assessment/management bases for BTA determination, as well as to be internally consistent in establishing the Phase II rules, EPA should therefore base the BTA performance requirements and the process for assessing fish protection benefits on reducing the loss (i.e. mortality) of entrained organisms, as EPA has done in the case of impingement.

1.3 To assure BTA performance requirements are protective, they should be based on entrainment loss.

EPA's assumption of a 100 percent entrainment mortality rate (i.e., using total entrainment rather than entrainment loss) is an appropriate precautionary approach only for establishing baseline conditions for the BTA determination, not for assessing the impacts of the existing CWIS or proposed alternatives. Assuming 100% entrainment mortality is appropriate for the baseline condition since, as correctly noted by EPA, the entrainment survival rates are highly species- and size-specific and can be greatly influenced by a variety of environmental (e.g., water temperature) and plant operating (e.g., ΔT, transit time) factors. Previous studies have demonstrated that across the range of species sensitivities and plant and environmental conditions, entrainment survival can range from 0 to 100 percent. Hence in the absence of entrainment survival estimates applicable to a facility, it is reasonable to initially assume that all organisms perish as a result of entrainment as a means of dealing with the uncertainty associated with this lack of information in a way that is maximally protective of the environment.

However, the assumption of 100 percent entrainment mortality is not necessarily environmentally protective for setting BTA performance requirements (i.e. assessing protection benefits provided by the existing CWIS or proposed alternatives). As described above, the loss of organisms through entrainment is determined by organisms' presence in the cooling water flow (exposure) and the mortality rate experienced by the organisms upon passage through the CWIS (sensitivity). Intake alternatives, whether structural or operational, can reduce entrainment loss by reducing one or both of these two factors (exposure and sensitivity). However, some alternatives can affect exposure and sensitivity in opposite directions. For example, reducing cooling water flow and, hence, numbers entrained can result in higher discharge temperatures and transit times leading to higher entrainment mortality rates and higher entrainment losses. On the other hand, increased cooling water flow can result in higher numbers entrained but lower entrainment mortality rates by reducing ΔT and transit time and potentially lowering entrainment losses.

The tradeoffs in intake alternative effects between entrainment exposure and entrainment mortality need to be carefully considered in selecting an optimal intake alternative. An intake alternative that appears protective based on numbers entrained could even result in greater environmental impact than the existing intake. For example, some species with relatively high entrainment involvement (e.g., striped bass, white perch) are highly tolerant of the mechanical stresses of entrainment. For these species, meeting the performance requirement by reducing flow could cause high thermal mortality by increasing condenser discharge temperature above the temperature tolerance of the species. Similarly, meeting the performance requirement by screening may increase the number killed by trading off low entrainment mortality for high impingement mortality. In both of these cases, the actual number killed by entrainment could easily be higher under the proposed alternative than with the existing intake, despite the reduction in numbers entrained. Under such a scenario, a regulatory requirement based solely on reducing numbers entrained could result in increasing the environmental effects of cooling water withdrawals.

In contrast to the need to use entrainment losses (i.e. numbers killed rather than numbers entrained) in evaluating alternatives, it is nevertheless appropriate that the baseline for potential entrainment impacts be calculated assuming a 100% entrainment mortality rate. At the time §316(b) was initially enacted, little or no thought was given to how cooling systems could be operated to reduce the entrainment mortality rate because it was generally believed to be 100% for all entrained organisms. Now that we have conclusive evidence that mortality can be less than 100% when thermal parameters are maintained within certain limits, when biocide use is restricted, and when the physical stresses are reasonably low (See Section 2.1), it is highly appropriate that stations incorporating design features and operational practices that reduce entrainment mortality rate be encouraged to maintain these features and practices by comparing their benefits to a situation in which they are absent.

EPA has appropriately considered the impingement rate baseline to be a situation in which 100% of impinged organisms perish, and evaluating the existing intake configuration and alternatives on the basis of their ability to reduce the numbers impinged and/or to reduce the mortality rate of impinged organisms. There is no logical reason for treating entrainment differently.

1.4 Facility operators should be allowed to address the baseline assumption of 100% entrainment mortality by inclusion of entrainment survival estimates in the BTA assessment, as EPA proposes for impingement.

There are two ways to reduce the uncertainty that underlies the precautionary assumption of 100% entrainment mortality used in the baseline: 1) demonstrate otherwise by providing unbiased estimates of entrainment survival for the existing CWIS and appropriately characterize the uncertainty of those estimates; and 2) optimize the CWIS fish protection performance by evaluating alternatives that further reduce entrainment losses. Incorporation of entrainment survival into both approaches would provide realistic estimates of ecological risks of the existing CWIS and better perspective on the relative benefits of management alternatives.

Comparing estimates of actual entrainment losses, based on demonstrated entrainment survival at the existing CWIS, with losses for the baseline (assuming 0% survival), provides more realistic estimates of facility-specific ecological risks, which should form the basis for risk management action. For example, a CWIS at which entrainment survival approached 100% would likely represent little or no ecological risk, and therefore require no risk management action. To ignore entrainment survival in making this comparison would fly in the face of the accumulated evidence from §316(b) studies and assessments over the past several decades. The significant entrainment survival measured in numerous site studies (EPRI 2000), may explain, in part, the absence of any observable adverse impacts on sustainable resources from power plant operations to date.

Comparing estimates of actual entrainment losses, based on demonstrated entrainment survival at the existing CWIS, with losses for the baseline, provides better perspective on the relative fish protection benefits of, and economic justification for, implementing CWIS alternatives. That is, the risk scale (relative to entrainment mortality rate) extends from the 100% mortality rate baseline (assumed maximal risk), to 0% mortality rate (no risk), and all CWIS alternatives, including the existing intake, can be ranked along this scale.

1.5 To assure BTA performance standards are protective, and to provide a basis for evaluating tradeoffs among species as part of BTA determination they should provide for consideration of risks to higher biological levels in the BTA determination.

Even when entrainment mortality is explicitly included, focusing the BTA performance requirement solely on direct losses of organisms from entrainment and impingement could also be unprotective. Selecting BTA alternatives based solely on proscribed or achievable reductions in exposure, susceptibility, or entrainment and impingement losses does not, a priori, assure the protection of valued ecological entities, such as the populations of entrained and impinged species and the beneficial uses they support. Assuring that the performance requirements are conceptually linked to ecological assessment endpoints (Figure 1), would provide a protective approach, as well providing the most complete picture of the potential risk reduction benefits of each CWIS alternative and the most information for understanding tradeoffs of BTA alternatives among different species. Balancing tradeoffs among species will undoubtedly be required since CWIS alternatives will provide different levels of loss reductions for different species.

In addition, risk managers will undoubtedly be faced with the need for information on risks posed by the CWIS at population and community levels in order to determine whether costs are ‘significantly’ higher than benefits, under EPA’s proposed method for qualifying for a site-specific BTA determination. Appropriately balancing costs and benefits of CWIS alternatives ultimately requires an understanding of the threat that the existing CWIS poses to the biotic integrity or “health” of the water body. We recommend that the ecological risk assessment (ERA) process, as adapted for §316(b) determinations (EPRI 2002b), be incorporated into the Phase II rules as a methodology for addressing all of the issues discussed above. Characterization of risks using this process will help risk managers determine whether the reduction in entrainment and impingement losses achievable with alternate CWIS technologies at a specific facility represent an appreciable and economically justifiable reduction in risk to aquatic populations and communities, under the cost-benefit option provided in the proposed rules.

Finally, conceptually linking the performance standard to risks at the population and community levels provides a stronger foundation for a tiered approach to implementing §316(b). For example, a variety of factors, including entrainment survival estimates, can be integrated to screen facilities based on the relative risks they pose for impacting sustainable resources (EPRI 2002b).

1.6 Comparability in quantifying resource impacts and determining BTA at different sites and waterbodies requires that the entrainment mortality rate be considered.

The entrainment survival studies conducted to date clearly indicate that survival varies widely depending on species, CWIS attributes, and waterbody characteristics. EPA justifies its assumption of 100 percent mortality in part based on a desire for comparability in quantifying resource impacts at different facilities and waterbodies (Ch A-7, Section A7-5). However, in reality this approach is likely to achieve the opposite result—ecological risk estimates that are not realistic and not comparable among different locations—because it assumes that entrainment mortality is equal (100 percent) for all species and at all sites. However, this is clearly not the case. Thus, EPA approach does not result in consistently accurate measures of ecological risk. We recommend, instead, that EPA address the objective of comparability among sites by: 1) adopting a standardized approach such as the ecological risk assessment framework, which has recently been adapted for use in §316(b) assessments (EPRI 2002b <FN 1>), and 2) emphasizing realistic (i.e., unbiased) estimates of entrainment/impingement losses for each CWIS alternative using all reasonably available information.

1.7 The description of the entrainment vulnerability is overly broad and misleading.

EPA assigns high vulnerability to fish eggs and larvae (Section A7-1.1). However, entrainment does not affect all fish species equally and vulnerability depends upon life history characteristics and intake structure design features. Fish eggs and larvae, to be subject to entrainment, must occur in the water column. Many species, such as the catfishes, sunfishes, and pikes, build nests and/or spawn in the shore zone, and therefore are seldom entrained. Species that are most commonly entrained in high numbers are pelagic spawners or have larval and/or juvenile stages that move into the water column. This type of life history is also usually associated with high fecundity, and high mortality rates from the egg stage to adulthood. Such a life history strategy (i.e., high fecundity, high early life stage mortality) is common among species that utilize highly variable environments (e.g., estuaries, pelagic areas of large lakes and the ocean). This high reproductive potential must coincide with strong density-dependent processes to keep the population within levels supportable by available habitat. Hence, those species that are most commonly entrained tend to be pelagic species with high reproductive potential and strong density-dependence that can compensate for early life stage mortality whether natural or from man-induced sources such as entrainment.

Further, the high natural mortality does not necessarily occur within the egg stage, and high natural mortality rates are not necessarily indicative of high entrainment mortality, i.e. high natural mortality could be due to predation. EPA should also recognize that entrainment of a life stage with a high natural mortality rate, or a high natural mortality rate in subsequent life stages, will mean that most of the entrainment losses would have been removed from the population at a later stage due to natural causes, thus the population effect is not accurately characterized by the number lost to entrainment.

2. ESTIMATES OF ENTRAINMENT MORTALITY RATE CAN AND SHOULD BE USED IN BENEFITS ASSESSMENT

EPA indicates that the proposed Phase II rule does not preclude the use of estimates of entrainment mortality and/or survival rates when estimating benefits to be achieved through installation of BTA (Section VI.A.8.b). However, EPA expresses some reservations about the quality of existing entrainment survival data and the potential of collecting reliable survival data in the future based on its review of 13 entrainment survival studies, which it provides in Chapter A7.
We believe that it is scientifically appropriate to allow consideration of entrainment mortality rates in benefits estimation for the same reasons discussed in item 1, above. Further, as elaborated below, previous entrainment studies, including those reviewed by EPA, were conducted during a period when equipment and procedures for estimating entrainment survival were being refined to minimize the potential confounding influences of handling stress. Consequently, not all previous entrainment

survival studies can be viewed with the same degree of scientific certainty. However, much valuable information exists (far more than "a provocative set of anecdotes") that could and should be used as part of the evaluation of alternatives. Finally, the success of some of the most recently conducted studies clearly demonstrates that entrainment mortality can be estimated with a level of confidence comparable to that of other biological testing (e.g., bioassay testing). Thus, assuming a 100 percent entrainment mortality rate for the many relatively hardy species would clearly result in biased estimates of entrainment loss and introduce much greater uncertainty in the decision-making process than would inclusion of best available estimates of entrainment mortality rate. In such cases, an assumption of 100 percent entrainment mortality rate cannot be scientifically justified.

2.1 Entrainment survival is a scientifically demonstrated reality for some species

We believe that the information presented by EPA in Chapter A7 is incomplete and has provided a skewed perspective on the status of existing entrainment survival information and methodology, which has led EPA to draw incorrect conclusions about the status of existing information and methods for measuring entrainment survival. This perspective is clearly indicated in Chapter A7 (at A7-1.1), where EPA implies that biologists currently presume that entrainment "…would kill most if not all organisms", so that "…any assertions that survival rates are appreciably greater than zero should be viewed with skepticism". This statement may reflect the opinion of informed biologists in the late 1960' and early 1970's, but not now. The carefully evaluated evidence from entrainment survival studies conducted since then has once again demonstrated the appropriateness of the scientific method, rather than presumption based on intuition, as the basis for drawing conclusions on important issues.

Scientists informed about entrainment and impingement now recognize the reality of entrainment survival and that some species may have quite high entrainment survival rates. This transition in attitude occurred in the late 1970s under the highest-level of scientific scrutiny associated with the Hudson River case involving the EPA and numerous other federal and state regulatory agencies and their scientific consultants. It involved the development and evolution of sampling gear and methods for measuring entrainment survival. For example, Oak Ridge National Laboratory staff, acting as EPA's consultants, not only reviewed study methods and results, but personally participated in the studies and observed high percentages of larval striped bass, white perch and other species alive and vigorously swimming in collections from the discharges of the power plants. The establishment of valid estimates of entrainment survival through these studies was acknowledged as a critical step in defining management action in the Hudson River case:

"This [entrainment survival larval table] collection device improved the measurement of in-plant entrainment mortality by minimizing collection-induced mortality and consequently increased the accuracy and precision of mortality estimates (Vaughn and Kumar 1982). Development of the larval table was an important step in the progression of knowledge that led initially to a convergence of utility and regulatory agency estimates of conditional entrainment mortality estimates and ultimately to the settlement agreement" (Klauda et. al. 1988).

Entrainment survival estimates have since been widely used in assessing impacts and comparing benefits of alternatives (Gammon 1976; McNaught 1976 Schlicht 1976; Englert and Boreman 1988; Boreman and Goodyear 1988; PSEG 1999, 2001; CHGE et. al. 1999) verifying their utility for those purposes. In addition, many of the studies on entrainment survival have been published in the peer-reviewed scientific literature, lending credibility to their findings (e.g., McGroddy and Wyman 1977; Jinks et al. 1981; Muessig et al. 1988).

The review of entrainment survival studies cited by EPA (EPRI 2000) reports large number of entrainment survival estimates for more than 50 species and taxonomic groups from 21 power plants. This review found few reports of no entrainment survival (i.e., 100 percent entrainment mortality) and the authors concluded, "…assuming 100 percent mortality or loss of entrained organisms cannot be supported by available data" (p. 3-8). This review concluded that entrainment survival for most species and taxonomic groups exceeded 50 percent and that high mortality was limited to a few relatively delicate species (e.g., clupeids and anchovies). Thus, it would appear that assuming 100 percent entrainment mortality would result in estimates of entrainment loss that are consistently biased and that are typically more than 100 percent too high.

2.2 Entrainment mortality rate is estimatable with sufficient precision

For more than a decade, a number of studies were conducted in an effort to estimate entrainment mortality as part of a larger effort to assess the potential for adverse environmental impacts of cooling water withdrawals at electric generating stations. These studies are summarized in EPRI (2000), which the EPA included in their review of entrainment survival. However, as previously noted, substantial improvements were made in sampling equipment and procedures over the course of these studies that lead to significantly improved estimates of entrainment survival. The improvements in sampling methods are reviewed by Muessig et al. (1988) and are brief described below. These improvements in sampling methods explain many of the differences in entrainment survival observed across years and locations.

The question of entrainment survival at power plants was first addressed in the late 1960s and early 1970s. These earliest studies focused on relatively delicate species (river herring) and found little evidence of entrainment survival (e.g., Marcy 1971). The results of these studies were used to support the general assumption that entrainment high for all species was high and approaching 100 percent. However, subsequent studies (especially on the Hudson) documented that some commonly entrained species (e.g., striped bass and white perch) can and do survive passage through the cooling water systems (e.g. Lauer et al. 1974). These same studies also revealed that the mortality associated with the collection of these organisms was high and that this sampling stress was not the same between intake and discharge samples. These two factors made reliable estimation of the mortality rate associated with entrainment alone, exceedingly difficult. The findings of the Hudson studies lead to substantial efforts to both reduce the stresses associated with sample collection and to make sampling stresses at both intake and discharge locations as similar as possible.

The first step in improving estimates of entrainment survival was the development of the larval table. Larval tables, first tested in 1974, are basically flumes modified for the collection of planktonic organisms. Water is supplied from the intake and discharge by pump, and the flume provided equivalent velocities and sampling stresses at both the intake and discharge locations. Using the flume, sampling stress and associated collection mortality was substantially reduced. For example, the fraction of striped bass post yolk-sac larvae alive at the intake increased from approximately 19 percent observed with nets to 45 to 61 percent with the larval table. Unfortunately, confidence intervals about the estimates of entrainment survival remained quite wide.
The next step in improving entrainment survival estimates was the development of the rear-draw

flume. This modification eliminated the passage of organisms though a pump by moving the pump to downstream of the collection device. This design was first implemented in 1979 and refined in 1980. Using this technology, sampling stress and associated collection mortality was even further reduced. For example, fraction of striped bass post yolk-sac larvae alive at the intake increased to more than 95 percent with the rear-draw flume and confidence intervals about the estimates of entrainment survival were significantly reduced.

The final step in improving entrainment survival estimates (although not described in Muessig et al. 1988) was the recognition that the length of larvae was an important determinant of entrainment survival. This led to the explicit inclusion of length as a covariable in the analysis and estimation of larval entrainment survival (EA 1989). Inclusion of length as a covariable can potentially explain many of the differences observed in entrainment survival between time periods and year.

These advances in sampling methodology, coupled with analytical advances (Vaughan and Kumar 1983; EA 1989), have provided the means, given sufficient sample sizes, to estimate entrainment survival with precision comparable to that accepted for use in other areas of regulatory compliance. Due to the heterogenous nature of entrainable fish eggs and larvae in the wild, entrainment survival estimates typically will require higher sample sizes than bioassay studies in order to achieve comparable levels of precision. However, well-planned sampling that matches the occurrence of entrainable organisms (e.g. EA 1989) can provide sufficiently precise estimates.

2.3 Existing data has utility in benefits assessment

Although not all commonly entrained species have been studied in sufficient detail, existing information related to entrainment survival does cover many of the commonly entrained species and can have important utility for evaluating the potential benefits of CWIS alternatives. Information on entrainment survival has long been recognized as an important evaluative tool for making better decisions on the selection of technologies for minimizing impacts (Jinks et. al. 1981). In addition to the results of previously conducted field studies of entrainment survival, other available information that assessors should consider includes:

-Thermal tolerance data relevant to short-term exposures of early life stages to elevated temperatures;

-Pressure bomb and condenser simulator studies that help to define the general range of mechanical stresses tolerated by fish eggs and larvae.

-Direct release studies of through-plant survival using live hatchery-reared eggs and larvae

-Monitoring data demonstrating species and life stages obtained and seasonal distribution.

While actual entrainment survival assessments have been conducted at only a relatively small number of existing power plants, the studies to date support the transferability of results to other power plants with similar pumping and thermal regimes. Hence, the results of studies conducted at one facility can be used to support the evaluation of potential benefits of intake alternatives at other, similar facilities.

The following example serves to illustrate how existing entrainment survival information can be used to aid in the selection of potential intake alternatives to reduce CWIS impacts:

An existing steam-electric generating facility operates in load following mode at less than full generating capacity throughout most of the year. Load is typically lowest during late evening and nighttime hours. Unfortunately, the existing cooling water pumps run at a fixed speed regardless of facility generating load and cooling requirements. Therefore, it appears that a significant reduction in entrainment exposure might be achieved through reductions in cooling water withdrawal by installation of variable speed pumps that could better match the changing cooling water need of the facility. However, both the permitting authority and the facility operators are concerned that installation of variable speed pumps could result in elevated condenser discharge temperatures and higher thermal stress. This increased stress might result in a higher entrainment mortality rate that could offset potential reductions in the numbers entrained for the species being entrained. Facility operators are further concerned that flow reductions being sought with the use of variable speed pumps will result in losses of condenser efficiency resulting in severe economic penalties to operation of the facility.

A review of available information for the facility indicates that no site-specific measurements of through-plant survival are available for any of six species that are most abundant in entrainment at the facility. However, estimates of entrainment survival are available for two of the species and on a congeneric of a third species at other facilities. These data indicate that these three species could be very tolerant of the mechanical stresses of entrainment at the facility being evaluated. In addition, laboratory-based thermal tolerance data for short-term exposures to temperature elevation is also available on the early life-stages of these species. Although no entrainment survival data is available anywhere for the other three species, data for related family members indicates low (0-15 percent) entrainment survival.

All parties decide to include an analysis of the limits on flow reduction imposed by thermal mortality and condenser performance in the benefit assessment. The permitting authority and facility operators felt that the most realistic estimates of potential benefits for the three focal species that have potentially high entrainment survival would be obtained by using mechanical mortality rate estimates and thermal tolerance threshold limits available from studies conducted at other facilities. The analysis assumed 100 percent mortality rates for the other three focal species. Losses were estimated for variable speed pumps and for projected typical operation of the existing intake. By comparing these results with losses for a baseline assuming 100 percent mortality rate for organisms entrained at full capacity operation, the assessors provided information on the incremental benefits of variable speed pump installation compared to the protection already implemented by facility operation. Further, should the assessment show significant potential benefits of installing variable speed pumps, the facility plans to incorporate site-specific studies to verify entrainment mortality rates for the entrained species as part of the overall engineering and implementation plans.

Footnotes

1 This EPRI report, as discussed in our introduction, has been provided to the Water Docket and to key EPA Cooling Systems Task Force staff. EPRI requests EPA Task Force review of the document as a potential framework for performing 316(b) assessments. EPRI also requests that the EPA Task Force forward the report to the EPA personnel responsible for developing EPA's Ecological Risk Assessment Framework for their professional peer review of the report.

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards. Please see response to comment 316bEFR.002.015 regarding the inclusion of entrainment survival estimates in site-specific benefit analysis. Please see the response to comment 316bEFR.306.506 for the discussion regarding EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule. Please see the updated chapter, Entrainment Survival, in the Regional Studies for the Final Section 316(b) Phase II Existing Facilities Rule.

RFC: Entrainment vs. entrainment mortality

[comment continued from 316bEFR.074.501]

3. SPECIFIC ISSUES FROM EPA REVIEW

In addition to the general issues discussed above, EPA raises several specific concerns with the use of entrainment survival estimates based on their review of 13 of 31 entrainment survival studies reported in EPRI (2000) with which we disagree. These concerns and our responses are discussed below.

3.1.1 Majority of studies reviewed collected samples at times of low organism abundance, had small sample sizes, and did not estimate survival for all species entrained.

Although large samples are always desirable to increase the precision of estimates, sample sizes in entrainment survival studies are limited by several factors. First, it is very difficult to sample large volumes of water in a manner that will not kill eggs and larvae during the sampling process. The evolution of entrainment survival sampling from the standard plankton nets used in early studies, to nets with flow-reducing cones, to pump-fed larval tables, to rear-draw and pumpless flumes has shown the value of reducing sampling mortality, but a concomitant effect is that volumes sampled, and therefore number of organisms collected, are reduced.

A second reason for small sample sizes, for some species, is that many species are not all that abundant in the water column. Even though it would be useful to have large samples for all species, in most cases over 95 percent of entrained fish are composed of only a few species. These commonly entrained species typically have been the focus of prior entrainment survival studies. Obtaining large samples for the species that make up the last 5 percent of those entrained would require an impractically large amount of sampling and would be unnecessary given their relatively low entrainment abundance.

Third, even for the most commonly entrained species, the temporal occurrence in entrainment is highly seasonal, often lasting on the order of one month or less. Thus the time during which large numbers of organisms, especially of any single species and life stage, are available for sampling may be limited.

Although EPA recommends studies throughout the year (A7-4.1), year-round sampling would be very expensive, and would not collect useful information for much of the time. A better strategy would be to use existing data on the seasonality of entrainment, or knowledge of the spawning seasons of the dominant taxa, to tailor the survival sampling to the proper periods.

Finally, EPA should recognize that sample sizes for the dominant taxa were not necessarily low. Many of the entrainment survival estimates presented in EPRI (2000) and reviewed by EPA were based on collections of hundreds, if not thousands, of organisms. These numbers are considerably larger than sample sizes used in most bioassay studies, which have the similar goal of estimating man-induced mortality rates.

3.1.2 Majority of studies reviewed collected samples at times when the facility was not operating at full capacity, or did not study worst-case conditions.

Entrainment studies were typically conducted during periods of normal facility operations. Reduced operating capacity of a facility at the time of an entrainment survival study may not be particularly important for several reasons: 1) At multi-unit facilities, one unit may be operational while other units may not be. The conditions experienced by organisms entrained at the operating unit may be independent of the operational status of other units. 2) At facilities that vary their operational levels seasonally, the occurrence of significant entrainment may not typically coincide with high generating loads. This is common where peak entrainment occurs during the late spring spawning period (e.g. Alosids, Morone), yet peak ambient temperatures and peak generating loads occur during mid-summer. 3) The conditions that occur during the study represent typical conditions (plant operation, ambient temperatures, stream flows) for that time of year, and thus are representative of survival rates expected. Consequently, the entrainment survival estimates obtained during these studies should also be representative of conditions typical for those species at that facility.

3.1.3 Majority of studies reviewed collected samples at times when biocides were not in use.

In 1974, EPA published its Development Document for Effluent Limitations Guidelines and New Source Performance Standards for the Steam Electric Power Generating Point Source Category, which established Best Practical Control Technology Currently Available as: limitation of free chlorine residual concentrations to an average of 0.2 mg/l and a maximum of 0.5 mg/l during the maximum time of 2 hours (aggregate for all units at a facility) that chlorination of the cooling system could be conducted. These conditions were incorporated into the conditions for subsequent NPDES/SPDES permits. For example, the SPDES discharge permit issued for the Indian Point (NY) units in 1987 limited use of chlorine in the cooling water system to a maximum of 2 hours per day at any unit, and 9 hours per week at all units combined. Although chlorination of the cooling system is still permitted, Indian Point has ceased any use of chlorine in the condenser cooling system and only chlorinates the service water system. Biocide use has also been reduced or eliminated at other power plants as well. For example, biocides are not used in the cooling water systems of the Bowline Point, Lovett, Roseton, and Danskammer Point generating stations on the Hudson.

In addition, while many of the studies reviewed did not explicitly describe biocide use at the time of sampling, the period of biocide use is regulated by the EPA guidelines described above. Thus, exposure of organisms to biocides is likely to occur during a small fraction of the day (maximum of 2 out of 24 hours or just over 8 percent of the time). While the studies conducted may not be representative of survival during periods of biocide use, they are representative of typical conditions, i.e. those that occur the majority of the time. Even a conservative assumption of 100 percent mortality rate during the time biocides are used would not be likely to result in significant change to total entrainment mortality.

3.1.4 Majority of studies reviewed collected samples at times that may not reflect current entrainment rates at the facilities.

The entrainment rates, the numbers of organisms entrained per unit volume of water withdrawn, may change as the sizes of the fish populations residing in the source water body change. However, the entrainment survival rate (probability of surviving entrainment) would be independent of the entrainment rate, thus even if current entrainment rates are substantially different than historical rates, the entrainment survival information may still be valid.

Factors that may cause entrainment survival rates to change include significant changes to the physical equipment in the cooling system (e.g. pumps, condensers, conduit materials or lengths), or changes in operating practices that result in different thermal exposure regimes. If new operational practices cause a facility to operate outside the parameter envelope encompassed by previous studies, then new entrainment survival information may be warranted.

3.1.5 Entrainment survival estimates were based on mortal effects only and did not address sublethal effects, which can include changes to growth, development, and reproduction.

EPA's comments on sublethal effects raise irrelevant questions that entrainment survival studies cannot and should not be expected to answer. Entrainment survival studies examine the effects of exposures to primarily mechanical and thermal stresses that occur over a period of generally 15 minutes to 1 hour. The organisms exposed are small, relatively fragile, and often are severely affected not just by the entrainment process, but also by the sampling process, as evidenced by the mortality of organisms captured at the intakes. In addition, even unentrained organisms of these life stages typically have high natural morality rates. Therefore, as would be expected, any damage to entrained fish eggs and larvae shows up very quickly as a lethal effect within the typical 24 to 96 hour observation period.

If one were to attempt to examine potential effects of entrainment that are not manifested as mortality within the latent effect observation period, such as reduced growth, abnormal development, or reduced reproduction, one would first need a plausible biological hypothesis for how such delayed effects would arise. Even with a plausible mechanism, measurement of such effects, if they were to occur, would be extremely difficult. First, the number of organisms that would be required for measurement of the effect at the desired endpoint would dictate that initial sample sizes be extremely large, certainly far greater than could be provided with a reasonably sized sampling effort. Second, the size of the on-site laboratory facilities that would be needed to hold the required number of organisms until the desired endpoint would be impractical, especially for endpoints more than a couple weeks post-entrainment. Third, the experimental environment itself is very unnatural, and becomes increasingly unnatural as the organisms grow. The artificiality of the holding environment would induce additional effects that could confound the effect being measured. It is for these reasons that bioassay studies utilize laboratory-reared, rather than wild-collected, organisms. Although the experimental environment eliminates interspecific predation as a possible confounding factor, many other possibilities remain, e.g. cannibalism, food limitation and starvation, and disease.

The current practice of 24 to 96 hours for observation of latent effects represents a reasonable compromise that allows the effects of any physical damage or (initially) sublethal temperature stress to be manifested as mortality, without extending the experiment to the point that the holding period itself becomes lethal.

Measurement of the effect of entrainment on eggs is the one area where additional observations might prove fruitful. Although, in many studies, eggs were held until hatch rather than for a specified time period, observation to a fixed time post-hatch might allow for the effects of possible developmental anomalies to be manifested and observed.

3.1.6 Critical information on cooling system characteristics, water quality, and environmental conditions was not collected.

In Section A7-1.2 (Thermal stress), EPA lists a large number of temperature-related variables that potentially affect entrainment survival rates. Although these factors may be theoretically relevant, past studies have shown that exposure temperature (i.e. the temperature measured in the discharge after it exits the condensers) is typically the most important factor. For instance, in Jinks et al. (1978) demonstrated that entrainment mortality for striped bass could be reasonably predicted from exposure temperature alone. Even if the temperature data EPA requests were recorded, it would be practically impossible to collect sufficient sample sizes of many entrained species to statistically test the influence of all the factors, and potential interactions of the factors, that EPA lists.

A great deal of the information EPA requests in Section A7-4.1, paragraph 4, is superfluous to measuring entrainment survival at a particular plant (e.g. impacts caused by speed and pressure changes within the condenser, the occurrence of abrasive surfaces, turbulences within the condenser). While collection of all te information EPA requests could aid in development of predictive models for entrainment survival, it is highly unlikely that any sampling program could provide sufficient samples to conduct a valid analysis to examine their potential effects.

An intensive program which can adequately describe entrainment survival under typical operating conditions need not produce a complete understanding of the actual levels of mechanical, thermal and chemical stress, and their interactions, in order to be useful or valid. Information on the mechanisms of entrainment mortality, and interactions among sources of stress, can best be developed using simulation studies where conditions can be closely controlled, and large sample sizes of the required species can be obtained. Although survival studies should collect as much of the indicated data as possible, it should not be viewed as a requirement that all of these variables be measured.

3.1.7 Estimation of entrainment mortality rates should be based on raw survival values in discharge samples, without adjustment for intake (control) mortality.

In its review of studies at the Braidwood station, EPA suggests that "…the percent survival of all individuals sampled from the discharge without correcting for sampling equipment related mortality be used to ensure a fair, accurate, and conservative estimate of entrainment survival." (p. A7-5). Further, in it’s critique of the Cayuga studies EPA claims that adjustment of discharge survival for intake survival gives "…falsely high survival rates"(p. A7-6). Both claims are without scientific merit. Intake (control) sampling is designed to address two sources of mortality unrelated to entrainment: sampling stress and natural mortality. Note that the early life stages of many of the most commonly entrained species experience high natural mortality rates (up 10-15 percent per day or more). Hence, the likelihood of there being significant numbers of dead organisms in the sample prior to being entrained cannot be ignored.

Both of these sources of mortality will affect estimates of fraction observed dead at the discharge sampling station. Consequently, failure to account for these two sources of mortality will result in a biased estimate of entrainment mortality. Hence, since estimates of entrainment mortality based on discharge sampling alone are inherently biased they cannot be considered accurate. Further, EPA offers no justification for their claim that intake sample results should be ignored. Interestingly, in their review of the Quad Cities study (p. A7-11), EPA suggests use of control data to account for mortality due to natural causes; a position that appears to contradict earlier admonitions no to adjust estimates for control mortality.

The suggestion to eliminate correction of the raw discharge proportion for (control) intake survival should not be implemented and would not help ensure a fair and accurate estimate. Use of the raw discharge proportion as a “conservative” estimate will be biased low, depending on the severity of sampling mortality and/or the proportion of already dead organisms in the samples.

3.1.8 Entrainment mortality should not be calculated when “erroneous” results (e.g. discharge survival proportions higher than intake survival proportions) occur.

When entrainment mortality rates are low (i.e., entrainment survival is high), it is entirely possible, and even likely, that at least some valid samples (i.e. samples meet the assumption of equal sampling stress at intake and discharge) will have higher survival proportions at the discharge than at the intake owing to random chance alone. Rather than indicating invalid data, these results indicate that entrainment mortality rate is low. In such cases, the maximum likelihood estimate of entrainment mortality rate is zero, but the estimate should also include confidence bounds that will place an upper limit on the entrainment mortality rate.

EPA’s recommendation to discard study results is surprising when one considers the similar situation that can arise in bioassay testing when control mortality exceeds the mortality under at least some of the toxicant concentrations. In EPA’s “Methods for Measuring the Acute Toxicity of Effluents and Receiving Waters to Freshwater and Marine Organisms”, which similarly uses Abbot’s formula to adjust for control mortality, there are no recommendations to throw out or ignore such data as long as the control mortality is acceptably low (i.e. <= 10 percent). For reasons discussed in section 3.1.12, we feel the imposition of a fixed standard for control mortality is not appropriate for entrainment survival studies, but appropriate analytical procedures should be used to place lower and upper bound on the estimated entrainment mortality rates.

3.1.9 Latent effects of entrainment were studied under unnatural conditions.

In Section A7-3 (Cayuga and Indian Point), EPA criticizes the handling and latent effects studies because the conditions "…may not accurately simulate the actual conditions to which organisms are exposed after discharge from the facility." Typically, latent period holding is done at ambient temperatures. Cooling from the exposure temperature occurs gradually as the sampling apparatus is drained and the sample is sorted in the laboratory. Of course, the unsampled entrained organisms undergo a highly variable process of temperature decline depending on how long they remain in the thermal plume, and how rapidly the plume mixes with the ambient-temperature source water.

If EPA is referring to other aspects of the latent effects studies as being unnatural, then it is setting an impossibly high standard for the studies. It is not possible to reproduce natural conditions and still be able to monitor the status of large numbers of individual eggs and larvae. The important point is that the entrained and control organisms are both held in the same environment, so that their relative mortality rates can be appropriately compared.

In other contexts, such as Whole Effluent Toxicity testing, EPA sanctions the use of unnatural settings as a way to measure the effects of pollutants. The experimental setting, although unnatural, allows the researcher control of many extraneous factors that could affect the interpretation of results.

3.1.10 Unequal sample sizes for intake and discharge samples have an adverse effect on accuracy and precision of estimates.

In A7-3 (Port Jefferson; Page A7-10, paragraph 3 and elsewhere), EPA infers that unequal sample sizes at intake and discharge are problematic. We know of no statistical requirement for equal or nearly equal sample sizes, although equal sample sizes at both stations may produce the most precise estimates for a given total sample size.

A more serious issue with unequal sample sizes is whether the inequality may indicate non-random sampling at one or both of the stations. This issue is difficult to address experimentally, but information on the survival rates, species compositions, and length frequencies at both stations can generally be used to shed some light on issue. At the discharge, the turbulence of the discharge flow can generally be counted on to assist in randomizing the distribution of eggs and larvae and reducing their ability to avoid the sampler (should they still be alive). However, at the intakes flow may be slower and far less turbulent and organisms may be stratified within the inflow, perhaps more abundant in areas away from the actual point of sample withdrawal. This stratification may partially account for those instances where discharge samples are significantly larger than intake samples. In addition, sample design may result in greater quantities of water being sampled at the discharge than at the intake. For example in the 1988 Indian Point studies, the discharge sample volume was approximately twice as large as the intake sample volume.

3.1.11 Past studies are plagued by design flaws and incorrect data analysis decisions.

In section A7-3 (Braidwood Nuclear and elsewhere), EPA comments on the need to lag the starting time of the discharge samples so that both intake and discharge samples are drawing from the same pool of organisms. While this seems to be a useful design concept, in practice the slight conceptual advantage of appropriately lagged samples might be overweighed by the opportunity to process intake and discharge samples simultaneously and thus ensure identical post-sample treatment. (However, we note that in many cases, such as entrainment survival studies conducted at power plants on the Hudson River, discharge samples were, in fact, lagged).

In the same section, EPA concludes that dead-opaque larvae should be included with dead in order to calculate entrainment survival instead of removing them from the analysis as was originally done. However, it is important to recognize that fish eggs and larvae are typically translucent and almost transparent when they are alive. This translucency appears to be a camouflaging mechanism that may reduce predation mortality. It is only upon death that the tissues begin to breakdown and the eggs/larvae loose their translucency and become opaque. This opacity is commonly used in hatchery operations to identify dead fish eggs and larvae for removal. Because opacity requires some amount of time to develop, typically an hour or more, one can be assured that any opaque organisms found in a sample at collection have been dead for some time and are not opaque as a result of mortality at the time of collection. Hence, inclusion of these larvae in the analysis will decrease both the accuracy and the precision of the entrainment survival estimate. Therefore, the best (most accurate and precise) estimates of entrainment survival will result from exclusion of previously dead organisms that are entrained in the cooling water flow.

3.1.12 Precise estimates of entrainment mortality rates and model parameters are required.

Although EPA is clear that it requires precise estimates of entrainment mortality rates and model parameters for predictive models of entrainment mortality, it provides no standards for determining adequacy. We agree that no thresholds of precision should be established. Instead, the results of any valid study of entrainment mortality should be used in a weight-of-evidence evaluation. The more precise the estimates, the more weight should be given to the results in evaluating the impacts.

Although entrainment survival studies are superficially similar in concept to bioassays where survival of organisms exposed to various concentrations of a toxicant is compared (adjusted) to survival of control organisms, they differ from bioassays in three very fundamental ways. First, while the test organisms in a bioassay are generally of the same age, genetic lineage, and physical condition, the organisms sampled in an entrainment survival study are very heterogeneous. Even within the same life stage of the same species, there will be a great deal of variability in age, genetic lineage, and physiological state. This variation often results in relatively high mortality in control organisms, even when extreme care is used to minimize stress. Thus we feel it is not appropriate to set thresholds on control mortality or precision of the resulting entrainment survival estimate to have an acceptable result.

The second key difference between bioassays and entrainment survival studies is that bioassays utilize test organisms that have been selected to survive well under laboratory conditions. Thus, they are relatively insensitive to the routine stresses associated with the handling and care associated with laboratory rearing and testing. With such “tried and true” organisms it is reasonable to expect high survival of control organisms and relatively precise estimates of toxicant effects. On the other hand, entrainment survival studies are conducted using wild-caught individuals; many of which are difficult to hold under laboratory conditions.

The third key difference between bioassays and entrainment survival studies is that bioassays can increase precision by either repeating the experiment, or by using larger sample sizes initially. In entrainment survival sampling there is a distinct trade-off between sampling rate (volume/time) and sampling stress. It is very difficult to sample large volumes of water over a short period of time and do so in a manner that does not stress the organisms. Use of additional sampling gear might be limited by space available, and additional organisms require additional on-site laboratory space for sample sorting and latent effects observations. In short, it is not a trivial matter to increase sample size by increasing sampling intensity or duration.

We agree that precise estimates are desirable, but feel that arbitrary thresholds for precision are not appropriate. Studies should report precision of their results and agencies should then properly consider the weight they should be given and the manner in which they should be used in the assessment. Even where confidence intervals are relatively large, entrainment survival estimates can be factored into BTA assessments by appropriate handling of the uncertainty (e.g., by bounding the estimate or treating it probabilistically in the assessment).

A final point to consider is that, when taken as a whole, all 13 of the studies EPA has reviewed in Chapter A7, demonstrate that entrainment mortality is not 100%—there is a consistent pattern of some significant level of survival in all studies. Use of the 100% mortality assumption may appear to make it simpler to compare situations across power plants, but an erroneous use of the assumption will confound the plant and regional comparisons EPA is interested in, inflate the apparent benefits of certain alternatives, and could potentially result in actual negative benefits for some alternatives. In the face of overwhelming evidence for substantial entrainment survival, EPA's generic assumption of 100% mortality is not supported by the concerns raised by EPA in its review of these prior studies.

General Statement of Opposition

As it is a presently formulated, the Agency's Preferred Option could serve as an excellent starting point for crafting regulations that would be consistent with the statutory mandate of 316(b) and that would reflect good science and economics and therefore sound public policy. Notwithstanding this, PSEG believes that there are numerous flaws in the analyses conducted by the Agency's contractors, which calls into question many of the underpinnings of this rulemaking.

EPA Response

No response is required, as this comment summarizes the author's comments. Each issue is addressed individually in subsequent responses.

Option: Site-specific determination of BTA

As EPA is well aware, PSEG implemented permits issed by the New Jersey Department of Environmental Protection ("NJDEP") which the Agency reviewed and approved for its Salem Generating Station. These permits relied upon a suite of innovative technological and restoration measures to address the requirements of 316b. In complying with those permits, PSEG has made substantial investments and has advanced the state-of-the-art in intake screen technologies and the state-of-the-science on wetlands restoration and the links between coastal marsh and estuarine and marine fisheries. PSEG believes that the outcome of this rulemaking should confirm the wisdom of the Agency's prior actions in approving Salem's permit.

EPA Response

A goal of today’s rule is to set national minimum performance standards that reflect the best technology available for minimizing adverse environmental impacts. Given that previous determinations of best technology available were not made in reference to the national performance standards, EPA believes that the Director should not rely entirely on historical determinations. EPA believes that these national requirements will promote more effective and consistent implementation of section 316(b) requirements, and ultimately minimize adverse environmental impacts associated with the use of cooling water intake structures by Phase II existing facilities.

Subject Matter Code 17.06

Option: Site-specific determination of BTA

PSEG owns and/or operates steam electric generating stations that each withdraw more than 50 million gallons a day ("MGD") of cooling water through cooling water intake structures ("CWIS"). These stations, including the Salem Generating Station ("Salem"), will be subject to the requirements of the Proposed Phase II Rule. PSEG operates state of the art CWIS technologies at the Salem facility, and has implemented a major habitat restoration program that provides significant benefits to the Delaware Estuary ecosystem. Data and information from Salem were collected and subsequently used by EPA in a case study that formed a partial basis for the Agency's assessment of benefits associated with the Proposed Phase II Rule. The outcome of the Proposed Phase II Rule will determine whether PSEG's substantial investment in scientific study and evaluation, technological development and implementation, and significant ecosystem enhancement will continue to be recognized as a viable approach to providing valuable benefits to society and to the environment. PSEG strongly encourages EPA to promulgate a final rule that allows and encourages flexibility to continue measures such as those implemented at Salem to maximize benefits to the environment and society.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

Please refer to the response to comment 316bEFR.005.020 for a discussion of the application of the cost-benefit test to assessing the value of alternative approaches.

A goal of today's rule is to set national minimum performance standards that reflect the best technology available for minimizing adverse environmental impacts. Given that previous determinations of best technology available were not made in reference to the national performance standards, EPA believes that the Director should not rely entirely on historical determinations. EPA believes that these national requirements will promote more effective and consistent implementation of section 316(b) requirements, and ultimately minimize adverse environmental impacts associated with the use of cooling water intake structures by Phase II existing facilities.

Option: Site-specific determination of BTA

THE AGENCY HAS SOUGHT COMMENT ON A WIDE RANGE OF REGULATORY APPROACHES OF VARYING MERIT

In general, PSEG supports an approach that recognizes that the protection of the aquatic ecosystems by the regulation of existing facilities under § 316(b) of the Clean Water Act ("CWA") can only be accomplished through assurances to the permittee and the regulator that the unique nature of each facility and ecosystem will be considered. Simply stated, § 316(b) should be applied on a site-specific basis with great consideration given to site-specific conditions.

The CWA, the regulatory history and the Docket in this rulemaking clearly support site-specific regulatory approaches for implementing § 316(b). USEPA's Preferred Regulatory Option relies on technology based performance standards, and provides some flexibility. For this approach to be workable in practice, however, certain clarifications and enhancements are necessary.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Option: PSEG site-specific alternative

Site-Specific Approaches

USEPA sought comment on several site-specific alternatives, including one submitted by PSEG in January 2002. PSEG's regulatory approach contemplates three demonstration options. The first would allow permit writers to rely on prior analyses, data and best technology available ("BTA") determinations if still valid and representative of current conditions. The second would utilize alternative technology assessments and a determination of BTA based upon a cost-benefit analysis; under this demonstration type there would be no separate analysis of adverse environmental impacts ("AEI") since the impacts of impingement and entrainment ("I&E") losses on the population level would be addressed in a cursory fashion through the estimation of benefits derived from the application of alternative technologies. The third demonstration option would begin with a full assessment of the potential for AEI, using adverse impact at the population/community level as the standard. If AEI were detected, the permittee would determine BTA based on the analyses outlined in the second demonstration type. PSEG's regulatory approach also specifically authorized the use of restoration measures, when volunteered by the permittee, as a means to minimize AEI.

PSEG continues to endorse this approach, and also endorses the Utility Water Act Group ("UWAG") approach, and believes it is a better option than the Agency's site-specific approach. The language of § 316(b), the Agency's long-standing practice, and the absence of significant credible scientific data or information suggesting that the operation of CWISs at existing facilities have had a negative impact on fisheries or aquatic biota all support the selection of a site-specific rule for existing facilities.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Subject Matter Code 7.01

RFC: Three-option framework for determining BTA

USEPA's Preferred Regulatory Option

USEPA's Preferred Option is based on performance standards for reductions in impingement mortality and entrainment. Compliance with the performance standards can be achieved by demonstrating either (1) intake flow commensurate with closed cycle cooling using cooling towers or ponds or similar methods of recirculation or (2) an 80-95% reduction in impingement mortality and, for many facilities, a 60-90% reduction in entrainment.

USEPA's Preferred Option would allow the permittee to rely upon an alternative site-specific performance standard upon a demonstration that its cost of compliance with the performance standards would be "significantly greater" than either the costs the Agency considered in developing the Phase II Rule or the benefits that would accrue. USEPA also proposes to allow alternative requirements under other specified circumstances.

USEPA's Preferred Option would allow permittees to use restoration measures (for example, creating or restoring a wetland or operating a fish hatchery) instead of, or along with, intake technologies if a permittee can make certain demonstrations concerning the efficacy of the restoration. USEPA's proposal also requires substantial engineering and biological studies for permit application and multiple years of monitoring during the permit term to verify compliance with the performance standards.

The Preferred Option for the Proposed Draft Phase II Rule represents a positive, critical departure from the approach taken in EPA's Phase I Rule by not proposing one particular technology as BTA. EPA does not appear to intend to require existing facilities to retrofit to closed cycle cooling. For these reasons, PSEG endorses the general approach of the Preferred Option, which allows permittees considerable flexibility in determining the most appropriate means of achieving compliance with §316(b).

Nonetheless, EPA should make several clarifications and enhancements for its Preferred Option.

EPA Response

The commenter has summarized the basic elements of the proposed rule. EPA appreciates the commenter's support of the regulatory approach in the proposal, and notes that the final rule uses a similar approach. Please refer to the response to comment 316bEFR.072.029 for a discussion of the framework of the final rule.

The commenter has characterized the proposed rule; therefore, no response is necessary.

EPA notes that it has not required, in this rule, that existing facilities retrofit to closed-cycle cooling.

For a discussion of this issue, please refer to the preamble in the final rule.

No further response is required, as the concerns referred to in this comment will be addressed individually in other comments.

Subject Matter Code 7.02

Performance standards

The performance standards proposed by USEPA are overly stringent and go beyond what would likely be required to ensure protection of aquatic resources.

The values the USEPA proposed as performance standards are arbitrary; the ability to achieve the proposed levels are too highly site specific. Site-specific analyses PSEG has conducted at existing facilities demonstrate that the biological efficacy and/or availability of alternative technologies to reduce entrainment and impingement losses are highly site-specific. USEPA acknowledges that the mortality rate of entrained fish and macroinvertebrates can vary from 2 to 97 percent depending upon the species and life stages entrained. The fact that entrainment survival does not occur everywhere at the same rate is no reason to refuse to consider it at all, especially at a site where the permittee has data establishing survival rates.

Some of the proposed technologies have only been tested in a limited number of waterbodies and with the fish and shellfish species and life stages that are unique to the particular location. PSEG believes the performance standards should be targets and not absolute values because there is limited experience with certain of the technologies used to establish the values. The preamble of the USEPA Proposed Phase II Rule states that the presumptive performance standards specified at § 125.94(b) through (d) for impingement mortality reduction and entrainment reduction are based the following technologies: fine and wide mesh wedgewire screens, aquatic filter barrier systems, barrier nets, modified screens and fish return systems, fish diversion systems, and fine mesh traveling screens and fish return systems. The technologies on which USEPA has based the criteria for impingement survival efficiency and entrainment are not readily applicable in all applications or could be considered experimental and unavailable at certain sites. In larger capacity plants that require larger flows or areas with site-specific characteristics such as high intake velocities, these technologies would not be appropriate.

EPA Response

Submittal of required information

The Agency also should establish more reasonable requirements relating to the implementation of § 316(b) in National Pollutant Discharge Elimination System ("NPDES") permits. Specifically, the proposed schedule will not work in the real world; the timing of and requirements for the comprehensive demonstration study are unrealistic. Although the proposed regulatory language gives a State Director great flexibility in determining monitoring requirements, the preamble language identifies burdensome monitoring recommendations that could be incorporated into permits. USEPA should clarify the discretion to permitting agencies relative to monitoring. EPA's Preferred Option, with certain clarifications, could prevent adverse environmental impacts to the aquatic environment using BTA.

EPA Response

EPA has clarified timing requirements the preamble to today's final rule. Please see response to comment 316bEFR.034.066 for details.

Today's final rule requires that monitoring be conducted in accordance with the verification monitoring plan (125.95(b)(7), the Technology Installation and Operation Plan (125.95(b)(4)(ii)), if selected, and, if applicable, the Restoration Plan required at 125.95(b)(5). The Director may consider additional monitoring requirements as well. Specific study parameters may be proposed by the applicant for review and approval by the Director.

Subject Matter Code 17.0

Other technology-based opt. under consideration

The Agency also sought comment on three additional technology based options that are uniformly unreasonable, unworkable, and contrary to the statutory provisions of § 316(b). In general, the costs and impacts on energy supply and system reliability are underestimated, and the benefits on the aquatic ecosystem are overestimated. None of these three options should receive further consideration by EPA.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161). Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

Comment ID 316bEFR.075.012

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

Subject Matter Code 18.01.02

PSEG definition of "adverse environmental impact"

THE AGENCY MUST MAKE REASONED DECISIONS ON KEY POINTS, REGARDLESS OF THE REGULATORY APPROACH ADOPTED

In addition to seeking comment on a range of regulatory options, USEPA has put forward definitions, standards or approaches for addressing a wide range of issues that cut across some or all of the regulatory options discussed in the proposal. In this section, PSEG holds strong views, based on decades of operating and regulatory experience, on several of these issues. First, the Agency should adopt a definition of adverse environmental impact. USEPA intentionally omits the regulatory definition of Adverse Environmental Impact ("AEI") because the determination of AEI can take a considerable length of time and EPA believes the determination of AEI imposes a burden on the regulatory agencies according to the Agency. Establishing a clear definition of AEI would provide for informed, scientifically-based decisions consistent with the statutory mandate. The burden on regulatory agencies will not be increased and cost-effective and appropriate implementation of the CWA would occur if AEI were defined as proposed by UWAG.

Section 316(b) requires intakes to reflect "best technology available for minimizing adverse environmental impact." The plain language of § 316(b) interposes an environmental-effects test to determine whether an intake structure reflects the BTA standard. If there is no "adverse environmental impact," then there is nothing "for minimizing," and the objective of BTA is satisfied. As the Agency has stated on previous occasions "adverse environmental impact" is an important legal concept that needs to be addressed in the § 316(b) regulations.

EPA has solicited comment on an alternative definition of Adverse Environmental Impact that includes a component that focuses on entrainment and impingement of significant numbers of critical aquatic organisms without considering the source and magnitude of the change and its resultant impact on the relevant aquatic populations, communities, and ecosystems. Significant numbers of aquatic organisms can be impinged or entrained without affecting the community or population of the ecosystem. PSEG supports modifying the AEI definition in accordance with UWAG's comments which provides a foundation of assessing the impacts on ecosystem, community, or population basis, which is appropriate under § 316(b).

EPA Response

EPA has rejected the definition of adverse environmental impact as proposed by UWAG. EPA does not believe that the plain language of section 316(b) of the Clean Water Act requires "an environmental-effects test" that would require no technology unless an impact is determined to occur (and be attributable to a particular cooling water intake structure) on an ecosystem, community or population level. There are many environmental factors which can act concurrently and impact fisheries. In today's final rule, EPA seeks to simplify the section 316(b) determination process and include compliance options requiring the reduction of impingement and entrainment by a performance standard. These reductions will reduce stress on fish populations. Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define adverse environmental impact for today's final rule.

Comment ID 316bEFR.075.013

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

The economic test proposed by USEPA for evaluating costs and the benefits under § 316(b) must reflect credible methods and practices that are widely accepted in the environmental economics profession. USEPA has requested comment on the role of cost and benefit analyses for determining the best technology available for minimizing adverse environmental impact. PSEG supports USEPA's proposal to include a cost-benefit test in both its Preferred Option and its site-specific option and believes it essential to any reasonable rule implementing § 316(b). This is the case whether USEPA ultimately adopts a site-specific approach as urged by PSEG and UWAG or whether the Agency adopts its Preferred Option based upon Performance Standards. Congress clearly mandated that costs must be considered when determining BTA. PSEG supports UWAG's position that "maximize net benefits" is the most appropriate test for evaluating the cost and benefits of cooling water intake structure technologies and any operational and/or restoration measures considered in site-specific BTA evaluations.

EPA Response

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Please refer to the responses to comments 316bEFR.005.020 and 316bEFR.410.001 for a discussion of the application of the cost-benefit and cost-cost tests.

Comment ID 316bEFR.075.014

Organization PSEG Services Corporation, Ofc of Environmental Counsel

Subject Matter Code 10.02

Benefit Estimation Methodology

In addition, the accurate valuation of benefits is critical. USEPA requested comment on the appropriate methodology for benefits assessment. The accurate valuation of benefits is critical to make an informed decision regarding whether a technology is BTA for minimizing adverse environmental impact. Without an accurate valuation of benefits, determination of the maximum net benefit will not allow decision makers to make an informed determination. Similarly, without an accurate valuation of benefits, the cost-benefit test described by EPA in its "Site-Specific Determination of Best Technology Available" will be unusable.

EPA Response

EPA agrees that accurate valuation of benefits is critical when applying the benefit-cost test. However, no methods are available for estimating either costs or benefits with perfect accuracy or without uncertainty. Therefore, informed decisions must be made with the best available information and analysis.

Subject Matter Code 10.02.04

Valuing Forage Species (incl non-use and non-landed)

The narrative benefits assessment approach should not be used to develop nonuse values. Nonuse values cannot be credibly established on a national or national waterbody scale. If non-use values are appropriate, they should be developed on a case-by-case, site-specific basis, which could take into account more realistically any actual nonuse values that could be assigned in a scientifically defensible manner.

EPA Response

For the final 316b rule analysis, EPA has not included quantitative measures of nonuse values due to unavoidable uncertainty in monetizing non-use values for this rule. The Agency, however, has provided several measures that indicate the potential magnitude of non-use values, including meta-analysis, the benefit transfer method, and break-even analysis. See Chapters A12, Non-use Meta-analysis Methodology, and A9, Economic Benefit Categories and Valuation Methods of the final Phase II Regional Studies Document (DCN #6-0003). Please see Chapter D1 of the final Phase II EBA document regarding break-even analysis (DCN #6-0002).

Please see response to comment 316bEFR306.105 for additional discussion of the constraints the Agency faces in conducting primary stated preference research on nonuse values.

Subject Matter Code 11.01

RFC: Proposed use of restoration measures

PSEG supports USEPA's proposal to include restoration measures in the Phase II Proposed Rules, including USEPA's Preferred Option, as well as its other options, that allow implementation of restoration measures by a facility in lieu of or in combination with reductions in impingement mortality and entrainment. PSEG firmly believes that, for many facilities, implementation of restoration measures can provide increased ecological benefits over a purely technology-based approach.

EPA Response

EPA does not believe restoration measures necessarily provide greater benefits than design and construction technologies or operational measures. However, allowing restoration measures as a compliance option under the final rule provides permitting agencies and permit applicants with additional options, some of which will provide greater ecological benefits than others.

Comment ID 316bEFR.075.018

Performance standards

USEPA recognizes that it may not always be possible to establish quantitatively that the reduction in impact on fish and shellfish resulting from the implementation of conservation measures is comparable to that intended through compliance with the performance standards. USEPA should allow flexibility in the Final Rules for application of multiple approaches to demonstrate “substantial similar performance” of restoration measures and should allow the Director to determine on a permit-by-permit basis what data and methodologies are sufficient to demonstrate that restoration measures will maintain fish and shellfish at a level comparable to that which would be achieved through application of the performance standards (§ 125.95(b)(5)).

EPA Response

Please see response to comment 316bEFR.060.026.

Organization PSEG Services Corporation, Ofc of Environmental Counsel

Subject Matter Code 20.01

RFC: Should EPA include impingement trading?

PSEG also agrees with USEPA's promotion of the voluntary use of trading as an innovative way to develop common sense and cost-effective solutions for a variety of environmental issues. Limiting the scope of trading to entrainment losses, however, is unnecessarily restrictive. Trading both impingement and entrainment losses would afford maximum flexibility and provide enhanced environmental benefits under § 316(b). PSEG believes that the goal of trading is not only cost-effective solutions, but solutions that optimize the benefits to the potentially impacted resource and provide the maximum net benefit to society. PSEG's experience suggests that any of the trading units (i.e., density counts, biomass) suggested by USEPA will be subject to various limitations. To reduce the complexity, PSEG suggests that the trading focus on the biomass of dominant species and life stages of fish and shellfish impinged and entrained over a representative monitoring period.

EPA Response

Please see response to comment 316bEFR.034.027 regarding the role of trading in today's final rule. Please see response to comment 316bEFR.077.052 regarding the appropriate units for trading.

Spatial scale for entrainment trading

PSEG believes that trading should not be limited to the watershed level because of the relatively small areas encompassed by specific watersheds as compared to the large spatial areas covered by the natural distribution of a number of potentially affected species (e.g., striped bass, weakfish, herrings). If the USEPA adopts PSEG's recommendation and allows the specifics of trading to be established by the local Director, then these types of issues, based on ecological facts, should also be resolved by the Director.

Organization PSEG Services Corporation, Ofc of Environmental Counsel

PSEG's comments on USEPA's Delaware Estuary Case Study focus on information regarding PSEG's Salem Generating Station, which formed the basis for the Delaware Estuary Case Study. PSEG is concerned that USEPA published incorrect or misleading information on Salem's I&E estimates and provides a summary of PSEG's critique of USEPA's I&E loss estimates for Salem and the economic value of Salem's I&E losses. PSEG also notes some factual errors regarding Salem in USEPA's case study. PSEG is concerned that USEPA's characterization of biases and uncertainties in USEPA's benefits estimates is misleading, and that USEPA's case study ignored critical information. In particular, PSEG is concerned that USEPA has overestimated the economic value of Salem's I&E losses. Finally, certain comments USEPA made in the Case Study Report and Economic Benefits Analysis regarding I&E loss estimates in general are not applicable to Salem.

EPA Response

Please see response to Comment 316bEFR.075.104. In addition, EPA wishes to point out that EPA's final analysis did not evaluate Salem's impingement and entrainment rates directly. Rather, EPA averaged impingement and entrainment estimates developed by EPA for multiple facilities in the mid-Atlantic region, in addition to Salem, to develop a regional estimate of impingement and entrainment.

RFC: Three-option framework for determining BTA

USEPA's Proposed Phase II Rule includes a preferred regulatory option ("Preferred Option") based on performance standards. USEPA is seeking comments on its Preferred Option and on a number of alternative regulatory options ("Alternative Options"), including an approach proposed by PSEG, as well as a myriad of issues that go to the very core of any rule implementing § 316(b). The Preferred Option proposes a comprehensive regulatory scheme, addressing many of the key statutory components as well as requirements for monitoring programs and renewal applications. In sum, the Agency's Preferred Option proposes three alternative means of demonstrating best technology available ("BTA"):

1. cooling water intake flow commensurate with operating with a closed recirculating cooling system;

2. compliance with the performance standards applicable to the waterbody type and facility capacity factor of a given facility through the implementation of technological, operational and/or restoration measures; or

3. a case-by-case determination of BTA, if the permittee can meet one of two proposed cost tests.

In addition, the Preferred Option also proposes requirements for baseline monitoring studies, a comprehensive demonstration study to be submitted with renewal applications, and monitoring to be required during the term of a permit.

EPA Response

Please refer to the response to comment 316bEFR.038.007.

RFC: Three-option framework for determining BTA

PSEG applauds and wholeheartedly endorses the Agency's recognition that the regulation of CWISs at existing facilities requires a substantially different approach than the establishment of uniform national technological requirements, <FN 4> which the Agency adopted in its final new facilities rule. <FN 5> Likewise, PSEG strongly supports the Agency's proposal to allow permittees to utilize restoration measures to demonstrate compliance with § 316(b) under either a performance standard or site-specific demonstration. Similarly, PSEG fully endorses the Agency's proposed determination that existing facilities operating with a recirculating cooling system would be deemed to be in full compliance with BTA.

Footnotes

4 See, e.g., 67 Fed. Reg. 17168. ("For example, under a uniform national requirement based on dry cooling, facilities in the southern regions of the U.S. would be at an unfair competitive disadvantage compared with those in cooler northern climates").

5 40 CFR § 125.80 - §125.89, 66 Fed. Reg. 65256 (December 18, 2001).

EPA Response

With respect to the approach taken in the Phase II rule, EPA recognizes that the requirements implementing section 316(b) are applied in a variety of settings and to Phase II existing facilities of different types and sizes. As such, no single technology is most effective at all existing facilities and a range of available technologies has been used to derive the performance standards. Please refer to section VII of the preamble for more information.

With respect to the role of restoration, please refer to sections VII and VIII in the preamble for the final rule.

With respect to facilities with closed-cycle recirculating cooling systems, EPA agrees that these facilities are to be considered to be in compliance with the rule. The final rule contains a separate compliance alternative for these facilities. Please see 125.94(a)(1) for more information.

Other technology-based opt. under consideration

II. THE AGENCY HAS SOUGHT COMMENT ON A WIDE RANGE OF REGULATORY OPTION OF VARYING MERIT

In the Proposed Phase II Rule, USEPA takes an approach similar to the approach taken in the Phase I Rulemaking - the Agency has put forward a Preferred Option (i.e., the Performance Standard draft rule) and then seeks comments on several Alternative Options. In this section, PSEG provides comments on each of the regulatory options discussed in the preamble. In general, PSEG supports the options that recognize that the regulation of existing facilities under § 316(b) can only be accomplished through rules that ensure maximum flexibility to the permittee and the regulator in establishing CWIS requirements. The Record the Agency has developed clearly supports this approach. Likewise, PSEG applauds the Agency's very wise determination not to propose requiring that all or some sub-set of existing facilities be retrofitted to operate with closed cycle cooling. There is no basis for such a costly and draconian requirement in the Record; in fact the available evidence points toward a contrary conclusion. However, as PSEG, UWAG, EEI and others have consistently argued and, as USEPA has implemented the statutory provision for thirty years, §316(b) should be applied on a site-specific basis.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161). Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

While EPA rejected a purely site-specific approach, EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the preamble for more information.

Subject Matter Code 17.06

Option: Site-specific determination of BTA

Each Of The Site-Specific Options USEPA Put Forward Has Merit

As noted above, USEPA is seeking comment on whether it should adopt regulations that would determine BTA for minimizing AEI at existing facilities on a site-specific basis. As PSEG and UWAG have long urged, USEPA should continue to implement this statutory provision on a site-specific basis. The language of the statute, the Agency's guidance and long standing practice and the very essence of what's being regulated -- the interaction of a CWIS with a specific aquatic environment -- all dictate that this is the best approach. This section explains PSEG's position on the alternative site-specific options in the Preamble as well as the language for a site-specific rule PSEG is proposing in these comments.

There is more than sufficient justification based on legal and regulatory precedent, and the information and data in the Docket to support the promulgation of a site-specific rule for existing facilities. The language of § 316(b), itself, together with the Agency's long-standing and consistent application supports such an approach. Moreover, as USEPA recognizes throughout the preamble and in the design of its preferred regulatory option, the engineering and economics at existing facilities pose materially different considerations than when dealing with a new facility. Finally and perhaps most importantly, there is little, if any, data or information in the Docket that suggests the operation of CWISs at existing facilities have had a negative impact on fisheries or aquatic biota. Attachment 3 to PSEG's comments provides a summary of the legal, regulatory and scientific bases supporting this contention.

Despite all of this, the Agency explains it is reluctant to continue with site-specific BTA determinations. <FN 7> The environmental groups who sued EPA allege that site-specific BTA determinations have resulted in inconsistent or non-existent regulation under §316(b). <FN 8> USEPA also cites concern with the burden a site-specific rule would place on permitting agencies. <FN 9> PSEG submits that all of these concerns can be addressed through promulgation of a clear and carefully drafted site-specific rule, which includes definitions of key terms and standards, and which references to existing USEPA guidance, or the promulgation of additional guidance. <FN 10> The Agency must recognize that the above-cited criticisms of and concerns with site-specific § 316(b) decision-making arose in the absence of regulations or, for that matter, final guidance.

As discussed in detail in the comments on the Agency's Proposed Phase I Rule <FN 11> by both UWAG <FN 12> and PSEG, <FN 13> both of which PSEG incorporate by reference herein, a site-specific determination must be made to achieve the objective.

Footnotes

Subject Matter Code 17.06.01

Sample site-specific rule (p.17159-61)

The Agency’s Sample Site-Specific Rule Has Merit

USEPA provides a draft regulatory language for implementing the requirements of § 316(b) on a site-specific basis. <FN 14> USEPA’s site-specific sample rule is a formal process for determining the BTA for minimizing AEI at particular facilities, focusing on the site-specific interactions between cooling water intakes and the affected environment and the costs of implementing controls. <FN 15>

The site-specific sample rule provides that a previously conducted § 316(b) demonstration may be used if it reflects current biological conditions in the waterbody and the current design of the intake structure. The determination of BTA for minimizing AEI may be based on a previously conducted § 316(b) demonstration or an analysis based on the Design and Construction Plan, operational measures, and restoration measures, considering an assessment of risks.

USEPA’s site-specific sample rule would not define adverse environmental impact but would instead establish factors to be considered for determining BTA including: (1) minimization of impingement mortality; (2) minimization of entrainment mortality; (3) consideration of non-aquatic environmental impacts; and (4) the costs and benefits using a “significantly greater” standard. Voluntary restoration measures could also be applied to minimize adverse environmental impact; however, coordination with "appropriate" fish and wildlife management agencies would be required. Finally, the Agency’s site-specific approach would also require biological surveys to identify and characterize the target aquatic populations of concern, protected species, and other chemical, water quality and anthropogenic stressors.

As noted above, the approach clearly has merit. First and foremost, it would continue site-specific determinations. Second, it would allow agencies to renew still valid, prior § 316(b) determinations. Third, it would provide a framework for making such determination. This would fill the present void and provide the requisite guidance to regulators and permittees on key issues, thereby streamlining the site-specific determination process. It would also recognize already existing state programs that achieve levels of protection comparable to those that would be achieved under the Agency’s sample rule. PSEG believes either its or UWAG’s site-specific approach has greater merit than the approach outlined in the Agency’s sample site-specific rule.

Notwithstanding the above support, unlike UWAG’s or PSEG’s approaches, the Agency’s sample site-specific rule would place the primary focus on the reduction of entrainment an impingement losses. PSEG believes this runs counter to assessing the effects of a given CWIS on the particular ecosystem it affects. In addition, this sample rule would impose onerous monitoring and application requirements.

Footnotes

14 67 Fed. Reg. 17159-17161.

15 67 Fed. Reg. 17159.

EPA Response

EPA did not adopt the sample site-specific rule language in the proposed rule. While EPA rejected a purely site-specific approach, EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

With respect to the use of previous studies, a goal of today's rule is to set national minimum performance standards that reflect the best technology available for minimizing adverse environmental impacts. Given that previous determinations of best technology available were not made in reference to the national performance standards, EPA believes that the Director should not rely entirely on historical determinations. EPA believes that these national requirements will promote more effective and consistent implementation of section 316(b) requirements, and ultimately minimize adverse environmental impacts associated with the use of cooling water intake structures by Phase II existing facilities.

For information on the role of restoration, please refer to the preamble to the final rule.

The final rule provides for EPA approval of alternative State program requirements where such State NPDES requirements will result in environmental performance within a watershed that is comparable to the reductions of impingement mortality and entrainment that would otherwise be achieved under § 125.94. (see § 125.90(c)).

Organization PSEG Services Corporation, Ofc of Environmental Counsel

Subject Matter Code 17.08

Option: UWAG's recommended approach

UWAG's Site-Specific Approach Has Merit

UWAG recommends <FN 16> a reasonable framework for a site-specific regulatory options that focuses on the critical components of a § 316(b) determination. As discussed below, UWAG defines adverse environmental impact and provides an approach for assessing alternative technologies. UWAG also endorses the use of a Representative Indicator Species as the focus of the assessment.

UWAG proposes three approaches for assessing the environmental impact of a cooling water intake structure: (1) re-assessment of a currently valid, prior § 316(b) demonstration; (2) use of ecological risk assessment by means of demonstration of adverse environmental impact using conservative decision criteria; and, (3) assessment of risk utilizing a structured decision making process consistent with current USEPA Ecological Risk Assessment Guidelines. These alternative approaches provide the opportunity for the permittee and the regulatory agency to develop the most appropriate assessment of environmental impact for the specific facility and ecosystem.

If an adverse environmental impact were identified, UWAG proposes that facilities would then identify and assess alternative intake technologies and then determine BTA, which would be the CWIS technology that maximizes net benefit. Finally, UWAG's approach would authorize agencies to consider the benefits of restoration measures if volunteered by permittees.

As noted above, PSEG endorses UWAG's approach and believes it to represent a better option than the Agency's site-specific approach. If promulgated as the Final Rule, it would, like the approach PSEG describes in Attachment 1, provide a reasonable site-specific regulatory framework, that is consistent with applicable law, and sound science and economics.

Footnotes

16 USEPA discussed this recommendation in the preamble. See, e.g., 67 Fed. Reg. 17162.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.075.040

Subject Matter Code 17.09

Option: PSEG site-specific alternative

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

PSEG’s Site-Specific Approach Has Merit

USEPA is also seeking comment on a site-specific alternative recommendation submitted by PSEG in January 2002. <FN 17> This regulatory approach contemplates three demonstration options. The first would allow permit writers to rely on prior analyses and data, and BTA determinations if still valid and representative of current conditions. The second would utilize alternative technology assessments and a determination of BTA, based upon a cost-benefit analysis. <FN 18> Under this second demonstration option, there would be no separate analysis of AEI since the impacts of impingement and entrainment (“I&E”) losses on the population would be implicitly addressed through the estimation of benefits derived from the application of alternative technologies. The third demonstration option would begin with a full assessment of the potential for AEI, using adverse impact at the population or community level as the standard. If AEI were detected, the permittee would determine BTA based on the analyses outlined in the second demonstration option. PSEG’s proposed regulatory alternative also specifically endorsed the use of restoration measures, when volunteered by the permittee, as a means to minimize AEI.

PSEG drafted its January 2002 site-specific proposal in an effort to demonstrate to the Agency that it was possible to craft a site-specific approach that would be workable, and would not impose undue burden on permittees or regulators. To this end, PSEG relied on standards or tests that the Agency had previously endorsed. <FN 19> PSEG believes this is still the case since the first demonstration option would require validation of prior determinations and the second option would not require full AEI demonstrations, which typically entail assessments of population level effects on the aquatic populations.

Footnotes

17 See, e.g., 67 Fed. Reg. 17162. A copy of this regulatory language is included as Attachment 1 to these Comments.

18 Although PSEG’s January 2002 proposal references the cost-benefit test previously endorsed by USEPA in a number of prior § 316(b) determinations and by the NJDEP in § 316(b) determinations for Salem, PSEG believes that the “maximize net benefits” test is the more appropriate test and is the test PSEG includes in its refined site-specific alternative, included as Attachment 2 to these comments.

19 PSEG adopted the concept of reaffirming prior, still valid § 316(b) determinations from the Agency's approach for renewals of thermal variances under § 316(a). As with the cost-benefit test, PSEG invoked factors for assessing AEI that USEPA had set out in its 1977 draft § 316(b) Guidance.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Subject Matter Code 7.01

RFC: Three-option framework for determining BTA

USEPA's Preferred Option Marks a Wise Departure From the Phase I Rule

USEPA’s Preferred Option is based on performance standards for reductions in impingement mortality and entrainment. Compliance with the performance standards can be achieved by demonstrating either (1) intake flow commensurate with closed cycle cooling using cooling towers or ponds or similar methods of recirculation <FN 20> or (2) an 80-95% reduction in impingement mortality and, for many plants, a 60-90% reduction in entrainment. The only plants that would not have the entrainment requirement would be facilities on lakes (other than the Great Lakes), facilities withdrawing 5% or less of the mean annual flow of a freshwater river or stream, and facilities with a capacity utilization rate of less than 15%.

Permitting agencies would establish the appropriate performance standard for a given waterbody or waterbody segment and the selection of an appropriate technology or technologies for a given CWIS would be site-specific. The reductions in impingement mortality and entrainment being achieved or to be achieved by a given technology (or restoration measure) would be compared to the “calculation baseline” losses (impingement mortality and entrainment). A calculation baseline would be the amount of impingement and entrainment that would occur if the facility had a shoreline intake, once-through cooling, and no impingement or entrainment reduction controls.

USEPA’s Preferred Option would allow permittees to use restoration measures (for example, creating or restoring a wetland or operating a fish hatchery) instead of, or along with, intake technologies or operational measures if a permittee can demonstrate (1) quantitatively that the restoration measures would produce benefits that achieve compliance with the performance standard or (2) qualitatively that the restoration measures would maintain fish and shellfish in the waterbody, including community structure and function, at a level of protection comparable to what could be met by intake technologies or operational measures.

USEPA’s Preferred Option would also allow the regulator to establish more lenient, site-specific, performance standards upon a demonstration from the permittee that the cost of compliance with the performance standards would be “significantly greater” than either the costs the Agency considered in developing the Phase II Rule or the benefits that would accrue. USEPA also proposes to allow alternative requirements if the Nuclear Regulatory Commission ("NRC") were to determine that compliance with the rule would conflict with NRC-established safety requirements.

USEPA’s Alternative (3) provides that a Site-Specific Determination of Best Technology Available may be made by the State Director if the “costs of compliance with the applicable performance standards and paragraph (b) of this section would be significantly greater than the costs considered by the Administrator when establishing such performance standards, or that your costs would be significantly greater than the benefits of complying with such performance standards at your site” (67 Fed. Reg. 17221).

The performance standards of Paragraph (b), as prescribed at § 125.94(b) in the proposal, include four alternative performance standards, one of which is reducing intake capacity to a level commensurate with the use of a closed-cycle, recirculating cooling system (§ 125.94(b)(1)).

If this is the performance standard that is used for comparison when determining whether your site-specific costs are greater than those considered by the Administrator in establishing the applicable performance standards, a facility could be required to demonstrate costs that exceed the cost of a closed-cycle recirculating cooling system before being allowed to utilize the site-specific determination alternative of § 125.94(a)(3). EPA should clarify that it does not intend to compare the site-specific costs of compliance with the performance standard set out in § 125.94(b)(1). The appropriate comparison should be between the site-specific costs and the costs the Administrator considered for intermediate (mid-range) technology costs for complying with the performance standards.

Finally, USEPA's proposal appears to require substantial engineering and biological studies. Permittees would be required to conduct in-stream and in-plant aquatic monitoring to determine "baseline" conditions and to select the "best available" technology. Permittees would also be required to perform engineering design studies for the technologies potentially applicable at the CWIS and compare those costs to USEPA's cost estimates for those facilities. Permittees would further be required to conduct multiple years of monitoring during the permit term to verify compliance with the performance standards. The Preferred Option would also establish a multi-step procedure in connection with initial and subsequent permit renewals once the Phase II Rules are in effect. These procedures would address plans of study, consultations with other resource protection agencies, the Comprehensive Demonstration Study, itself, as well as post-installation verification monitoring.

RFC: Three-option framework for determining BTA

With Certain Recommendations, USEPA's Preferred Approach Could Establish a Workable Framework for Implementing § 316

In crafting its Preferred Option for the Proposed Phase II Rule, USEPA clearly gave appropriate consideration to the inherent differences between new and existing facilities. <FN 21> The Preferred Option for the Proposed Phase II Rule represents a positive, critical departure from the approach taken in its Phase I Rule -- USEPA is not proposing to establish a single technology as BTA that would be applicable absent a facility's meeting the requirements for a site-specific demonstration. <FN 22> Moreover, USEPA does not propose to establish uniform requirements for impingement mortality and entrainment reductions of the same extreme magnitude as it did in its Phase I Rule and does not propose to require additional monitoring or retrofit requirements for existing facilities that operate with a closed cycle cooling system. Moreover, in developing its Preferred Option, USEPA again wisely recognized the scientifically demonstrated value that restoration measures can and do play in enhancing aquatic ecosystems, thereby addressing the effects of impingement and entrainment ("I&E"). The Preferred Option proposes that restoration measures be an available means for achieving compliance and, recognizing the limitations of science, would establish reasonable criteria for determining the benefits of restoration measures. For these reasons, PSEG fully endorses the general approach of the Preferred Option, which allows permittees considerable flexibility in determining the most appropriate means of achieving compliance with § 316(b).

PSEG, however, believes that USEPA should entertain certain modifications to its Preferred Option, as discussed below <FN 23> and recommends that USEPA consider the following points if promulgating the Preferred Option as the Final Phase II Rule. PSEG urges USEPA to consider: (1) the information presented in these comments as well as in the comments filed by UWAG and EPRI that clearly demonstrate that the performance standards proposed by USEPA are overly stringent and go beyond what would likely be required to ensure protection of aquatic resources; (2) whether the performance standards would be achievable based on the suite of technologies relied upon at the universe of Phase II facilities, given site-specific factors; (3) establishing a benefit/cost test that is consistent with the Agency's own Guidelines for Preparing Economic Analyses; <FN 24> (4) establishing clear standards for interpreting the "significantly greater" test put forward in the Preferred Option if the maximize net benefits test is rejected; (5) establishing more reasonable requirements relating to the implementation of §316(b) in National Pollutant Discharge Elimination System ("NPDES") permits, because the proposed schedule will not work in the real worlds and the timing of and requirements for the comprehensive demonstration study are unrealistic; and (6) allowing greater discretion to permitting Agencies relative to the implementation of the Preferred Option.

Footnotes

21 See, e.g., 67 Fed. Reg. 17125 ("New facilities have the opportunity to install the best and most efficient production processes and wastewater treatment technologies."); Id. at 17140 (USEPA did not vary the requirements for new facilities based on the type of waterbody, but did define five waterbody types for new facilities.); Id. at 17145 (USEPA applies a "wholly disproportionate" standard for new facilities and proposed a "significantly greater" standard for existing facilities.);

Id. at 17168 (USEPA acknowledged that retrofitting an existing facility costs more than installation of the same equipment in a new facility.)

22 PSEG does not intend that this be deemed in any way to be an endorsement of a uniform technology approach for new facilities. PSEG incorporates by reference its comments on the Draft Phase I Rule, dated November 8, 2000.

23 PSEG also directs the Agencies attention to UWAG's comments in this regard.

24 USEPA, Guidelines for Preparing Economic Analyses, Office of the Administrator, EPA 240-R-00-003 (Sept. 2000). PSEG endorses UWAG's Phase I and Phase II comments on the superiority of the "maximize net benefits" test.

EPA Response

RFC: Appropriateness of "significantly greater"

In making a determination under the site-specific determination of this technology available, a facility would have to demonstrate that its costs would be "significantly greater" than those considered by the Administrator when establishing performance standards, or that the cost would be significantly greater than the benefits of complying with the performance standards at the facility. USEPA does not define the term significantly greater. USEPA should clarify that "significantly greater" is not intended to be a rigidly applied test, and that the Director may consider a variety of factors in determining whether the threshold is met. Capital and operating costs at affected facilities for existing CWIS compliance may cost tens of millions of dollars.

Performance standards

Permitting Agencies Should have Discretion in Setting and Applying Performance Standards

Assessing and then "minimizing" the environmental impact of entrainment and impingement depends on many site-specific features and is highly variable from site to site. USEPA has addressed this complexity in its Preferred Option, first by setting not single number standards for reductions in losses to entrainment or impingement, but ranges (80-95% reduction of impingement mortality, 60-90% reduction of entrainment) and, second, by providing an alternative when the costs of the standards are "significantly greater" than the benefits or the costs USEPA used in this Phase II Rulemaking. The flexibility offered, first, by a range instead of a single number and, second, by the alternative approach where costs are high, is clearly supported by the Record and reflects sound public policy.

PSEG questions, however, whether the Record includes adequate information to support the proposed levels of reductions in losses due to entrainment or impingement mortality proposed in the Preferred Option as national standards. As proposed by USEPA, a value within the ranges of the performance standards would apply to each Phase II facility regardless of the CWIS characteristics or ecology and species present (unless one of the cost tests is met). PSEG believes, instead, that the Record supports a contrary conclusion. It is highly likely based on PSEG's experience at its generating stations that the resources are protected and would continue to be protected if the performance standards were to require lower levels of reductions in these losses. <FN 25> Moreover, as noted in UWAG's Phase II Comments, Dr. Hartman correctly presents numerous examples that biological populations affected by CWISs vary considerably within a waterbody category (e.g., tidal rivers or estuaries) or even within the same waterbody. Moreover, as discussed below, the ability of the technologies to achieve these standards will vary considerably from site to site.

Assuming that USEPA's Preferred Option is promulgated as the Final Rule, the Agency should allow permitting agencies to take this appropriate flexibility one step further. Either USEPA should establish targets for reductions in losses rather than nationally applicable performance standards or permitting agencies should be afforded discretion to determine, based on its site-specific knowledge of the status of the aquatic ecosystem, that a lower standard is sufficient to ensure protection of the resource in a given waterbody.

Likewise, if a facility were able to demonstrate an overall reduction in impingement mortality of 70% with installed and/or proposed technologies and the performance standard for the waterbody was an 80% reduction in impingement mortality, then the permitting director should have the authority to determine that the facility had achieved "substantial" compliance with the performance standard. <FN 26> Based on this demonstration of substantial compliance, the permitting agency should have the discretion to make a favorable BTA determination without requiring the facility to first prove it met one of the cost tests and then to make a full demonstration that less stringent standards are justified for the site. Allowing such discretion to permitting agencies would also address the Agency's concern with the level of burden associated with making determinations first that a site-specific demonstration would be appropriate and then setting site-specific BTA requirements without any substantial risk that harm to the ecosystem would be occurring.

Footnotes

25 See for example appendix H to Salem's 1999 Renewal Application that demonstrates that the losses at Salem have not caused or will not cause substantial declines in any of the species affected by the Station's CWIS.

26 As shown below, there is limited experience with certain of the technologies used to establish the ranges; therefore, the level of performance achievable with one or more of these technologies at a New York given site will vary.

RFC: Entrainment vs. entrainment mortality

If Based on the Preferred Option, The Final Rule Should Allow Permitting Agencies to Consider Entrainment Survival in Determining Compliance with the Performance Standard

USEPA's proposed performance standards for entrainment do not consider entrainment survival. A facility gets no credit for an egg or larva that passes through the cooling system unharmed, as many do. Many power plants were designed specifically to enhance survival of entrained organisms; these plants operate with high CWIS flows and low increases in temperature rise over ambient to minimize thermal mortality. This is the case even though USEPA acknowledges <FN 27> that the mortality rate of entrained fish and macroinvertebrates can vary from 2 to 97 percent depending upon the species and life stages entrained. Furthermore, if a facility is proceeding under a site-specific demonstration, entrainment survival would be a valid consideration in assessing the costs and benefits of potentially available alternatives.

If the Agency acknowledges that certain organisms survive entrainment and entrainment survival is a valid factor under a site-specific demonstration, there is no logical reason for prohibiting a permitting agency from considering this survival when making a site-specific determination of compliance with the performance standards under Proposed § 125.94(b) of the Preferred Option. USEPA has rightly noted that entrainment survival rates, like so many other things, are species-specific and site-specific. The fact that entrainment survival does not occur everywhere at the same rate may make it difficult for the Agency to establish nationally applicable ranges; however, this should not preclude the Agency from authorizing permitting agencies from considering it in determining whether a given facility has complied with the performance standard. This is the case, if a facility has data establishing site-specific survival rates or if studies from another site with similar species and operating parameters affecting entrainment survival (e.g., transit time, maximum temperature, temperature rise above ambient) are available for use at another facility. Contrary to USEPA's concerns, if addressed in the manner PSEG proposes, taking account of survival rates will not create unacceptable risks or introduce unmanageable uncertainty.

RFC: 5% threshold and supporting documents

Performance Standards for Freshwater Rivers and Streams Based Upon Percent Flow Should be Tied to Biologically Relevant Periods

Under §125.94(b)(3) of the Preferred Option, <FN 28> a facility must meet the 60-90% entrainment reduction standard if, among other things, its design intake flow is greater than 5% of the mean annual flow of a freshwater river or stream. USEPA has requested comments on this issue. <FN 29> PSEG recommends that the threshold not be 5% of the "mean annual flow" of the river or stream but 5% (or whatever threshold is ultimately deemed appropriate) of the flow during the period of entrainment or impingement vulnerability. For example, if entrainment is a concern only during spawning season (e.g., spring and early summer), then the threshold ought to be a specified percent of the flow at the time when entrainable eggs and larvae are present and vulnerable to being entrained.

Footnotes

28 67 Fed. Reg. 17221.
29 67 Fed. Reg. 17151, Col. 2 & 3.

EPA Response

Today's rule establishes a design intake flow criterion for Phase II existing facilities. For facilities withdrawing water from a freshwater stream or river, the design intake flow cannot exceed 5% of the source water's mean annual flow. This standard is not applicable to the daily operation of a facility's cooling water intake structure. That is, a facility is not expected to constantly monitor the instream flow of the source water and adjust its water intake accordingly.

EPA believes the alternative presented by the commenter would be difficult to incorporate into a permit as seasonal flows are rarely consistent year to year as are spawning and migration patterns. Incorporating a seasonal flow (or other standard) into a permit would introduce unnecessary implementation and monitoring costs on both the permitting authority and the facility. EPA believes the design intake flow standard for riverine facilities affords a level of protection for the source water body acceptable under most, if not all, stream conditions.

RFC: Regulating limited capacity facilities

Facilities Should be Able to Commit to Comply with the Capacity Utilization Factor

USEPA correctly recognizes that facilities with low capacity factors should be subject to less stringent regulations. PSEG applauds this. In its Preferred Option, USEPA proposes that the applicability of the capacity utilization rate be determined based upon the operating history of a station over the past five years. PSEG proposes that the Final Rule, if based on the Preferred Option, include a provision that would allow permittees to commit not to operate the facility so as to exceed the 15% capacity utilization rate (or whatever rate ultimately deemed appropriate <FN 30>) in the future. This commitment would, of course, become a condition of the facilities NPDES permit. This refinement to USEPA's approach in the Preferred Option would alleviate the need to expend resources on costly monitoring studies for a facility that would only be in operation for minimal numbers of days per year. It would also reduce the burden on regulatory agencies associated with reviewing the studies.

Footnotes

30 PSEG endorses UWAG’s comments on this issue.

EPA Response

The Agency agrees with the suggestion and has adopted the provision for the final rule.

Performance standards

USEPA Should Clarify How Compliance with the Performance Standards Will be Determined

As presently contemplated, compliance with the performance standards will depend on reductions in numbers of organisms entrained and numbers of organisms lost to impingement compared to these losses calculated for the baseline calculation. The baseline calculation is computed assuming a fixed CWIS design and location, which determines whether a particular organism is an "entrained organism" or an "impinged organism." Once alternate technologies are installed, the characteristics of what would be an “entrainable” or “impingeable” organism will change. USEPA should resolve this issue by defining an “entrainable” organism for purposes of compliance with the entrainment reduction standards as an organism that will fit through a standard 3/8-inch intake screen. This will lend certainty and consistency to the implementation of the Final Phase II Rule, if based upon USEPA's Preferred Option.

EPA Response

For a discussion of compliance issues, see response to comment 316bEFR.063.005. For a discussion of the definition of calculation baseline, please see 316bEFR.063.022.

EPA has modified the definition of calculation baseline to include standard 3/8-inch mesh screens. This allows a more consistent estimation of the organisms that are considered “entrainable” vs. “impingeable” by specifying a standard mesh size that can be related to the size of the organism that may potentially come in contact with the cooling water intake structure.

RFC: Performance/effectiveness of restoration

The Metrics for Quantitative Demonstrations of Restoration Benefits Should be Determined on a Site-Specific Basis in Consultation with the Permitting Agency

When restoration measures are components of the Comprehensive Demonstration Study submitted to satisfy the performance standards under Proposed § 125.95(b) of the Preferred Option, <FN 31> PSEG believes the metric should be determined as part of the consultation with the permitting agency on the restoration plan since the appropriateness of the metric will, of necessity, be tied directly to the type of restoration measure that had been implemented and/or is being proposed for implementation.

In the case of a wetlands restoration, PSEG believes that a metric based on total biomass basis may be the most practical metric. Estimates of biomass for at least a portion of the total production can be determined and be consistently exchanged among the measures used to evaluate impingement and entrainment effects and the increased production associated with the restoration. However, if releasing hatchery-reared fish were the restoration measure being implemented, the more appropriate metric may be numbers of fish released at a given life stage.

Footnotes

31 67 Fed. Reg. 17222.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

Subject Matter Code 7.03

Available I&E technologies

The Technologies Upon Which USEPA Has Based its Performance Standards May Not be Capable of Achieving the Same Levels of I&E Reductions at all Phase II Facilities

The preamble of the USEPA Proposed Phase II Rule <FN 32> states that the presumptive performance standards specified at § 125.94(b) through (d) of the Preferred Option for impingement mortality reduction and entrainment reduction are based the following technologies: fine and wide mesh wedgewire screens, aquatic filter barrier systems, barrier nets, modified screens and fish return systems, fish diversion systems, fine mesh traveling screens and fish return systems and variable speed pumps.

Chapter 3 of the Technical Development Document ("TDD") discusses alternative technologies that can be used to minimize I&E. USEPA's overall conclusion is that "performance and applicability vary to some degree based on site-specific conditions. However, the Agency has also determined that alternative technologies can be used effectively on a widespread basis with proper design, operation, and maintenance."(TDD, p. 3-1).

PSEG concurs with USEPA that alternative technologies can be applied to a variety of sites, but that the level of reductions achievable at any given site may be substantially less certain than alluded to by USEPA. Moreover, the applicability of these technologies is highly site-specific and depends on the location of the CWIS and the vulnerability of the species and life stages that are impinged and entrained. For the reasons discussed below, PSEG believes the performance standards cannot be met nationally using these technologies.

a. Modified Screens and Fish Return Systems

Based on work performed at Salem and other locations, PSEG concurs with USEPA that modified screens (e.g., ¼" x ½" Smooth-Tex mesh, "Fletcher-modified Ristroph" screens) with fish returns can generally achieve an overall 70 to 80 percent reduction in impingement mortality over conventional traveling screens (TDD, 3-5). However, certain fragile species (e.g., bay anchovy, alewife) and the early life stages of some species (e.g., weakfish) can exhibit lower survivals (PSEG, 2001a). <FN 33>

b. Wedgewire Screens

PSEG concurs with USEPA's statement that wide mesh (for purposes of these comments, PSEG is assuming a 10 mm opening, since the term was not defined by USEPA) wedgewire screens may minimize impingement (TDD, 3-6) and that fine mesh (<10 mm opening) wedgewire screens also have the potential to minimize further both I&E for facilities that have relatively low intake flow requirements (i.e., closed-cycle systems) and ambient currents that would reduce the time of impingement. However, PSEG believes the employment of wedgewire screens in conjunction with once-through systems potentially poses much greater obstacles than the Preamble or TDD suggest in certain environments. Prior to installing wedgewire screens it would be necessary to assess the potential for adverse effects due to: (1) shoreline excavation or dredging that exposes potentially hazardous dredged material; (2) the screens' interference with spawning and migration behaviors of fish; and (3) interference with boat navigation in the River.

The feasibility of applying wedgewire screens as a CWIS technology in marine and estuarine environments is not clear (Versar <FN 34> at VII-22). Installation of wedgewire screens would require site-specific, pilot scale tests of the screens in the configuration and flow field intended for use at the facility to obtain reliable estimates of screening efficiency and to determine if biofouling and re-impingement on adjacent screens are concerns that might limit the practical application of the screens. Furthermore, biofouling and detrital clogging have been identified as presenting serious operating impediments in estuarine applications (Hanson, <FN 35> Versar 1989). At two facilities, PSEG determined that if wedgewire screen were installed, they would have to be very large in scale. For example, the Mercer Generating Station ("Mercer") located in the tidal reach of the Delaware River (River), would require a new intake canal extending approximately 750 feet along the shore of the River to house the 28 wedgewire screens that would provide the approximate 690 MGD of intake flow needed to operate the facility. <FN 36> At Salem, the withdrawal of approximately 3,000 MGD would require about 240 wedgewire screens to produce a slot flow velocity of 0.5 feet per sec ("fps"). <FN 37> This wedgewire screen configuration would occupy an area of 45,500 square feet or greater than an acre of river bottom.

c. Aquatic Filter Barrier Systems

The Agency states that microfiltration barriers, including the Gunderboom, show significant promise for minimizing entrainment and acknowledges that the Gunderboom is currently "experimental in nature." <FN 38> PSEG believes that additional studies are required to resolve design and operational problems that have limited effective deployment to date. PSEG believes that the Gunderboom is currently not an available technology for most of its existing facilities because of water withdrawal volume requirements and the likely frequent maintenance that would be required to address sediment buildup and fouling, which have been problems experienced at another estuarine site. <FN 39> Future Gunderboom applications are probably limited to those facilities where water withdrawals are relatively low. <FN 40> At facilities with high intake flow rates, the size of a Gunderboom would have to be very large to maintain the low velocities through the filter barrier fabric required to achieve the predicted reductions in I&E losses. In such circumstances, the size of the Gunderboom would likely conflict with other waterbody uses (e.g., navigation).

d. Variable Speed Pumps

Section 3.5.11 of the TDD <FN 41> discusses other technology alternatives and states that the use of variable speed pumps can provide greater system efficiency and reduce flow requirements (and associated entrainment) by 10-30 percent. Based on analyses performed for a number of facilities, PSEG believes the installation of variable speed pumps would likely result in directly proportional increases in the temperature of cooling water from the condensers to the point of discharge into the waterbody. Flow reductions using variable speed pumps would likely occur in the spring or summer, times of high biological productivity, and would result in a reduction in the capacity (i.e., reductions in electrical output) of a facility. Contrary to USEPA's assertion in the TDD, use of variable speed pumps to reduce flow would decrease the efficiency of the units, not make them more efficient as stated by USEPA. <FN 42> Furthermore, the increased thermal effects on entrained organisms (i.e., longer transit times and higher temperatures increase thermal mortality) should be weighed against the potential reduction in numbers entrained. For example, at Salem a 20% seasonal flow reduction is projected to result in substantially higher losses of spot, opossum shrimp, scud, and Atlantic croaker due to increased thermal mortality. <FN 43> In addition, when a facility is operating below design capacity, particularly in the summer, significant amounts of power production and power capacity are lost. For example, a 45% flow reduction at Salem, which is rated at approximately 1100 MWe per unit, is projected to have a power penalty range from 132 MWe to 340 MWe depending upon the season. This means increased operation of other facilities or bringing inactive facilities on-line that may have other adverse environmental effects such as increased emissions of green house gases and other air pollutants.

The NJDEP analyzed the costs and benefits of reducing intake flows at Salem during the summer months. In conducting this analysis, the Department considered the studies submitted by PSEG <FN 44> and concluded that seasonal flow reductions, with or without the use of variable speed pumps, would produce relatively small environmental benefits at very high costs. <FN 45>

EPA Response

EPA agrees with the commenter's assertion that there is no single technology or suite of technologies that can be expected to achieve the same results in various waterbody types and at different facilities. Today's rule maintains the flexibility for the permittee and permitting authority to determine the most appropriate and cost-effective strategy for meeting the requirements of the rule. Please see the preamble for a discussion of the compliance alternatives, including the Technology Installation and Operation Plan and its role in meeting the obligations under today's rule.

EPA disagrees that the performance standards are unattainable on a national level and believes the record supports this assertion. EPA recognizes, however, that certain facilities may not be able to achieve the performance standards due to localized factors. For this reason, among others, EPA has included a site-specific alternative in today's rule based on cost-cost or cost-benefit considerations and has authorized compliance demonstrations by means of a TIOP.

a. Modified Ristroph Screens

For a discussion of modified Ristroph screens, please see response to comment 316bEFR.077.023 and Chapter 3 of the Technology Development Document.

b. Wedgewire Screens

EPA notes the inclusion of compliance alternative 4 in today's rule, which designates cylindrical wedgewire screens as Best Technology Available for facilities meeting certain criteria. EPA notes that all technologies, not just wedgewire screens must be evaluated for their potential effectiveness before deployment.

c. Aquatic Filter Barrier

For a discussion of aquatic filter barriers, please see response to comment 316bEFR.077.027 and Chapter 3 of the Technology Development Document.

d. Variable Speed Pumps

For a discussion of variable speed pumps, please see response to comment 316bEFR.077.033 and Chapter 3 of the Technology Development Document.

Performance standards

Meeting Proposed Performance Standards for All Life Stages of All Species of Concern May Not Be Accomplished at Some Facilities Using State-of – the Art Technologies

EPA proposed at § 125.94(b)(2)-(4) that Phase II Existing Facilities must meet performance standards to reduce impingement mortality and/or entrainment by specified percentage ranges "of all life stages of fish and shellfish." Requiring percentage reductions of all life stages of fish and shellfish creates unnecessary and unreasonable expectations, creates the potential for unnecessary and unreasonable monitoring requirements, has no basis in the record, and most importantly, may well be impossible to achieve, even at some facilities that have advanced, state of the art controls such as modified "Ristroph" screens with a fish return system. If EPA selects performance standards instead of the site-specific options in the final rule, it should establish performance standards based upon target percentages that apply to the relevant organisms, based upon a representative range of organisms and life cycles, that would allow the State Director flexibility to make determinations that adequately protect the sustainability of the aquatic community.

EPA Response

Please see response to comment 316bEFR.063.005.

Option: Reduce capacity comm. with closed-cycle

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

USEPA Wisely Did not Propose a Uniform Technology-Based Option for Implementing Section 316(b) as its Preferred Option

Although the Preamble to the Proposed Phase II Rule seeks comments on three alternative regulatory options based on reductions in cooling water flow to levels commensurate with closed cycle cooling, <FN 46> USEPA wisely did not propose one of these as its Preferred Option. These options would have required all, or varying subsets of, in-scope, once-through power plants to be retrofitted to operate with cooling towers and a closed-cycle cooling system. These options would also have allowed permittees to petition for the application of less stringent requirements, which would require a determination by the Director that the costs would have been significantly greater than the costs USEPA considered or that the retrofit would cause significant adverse impacts on local air quality or energy markets. <FN 47>

The first alternative closed-cycle cooling option would have applied to all Phase II in-scope, once-through facilities. This option would have required all Phase II existing facilities having a design intake flow of 50 MGD or greater to reduce the total design intake flow to a level, at a minimum, commensurate with that which could be attained by a closed-cycle recirculating cooling system using minimized makeup and blowdown flow. USEPA estimated the total annualized post tax cost of this alternative to be over $2 billion and expressed serious concerns about the short-term energy implications and the potential for electric supply disruptions. <FN 48>

Footnotes

46 See, 67 Fed. Reg. 17154 - 17159, Section VI.B. "Other Technology Based Options Under Consideration".

47 See Preamble, at 17154.

48 See, 67 Fed. Reg. 17154. This is referred to as Option 4 in USEPA's E&B Analysis and would have applied to 466 existing power plants. See, E&B Analysis at p. B7-9.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

Subject Matter Code 17.04

Option: Closed-cycle for oceans, tidal rivers or estuaries

The second closed-cycle cooling option would have applied to Phase II in-scope, once- through power plants with capacity utilization factors of 15% or greater and located on tidal rivers, estuaries or oceans. Although the costs of this option have not been estimated, USEPA noted that there is the potential for short-term energy impacts and supply disruptions in coastal areas. <FN 49>

Footnotes

49 See, 67 Fed. Reg. 17155. USEPA estimated that there would be 109 power plants that would have been affected by this alternative.

EPA Response

Please refer to the final rule preamble for EPA's rationale behind rejecting the waterbody/capacity based option.

Organization PSEG Services Corporation, Ofc of Environmental Counsel

Subject Matter Code 17.04.01

Option: Ocean/tidal facilities with large intake vol.

The third closed-cycle cooling option would have applied to an even smaller subset of Phase II facilities, i.e., those with flow withdrawal rates in excess of 1% of source water tidal excursion for tidal river or estuarine plants or 500 MGD for ocean plants. USEPA estimated the incremental cost of this option over its Preferred Option to be $413 million, and estimated the annualized incremental benefits to be $146 million. Despite this huge disparity between costs and benefits, USEPA, nonetheless, indicates it is considering this third option, which would require 51 power plants to be retrofit, <FN 50> for the final rule. <FN 51>

Subject Matter Code 17.04

Option: Closed-cycle for oceans, tidal rivers or estuaries

In addition to the requirements for closed cycle cooling described above, the second and third options would have allowed the imposition of additional requirements to reduce impingement and entrainment, beyond the reductions achieved by virtue of operation with a closed cycle cooling system, if fishery resource managers or permitting agencies had additional concerns about the effects of the CWIS, e.g., impacts on fisheries, threatened or endangered species or their habitats. USEPA asserts that this alternative would be justified based upon the susceptibility of these waters to CWIS operations. <FN 52>

USEPA <FN 53> states, "[i]n general, the more sensitive or biologically productive the waterbody, the more stringent the requirements proposed as reflecting the best technology available for minimizing adverse environmental impact." In addition, USEPA states, " For example, estuaries and tidal rivers have a higher potential for adverse impact because they contain essential fish habitat and nursery areas for the vast majority of commercial and recreational species of shell and fin fish, …Therefore, these areas require a higher level of control that includes both impingement and entrainment…". <FN 54> However, as USEPA correctly states later in the preamble of the Proposed Phase II Rule "…location is an important factor in assessing the impacts of (a) cooling water intake structure…". <FN 55> PSEG agrees that the location of the CWIS and how it operates in relation to the species of concern and their associated life history strategies are critical in assessing impacts and believes that if these aspects are properly considered then estuarine and tidal cooling water intake structures should not have any greater impact than similar structures located on other types of waterbodies. <FN 56> Therefore, PSEG disagrees with EPA's rationale for selecting the subset of facilities that would be required to retrofit to closed-cycle cooling under its second and third closed-cycle options.

Footnotes

52 See, Notice of Data Availability for the Phase I Rule, which sets forth the Agency's rationale for this conclusion.

53 See, 67 Fed. Reg. 17122.

54 See, 67 Fed. Reg. 17122, 17140.

55 Id.

56 By way of analogy, certain chemicals (e.g., copper) can produce adverse effects if the concentrations of the bioavailable forms of the chemical are high and the receptor (e.g., organism, population, community) is exposed to these concentrations for a sufficient period of time. However, no effects may be observed if the chemical is in a different form or if the chemicals and receptors do not interact, or only interact for a short period of time. Similar conclusions are appropriate in regard to whether adverse impacts will occur to fish and/or habitats in estuaries, tidal rivers, or any other waterbody type as a result of cooling water intake structure operation.

EPA Response

In today's final rule, EPA did not select either of the two compliance frameworks described by the commenter. For EPA's rationale for rejecting those frameworks, please refer to the final rule preamble.

Option: Reduce capacity comm. with closed-cycle

As stated in UWAG's and PSEG's comments on the Proposed Phase I Rule, the data and information collected relative to the effects of cooling water intakes on fisheries since the adoption of the Clean Water Act in 1972 does not support requirements for closed-cycle cooling at all new or existing power plants or at subsets of those facilities. <FN 57> Moreover, the costs for retrofitting an existing facility to operate with closed cycle cooling utilizing wet cooling towers are substantially higher than the costs of constructing a new facility to operate as a closed-cycle plant. As discussed in UWAG's, EEI's, and EPRI's comments, the Agency substantially underestimated (1) the costs of these retrofits, (2) the impacts to the nation's energy supply, and (3) the other adverse effects on the environment such as increased emissions of pollutants to the air. Furthermore, as UWAG's and PSEG's comments clearly demonstrate, USEPA overestimated the benefits. <FN 58>

Cooling system costs (e.g., dry, wet, recirculating)

USEPA Substantially Underestimated the Costs of Retrofitting to Closed Cycle Cooling

USEPA cannot justify any of the closed cycle cooling alternatives based on the data and information contained in the Docket. Even though, as shown below, the costs USEPA estimated are substantially lower than estimates based upon site-specific engineering estimates for existing facilities or extrapolations based on such analyses. USEPA, in the Preamble, rightly states that it did not select a nation-wide, closed-cycle requirement (i.e., the first closed-cycle option) "because of the generally high costs of such conversions… and serious concerns about the short term energy implications of a massive concurrent conversion and the potential for supply disruptions that it would entail." <FN 59> This was the right conclusion and PSEG believes it is equally applicable to the second and third closed-cycle options as well.

PSEG endorses USEPA's conclusion that the costs of retrofitting are too high, especially since USEPA substantially underestimated the costs for retrofitting existing facilities to operate with closed cycle cooling. USEPA provides the costs it relied upon to reach this conclusion in the EBA. <FN 60> USEPA estimated the total annualized cost for retrofitting all 426 power plants to be approximately 2.32 billion dollars or on average, approximately 5.45 million dollars per facility (annualized total cost). In connection with Section 316 (b) Demonstrations <FN 61> filed with the New Jersey Department of Environmental Protection ("NJDEP") between 1998 and 2001, PSEG commissioned preliminary engineering analyses and cost estimates for retrofitting three of its power plants located on estuaries or tidal rivers to operate with closed cycle cooling. These analyses were conducted for power plants that would have been within the scope of any of USEPA's three closed-cycle cooling options, and given the mix of fuel types and sizes of these plants, the cost estimates for these plants are likely to bound estimates that would be representative for a considerable range of facilities that would be affected by these options. As discussed below, Shaw Stone & Webster's report for UWAG <FN 62> corroborates PSEG's capital cost estimates for these facilities and echoes the conclusion that USEPA substantially underestimated the costs of retrofitting existing facilities for closed cycle cooling systems.

a. Mercer Generating Station

PSEG's Mercer Generating Station ("Mercer") consists of two coal-fired units withdrawing up to 345.6 MGD of once-through cooling water from the tidal river portion of the Delaware Estuary near Trenton, NJ. <FN 63> The present value capital cost to retrofit Mercer with wet mechanical draft cooling towers was estimated to be 55.74 million dollars. <FN 64> The total capital cost estimate presented in the Mercer C/B Analysis includes the following cost components: capital, labor and materials associated with construction and installation (Table 8-1). The PSEG total cost estimate of 55.74 million is very close to the 58.53 million estimated for Mercer Units 1 and 2 combined by Shaw Stone and Webster, Inc. <FN 65>

b. Hudson Generating Station

PSEG's Hudson Generating Station (“Hudson”) consists of Units 1 and 2 that are natural gas and coal or natural gas fired units respectively. Unit 1 withdraws 388.8 mgd and Unit 2 withdraws 504.0 mgd of once-through cooling water from the estuarine reach of the Hackensack River. The total present value cost to retrofit Hudson with wet mechanical draft cooling towers was estimated to be 104.57 million dollars. <FN 66> The total capital cost estimate presented in the Hudson C/B Analysis includes the following cost components: capital, labor and materials associated with construction and installation (Table 8-1). The PSEG total cost estimate of 104.57 million dollars is the close to the 117.48 million dollars estimated for Hudson Units 1 and 2 combined in Shaw Stone and Webster Report.

c. Salem Generating Station

PSEG's Salem Generating Station (“Salem”), a base-load nuclear facility, consists of two units <FN 67> with a combined intake flow of up to 3,024 MGD of once-through cooling water from the Delaware Estuary. <FN 68> The total present value capital cost estimate to retrofit Salem with wet mechanical draft cooling towers was 576.0 million dollars. <FN 69> The total capital cost estimate presented in Appendix F to Salem’s 1999 Application is comprised of the following cost components: capital, labor and materials associated with construction and installation, (Appendix F IX Table 1). The PSEG total cost estimate of 576.0 million is close to the 593.32 million estimated for Salem Units 1 and 2 combined in Shaw Stone & Webster Report.

The total present value capital cost estimates for Mercer, Hudson and Salem were adjusted to total annualized capital costs so direct comparisons could be made to USEPA’s facility cost estimate. The total annualized costs for retrofitting Mercer, Hudson, and Salem are estimated at $6.31, 8.69, and 51.07 million, respectively. <FN 70> The PSEG estimates for Mercer, Hudson, and Salem are substantially higher than USEPA’s average total annualized cost estimate for an individual facility (i.e., 5.45 million in dollars). The PSEG estimates and the Shaw Stone & Webster estimates are based on preliminary engineering analyses conducted for existing facilities. USEPA, on the other hand, developed its estimates by extrapolating from its estimate of the costs associated with installing cooling towers at a new facility. It clearly stands to reason that the PSEG and UWAG estimates of substantially greater costs are more reliable. Also, the differences between the PSEG and Shaw Stone & Webster’s estimate as compared to USEPA estimates indicate that consideration of site-specific factors are extremely important in providing realistic cost estimates for retrofitting existing facilities with mechanical draft cooling towers.

In short, USEPA has substantially underestimated the costs that would be borne by society if a closed-cycle cooling alternative were adopted. Even using these substantial under-estimates, the Agency rightfully determined that the costs would outweigh any benefits that might result. Even the inclusion of provisions, whereby permittees could have (1) implemented restoration measures in lieu of retrofitting upon a demonstration of comparable performance or (2) petitioned for less stringent requirements if certain tests could be met <FN 71> would be insufficient to overcome the fundamental flaw caused by the substantial underestimation of costs.

63 Mercer C/B Analysis, supra.

64 All Mercer cost estimates are present values as of January 1, 2002, in millions of 2000 dollars.

65 UWAG’s Phase II Comments, Appendix 15, Cost of Retrofitting Cooling Towners at Existing U.S. Power Plants (“UWAG – Appendix 15”).

66 All Hudson cost estimates are present values as of January 1, 2000, in millions of 1997 dollars.

67 Appendix F to Salem’s 1999 Application.

68 PSEG had also commissioned Stone & Webster Engineering Corporation ("SWEC") to perform a preliminary engineering analysis and cost estimate for retrofitting Salem in 1990, which were updated in 1993 and again in 1999. In 1993, at the request of the NJDEP, PSEG hired a second firm, Sargent & Lundy ("S&L") to conduct a validation and verification of SWEC's work product. S&L confirmed that SWEC’s design approach and cost estimates were reasonable and appropriate. S&L concluded that SWEC’s engineering analysis and their cost estimates associated with the closed-cycle cooling retrofit were reasonable and consistent with sound engineering practice (Appendix F to Salem’s 1999 Application, Section VIII). In 1999, SWEC reconfirmed the conclusions reached in 1990 and 1993 that retrofitting Salem with a closed-cycle cooling system would require an unprecedented and complex construction effort (Appendix F to Salem’s 1999 Application, Attachment 7).

69 All Salem cost estimates are present values as of January 1, 2001, in millions of 1998 dollars.

70 The Mercer estimate assumed a 7% discount rate with construction starting in 2002 and costs extending through 2015; the Hudson estimate assumed a 5.78% discount rate with construction starting in 2000 and costs extending through 2022; and the Salem estimate assumed a 6.19% discount rate with construction starting in 2001 and costs extending through 2021(All values are 2001 dollars).

Mkt-level impacts/Reliability/EO 13211: Energy Effects

USEPA's Application of the IPM Model for the Phase II Rulemaking Substantially Underestimated the Impacts of the Closed Cycle Alternatives on Energy Supply and System Reliability

As discussed in the comments submitted by EEI, USEPA's analysis of the economic impacts of USEPA's Preferred Option and the USEPA's Second and Third closed-cycle options using the Integrated Planning Model ("IPM") contained a systematic bias in the assumptions and operation of the model that results in an underestimation of market impacts.

The IPM is an engineering-economic optimization model of the electric power industry. It calculates the optimal solution to an objective function equal to the present value of the sum of all capital costs, fixed and variable O&M costs, and fuel costs. The model generates least-cost resource dispatch decisions based upon user-specified constraints. The model is capable of evaluating new resource investment options (capacity expansion/repowering of existing plants and investment in new plants) in addition to existing capacity during the optimization calculations.

EEI found that the general model assumptions used by USEPA in their analysis were outdated or biased or both. For instance, the IPM modeling analysis was based on the "IPM Base Case 2000." This base case incorporates market assumptions that have significantly changed over the past two years. Also, some of these assumptions used in the IPM runs for the Proposed Phase II Rule do not reflect the assumptions in the Bush Administration's Energy Task Force Recommendations. As a result, the IPM Base Case 2000 underestimates the key parameters of electricity markets (i.e., electricity demand growth, number of generation projects currently underway, and the projected price of natural gas) relative to current projections. Under-representing these electricity market parameters, in turn, leads to underestimates of the impacts of USEPA's closed-cycle options on energy supply and system reliability.

EEI also found that the application of the model was flawed. First, the model was not run for the Preferred Option; instead, the model results for the Preferred Option were extrapolated from the other model runs. This approach does not account for regional differences or interrelationships and requires a combination of analyses that may compound errors and inaccuracies in the original modeling analyses.

Also, USEPA's use of the IPM model did not address the potential impacts on reliability of electricity supplies. The IPM modeling analysis was not conducted in a manner that would address the potential for short-term or transient problems that could occur during the implementation phase of § 316(b) requirements. For example, the model was run only for years beyond 2008, a period when most, if not all, retrofits would already have taken place. Thus, the model did not attempt to analyze near-term market impacts, including reliability, during the transition period leading up to full compliance. In addition, the modeling analysis did not address seasonal effects due to energy penalties or outages.

The IPM runs for the Proposed Phase II Rule modeled the energy penalty associated with retrofit of cooling towers as an annual average penalty, ignoring seasonal impacts that can vary by a factor of at least 2-3 times (i.e., impacts during the summer peak demand season can be 2-3 times higher than annual average). As a result, electricity market impacts in the summer season were not properly characterized.

USEPA also used technical and economic assumptions specific to § 316(b) options that lead to underestimates of market impacts. For instance, EEI describes that EPA's use of EIA and survey data appears to have resulted in an underestimation of the number of facilities subject to the rule and thus the total economic impact of the rule. EEI also notes that EPA has also significantly underestimated the engineering compliance cost for the Preferred Option and waterbody option. For cooling tower retrofits, EPA's estimates are one half or less of the cost cited in reports prepared by Shaw Stone & Webster and the United States Department of Energy as well as PSEG's own analyses that considered site-specific factors. In addition, EPA underestimated the time required to perform a retrofit to closed-cycle cooling.

EEI also discusses concerns and flaws in EPA's assumptions regarding transaction costs, plant closures, temporary plant shutdowns and reliability impacts, the effect of future power plant technologies, and the remaining useful life of power plants retrofitted with closed cycle cooling.

Also, it does not appear that USEPA considered the full spectrum of requirements that power generators will be mandated to implement under other environmental regulatory programs, most notably the Clean Air Act, at the same time the Phase II § 316(b) regulations will go into effect. Most notably, it does not appear that USEPA considered the cost of the Bush Administration's Clear Skies initiative. A plant that may remain economic with either a cooling system retrofit or installation of NOx, SO2 and mercury controls may not remain economic if required to make both sets of modifications. Given the widespread applicability of Clear Skies, this is an important consideration.

To illustrate the effect of two of the more significant model inputs on USEPA's results, EEI modeled two regulatory scenarios with more accurate information regarding the cost of retrofits to closed-cycle cooling and seasonal energy penalties. As discussed in EEI's comments, this modeling effort, using the POEMS model, showed significantly greater economic impacts for the watershed scenario with regard to the number of facility closures, energy penalties, system reliability, wholesale electric prices and total costs to consumers and producers. Correction of the other flawed assumptions would likely result in the identification of even greater economic impacts.

EPA Response

EPA notes that the final Phase II rule does not contain requirements to retrofit cooling towers. For a response to the issues raised in this comment, please refer to the responses to comment 316bEFR.072.101 and 316bEFR.072.209 in subject matter code 9.03.

Subject Matter Code 9.0

Costs

In addition to the points made by EEI, PSEG notes that there is no indication that USEPA considered the availability of real estate to build cooling towers at the in-scope plants; they simply assumed a cost estimate and a timeframe to build. Building in space-constrained areas can greatly increase the construction and operating costs of a cooling system retrofit because of the potential for having to site the cooling towers at a greater distance from the power plant. This would, in turn, require longer piping runs, greater pumping demands, and more extensive excavations. It could also require driving piles in less desirable soils. In some extreme cases, additional property would have to be purchased or leased, if it were even available.

The need to comply with other regulatory requirements could exacerbate problems due to space constraints. Given the real estate that would be needed for the air pollution control equipment under the existing and anticipated air rules (primarily SCRs and scrubbers), this issue has the potential to become even more significant. For example, two of PSEG's in-scope Phase II facilities that would have been required to retrofit under any of USEPA's closed-cycle cooling options are now being required to install additional air pollution control technology (i.e., SCRs and scrubbers). Post-installation of these technologies, siting cooling towers may pose an even greater challenge due to land constraints at the stations.

EPA Response

EPA considered the air pollution impacts of cooling towers and the associated costs of controlling that additional pollution when deciding not to utilize cooling towers as a basis for the final rule.

Benefit Estimation Methodology

USEPA Overestimated the Benefits Associated with Retrofitting to Operate with Closed Cycle Cooling

Appendix 14 to UWAG's Phase II Comments <FN 72> provides a critique of USEPA's benefit estimates for the Proposed Phase II Rule and states that "the methods EPA employs to estimate benefits of the regulatory options contain serious flaws and inconsistencies." <FN 73> Examples of the major problems with USEPA's benefit estimate methods include: (1) assuming that benefits equal costs in employing the Habitat Replacement Cost ("HRC") method and the Societal Reveal Preference ("SRP") method; (2) overstating commercial fishing benefits because of incorrect benefit timing assumptions and inappropriate benefit transfer; (3) overstating recreational benefits because of several errors (e.g., sampling methodology, trip costs, participation modeling) in USEPA's Random Utility Model ("RUM"); (4) the appropriateness and empirical support for basing nonuse values on a simple 50% (of use values) "rule of thumb"; and (5) extrapolating national benefits for 539 facilities from five nonrandom case studies. <FN 74> After correcting for some of USEPA's most obvious flaws in the benefits analysis for the Preferred Option, Dr. Desvouges concluded that aggregate benefits would be reduced by 82% (from about 735 million dollars to 132 million dollars). These errors in the benefits analysis also affect USEPA's estimates of the benefits associated with retrofitting facilities with closed-cycle cooling option, causing USEPA's estimates to be biased high.

Footnotes

72 UWAG's Phase II Comments, Appendix 14, prepared by W.E. Desvousges et al., EPA Benefits Analyses of Cooling Water Intake Structure ("CWIS") Regulations", August 2002.

73 Id. At 3.

74 Id. At 4-11.

EPA Response

The commenter identifies 5 major problems with EPA's benefits estimation methods, including commercial fishery impacts, recreational fishery benefits, non-use benefits, use of the Habitat Replacement Costs and Societal Revealed preference approaches, and extrapolation of national benefits for 539 facilities from 5 nonrandom cases.

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment #316bEFR.005.029.

For EPA's response to comments on the methods used to estimate recreational fishing benefits please see the response to comments #316bEFR.075.504 and #316bEFR041.452.

As stated in the NODA, the rule-of-thumb approach to estimating non-use is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. Instead, the Agency presented a qualitative assessment of the non-use benefits of the environmental protections at issue in the final 316(b) benefit cost analysis.

The HRC method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see comment #316bEFR.005.035.

The SRP method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the SRP method, please see comment #316bEFR.005.006.

Finally, EPA does not use case studies of individual facilities in cost benefits analysis of the final 316(b) regulation. Instead, EPA developed a regional approach to estimating national benefits of the 316(b) regulation. See the Notice of Data Availability (67 FR 38752) and the Regional Analysis Document for the Proposed Section 316 (b) Phase II Existing Facilities Rule for details (DCN # 4-0003).

For EPA’s benefit transfer approach, please see EPA’s response to comment #316b.EFR.307.061 regarding using habitat values to estimate values for fish.

For EPA’s meta-analysis please see EPA’s responses to comments #316bEFR.338.044 regarding meta-analysis in general; comment #316bEFR.338.046 regarding the appropriateness of the studies selected, comparison of baseline and extent of change, and comparison of affected populations.

For EPA’s response to comments regarding the break-even analysis, please see response to comment #316bEFR.306.106.

RFC: Definition of "adverse environmental impact"

The Agency Should Adopt a Definition of Adverse Environmental Impact

USEPA has consistently espoused that a population, community, or ecosystem-level assessment of the impacts is required to determine if those impacts are "adverse" in the context of § 316(b). This has been the standard under which compliance with § 316(b) has been judged for almost 30 years. There is nothing in the record, which justifies a radical departure from this standard. Attachment 3 to PSEG's comments provide a summary of the legal and regulatory support for PSEG's position.

USEPA intentionally omits the regulatory definition of Adverse Environmental Impact ("AEI") <FN 75> because the determination of AEI can take a considerable length of time and that determination of AEI imposes a burden on the regulatory agencies. <FN 76> Even in its sample site-specific option, USEPA focuses on reduction in mortality of individual organism due to entrainment and impingement. PSEG believes that establishing a clear definition of AEI would provide for informed, scientifically based decisions. The burden on regulatory agencies would not necessary be increased and cost-effective and appropriate implementation of the Clean Water Act would occur. A recent article describing Maryland's evaluation of Chesapeake Bay power plant effects over a thirty year period concluded:
"The… impact assessment results and the… permitting actions at different categories of generating facilities in Maryland serve as basis for Maryland's perspectives on AEI… .

-Quantification of the effects of water withdrawal (i.e., numbers of organisms lost due to entrainment and impingement) is necessary, but not sufficient to determine whether AEIs are occurring; the key is whether these effects are of consequence to a biological entity of concern (e.g., RIS populations).

-Costs to the living resources and economic costs to the utilities and, ultimately, to the consumers must be taken into account when making permit decisions.

-The extent of impact of cooling-water withdrawal should be evaluated on a site-specific basis.

-In some instances, mitigation of some type may be the best way to ensure that the public's interests are addressed when CWIS decisions are made and permits are issued, approved, and enforced." <FN 77>

RFC: Alternative definition of "AEI"

The Alternative Definition of AEI Provided by USEPA Should be Modified

EPA has solicited comment on an alternative definition of Adverse Environmental Impact as follows:

Adverse environmental impact means one or more of the following: entrainment and impingement of significant numbers of a critical aquatic organism or percentages of aquatic populations; adverse impacts to threatened, endangered or other protected species, or their designated critical habitat; significant losses to populations, including reductions in indigenous species populations, commercial fisheries stocks, and recreational fisheries; and stresses to overall communities or ecosystems as evidenced by reductions in diversity or other changes in system structure or function.

The alternative definition of AEI proposed by EPA includes a number of factors that could indicate AEI. The first factor focuses on entrainment and impingement of significant numbers of critical aquatic organisms or percentages of aquatic populations <FN 78> without considering the source and magnitude of the change and its resultant impact on the relevant aquatic populations, communities, and ecosystems, absent consideration of compensatory mechanisms.

"Significant numbers" of aquatic organisms can be impinged or entrained without affecting the community or population of the ecosystem. <FN 79> Changes in populations, habitat, or communities may occur from many natural and anthropogenic conditions not related to the intake structure, such as natural variability in aquatic species density. In the alternative, USEPA's proposed definition would be improved by deleting the first factor, since USEPA's third factor addresses entrainment and impingement losses at biologically relevant endpoints. As noted in UWAG's Phase I comments, the protection of threatened and endangered species is accomplished using the Endangered Species Act. <FN 80>

Footnotes

78 Critical aquatic organisms were defined in EPA's 1977 draft guidance (see 67 Fed. Reg. 17163, Footnote 61).

79 See, e.g., In re Public Service Company of New Hampshire, Permit Application No. NH 0020338, No. 76-7 at 25 n13 (August 4, 1978) (The Administrator found that individual losses of planktonic stages of pollock and mackerel, "while large in absolute numbers, ... [are] extremely small when compared to the enormous mortalities that these ichthyoplankton typically sustain.")

80 16 U.S.C 1531 et seq. (2001). (The Endangered Species Act ("ESA") also involve a population- or community-based analysis of impacts. For example, in Humane Society v. Watt, 551 F. Supp. 1310 (D.D.C. 1982). The court upheld a decision by the FWS to allow sport hunting of black ducks. The Court rejected the plaintiff's argument that the "population" of protected ducks should be interpreted as the specific number of birds and instead defined population as the number of ducks for a required sustainable group.

EPA Response

EPA has rejected this definition of adverse environmental impact and has elected not to define the term in this rulemaking. Please see the response to comment 316bEFR.011.004 for more information.

UWAG definition of "adverse environmental impact"

UWAG's Definition of AEI Has Merit

PSEG also supports substituting the AEI definition UWAG proposed, <FN 81> which provides a foundation for assessing the impacts on a ecosystem, community, or population basis, which are the appropriate considerations under § 316(b). The definition recommended by UWAG provides more components to identify any potential adverse environmental impact and should be considered by USEPA. The UWAG definition of AEI is also consistent with the components considered by PSEG in its Salem 316(b) Demonstration. <FN 82> The comments of PSEG on the New Facility Rule relative to the components of AEI <FN 83> are equally applicable to the Phase II rulemaking.

PSEG also supports UWAG's recommendation that, where operating experience and knowledge of the local fishery provides regulatory authorities with confidence that fish populations are not being harmed by impingement and entrainment, the facility be identified as not causing an adverse environmental impact.

Subject Matter Code 10.1

General: cost tests

The Economic Tests Proposed by USEPA for Evaluating Costs and Benefits Under § 316(b) Should be Consistent with USEPA and OMB Guidelines And Should Reflect Widely Accepted Environmental Economics Methodologies.

USEPA has requested comment on the role of cost and benefit analyses for determining the best technology available for minimizing adverse environmental impact. <FN 84> PSEG supports USEPA's proposal to include a cost-benefit test in both its Preferred Option and its site-specific option and indeed believes it essential to any reasonable rule implementing § 316(b). This is the case whether USEPA ultimately adopts a site-specific approach as urged by PSEG and UWAG or whether the Agency adopts its Preferred Option based upon Performance Standards. Congress clearly mandated that costs must be considered when determining BTA. <FN 85>

Footnotes

84 See, e.g., 67 Fed. Reg. 17122 at 17153 (Col. 2), 17165 (Col. 3), 17166 (Col. 2).

85 § 316(b) uses "best available" to describe the technologies Congress wanted EPA to consider for minimizing AEI. One of the few things the legislative history says about BTA is that it means "best technology available at an economically practicable cost." 118 Cong. Rec. H9130 (daily ed. 33,762, 1972), Leg. Hist. at 264 (remarks of Congressman Clausen, for House Conferees).

EPA Response

The final rule includes a cost-benefit test, as requested by the commenter. In addition, costs have been considered in the analysis of the final rule, as the commenter requests. Therefore, the commenter's concerns have been met. EPA believes it is authorized to consider costs in establishing requirements under 316(b), and it did so for today's rule. Therefore, EPA does not need to reach the question whether Congress required consideration of costs.

RFC: Test: benefits should justify the costs

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

USEPA Should Adopt “Maximum Net Benefits” As The Appropriate Economic Test

USEPA requests comment on the "significantly greater" cost test, which would replace the "wholly disproportionate" cost test USEPA has applied since the Seabrook decision. Neither the "significantly greater" nor the "wholly disproportionate" cost tests are the best means for evaluating BTA for minimizing adverse environmental impact.

Both USEPA <FN 86> and OMB <FN 87> have recently issued guidelines for conducting cost benefit analyses. Based on these guidelines issued by USEPA and OMB, the “best” intake structure technology for a given site is the one that maximizes net social benefit.

According to the OMB’s best practices <FN 88> for regulatory actions, determinations should ensure that:

1. the potential benefits to society justify the potential costs;

2. the proposed action will maximize the net benefits to society, including potential economic, environmental, public health and safety, and other advantages, distributional impacts, and equity; and

3. the proposed action will be the most cost-effective.

OMB further provides that decisions should be based on the best reasonably obtainable scientific, technical, economic, and other information. OMB’s direction to “maximize the net benefits to society” is not only appropriate in the promulgation of regulations but in their implementation as well.

EPA has provided no basis for proposing methodologies that deviate from their own economic analysis methodologies in its Guidelines. Furthermore, USEPA should ensure consistency in the application of § 316(b) and reduce the burden on permittees and regulators alike by developing regulations that provide a clear framework for analyzing costs and benefits of alternative BTA compliance measures. USEPA could also achieve this objective by the timely issuance of guidance describing credible methods based on practices that are widely accepted in the environmental economics profession. The USEPA’s own Guidelines for Preparing Economic Analyses <FN 89> could provide the foundation upon which either regulatory language or § 316(b)-specific guidance would be developed.

PSEG supports the use of “maximize net benefits” as the most appropriate criteria for making site-specific BTA determinations. PSEG believes that USEPA should provide the framework for site-specific cost and benefit analyses through regulations or guidance and endorses UWAG’s comments on this issue. <FN 90> This is the test PSEG has applied in its § 316(b) Demonstration for its Salem, Hudson and Mercer stations. Moreover, this is the same method prescribed in EPA's own Guidelines for Preparing Economic Analysis and is used in regulatory impact analysis conducted under

Executive Order 12866.

88 Office of Management and Budget, Economic Analysis of Federal Regulations Under Executive Order 12866, January 11, 1996.

89 USEPA, Guidelines for Preparing Economic Analyses, Office of the Administrator, EPA 240-R-00-003 (Sept. 2000).

90 For an analysis of how such site-specific assessments can be developed, see David Harrison, Jr. et al., Economic Evaluation of EPA's Proposed
Rules for Cooling Water Intake Structures for New Facilities. Prepared for the Utility Water Act Group, November 2002.

EPA Response

EPA does not agree that maximizing net benefits is the most appropriate criterion in this case, in which many benefits could not be monetized. For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Benefit Estimation Methodology

The Accurate Valuation of Benefits is Critical

USEPA requested comment on the appropriate methodology for benefits assessment. The accurate valuation of benefits is critical to make an informed decision regarding whether a technology is BTA for minimizing adverse environmental impact. Without an accurate valuation of benefits, analyses of the maximum net benefit will not allow for informed determinations.

As discussed in Section V.D. below, PSEG conducted a review (Harrison, et al., 2002) of USEPA's methods for valuing I&E reductions at Salem. That review identified several serious errors in USEPA's methods that would lead to substantial overestimates of benefits. Included in Harrison, et al. (2002) are recommendations for improving economic benefit assessments. In response to USEPA's request for comments on appropriate methodologies for benefit assessments, those summary recommendations are reproduced in the following sections. These criticisms of the benefits assessment for the Delaware Estuary CSA are instructive and the recommendations for addressing the deficiencies noted in the CSA should inform USEPA's thinking on the development of guidance for conducting cost-benefit analysis under § 316(b).

EPA Response

EPA agrees that accurate valuation of benefits is critical when applying the benefit-cost test. However, no methods are available for estimating either costs or benefits with perfect accuracy or without uncertainty. Therefore, informed decisions must be made with the best available information and analysis. EPA disagrees that its methods for valuing benefits of the 316(b) regulation are flawed and thus would lead to substantial overstatement of benefits.

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment 316bEFR.005.029.

For EPA's response to comments on the methods used to estimate recreational fishing benefits please see the response to comment 316bEFR.075.504. See also response to comment 316bEFR.041.452.

Commercial Fishing Benefits

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

For commercial fishing benefits, USEPA should review the empirical foundations and revise its estimates

The commercial fishing benefits in the Delaware Case Study are overstated because they exaggerate the likely consumer and producer surplus associated with changes in the commercial catch. The values do not appropriately acknowledge the long-term tendency for producer surplus to be dissipated, which means that most additional gross ex vessel revenues will not constitute long-term benefits.

More important, USEPA uses a “multiplier” to translate changes in producer surplus into total “multi-market” surplus that is not justified. Such a multiplier implies substantial reductions in fish prices, and USEPA has provided no information to support such a claim. Indeed, given the relatively small effect changes in I&E at Salem would have on overall supply, it does not seem likely that consumers would receive any additional consumer surplus gains.

EPA should revise its estimated range of potential commercial fishing benefits from Salem I&E to reflect long-term effects on producer surplus and the lack of any likely effects on fish prices.

EPA Response

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits, please see the response to comment 316bEFR.005.029.

Comment ID 316bEFR.075.068

Subject Matter Code 10.02.01

Recreational Fishing Benefits

For recreational fishing benefits, USEPA should modify its application of the benefit transfer approach and revise (or ignore) its RUM study

EPA's recreational fishing benefits are based on the benefit transfer approach and a Random Utility Model ("RUM") study carried out by EPA. The benefit transfer study should be re-evaluated to consider using a more sophisticated approach that would allow the value per fish to vary with individual circumstances. The RUM study—which is used to value two of the relevant species—either should be ignored or should be revised to eliminate (or explain) apparent methodological problems.

EPA Response

The comment refers to the proposed rule analysis. For the final Phase II 316b analysis, EPA has reduced its reliance on benefit transfer to estimate recreational fishing benefits. For the recreational fishing analysis, benefit transfer is used for the inland region, and benefit function transfer is used for the North Atlantic region. EPA has estimated RUM models for all other coastal regions (Mid-Atlantic, South Atlantic, Gulf of Mexico, and California), and for the Great Lakes region. Where benefit transfer is used, EPA has followed generally accepted procedures, and has carefully applied benefit transfer methods. Further information on the methods EPA used to estimate recreational fishing benefits for the final Section 316(b) Phase II regulation is provided in the Regional Studies Document for the Final Section 316 (b) Phase II Existing Facilities Rule. See Chapter A11 and Chapter 4 in Parts B through H: RUM Analysis (DCN #6-0003).

For EPA's response to comments on the benefits transfer approach used at proposal, see response to comment #316bEFR.075.504.

The Agency disagrees that its RUM approach suffers from methodological problems and thus is unsuitable for estimating recreational fishing benefits of the 316(b) regulation. For EPA's response to comments on the RUM method, please see responses to comments 316bEFR.041.452, 316bEFR306.320, and 316bEFR337.010.

Valuing Forage Species (incl non-use and non-landed)

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

For nonuse fishing benefits, USEPA should discard the estimates derived from the 50 percent rule of thumb

EPA’s nonuse benefits are based upon a crude rule of thumb that has no validity and no applicability to I&E changes in the Delaware Estuary. Unless USEPA has specific evidence of nonuse benefits associated with changes in I&E in the Delaware Estuary, this category should be eliminated as part of the Delaware Case Study.

EPA Response

In the cost-benefit analyses for the NODA and for the final Section 316(b) Phase II rule, EPA did not use the 50% rule-of-thumb to estimate non-use benefits. For EPA's response to comments on the use of the 50% rule-of-thumb to estimate non-use benefits, please refer to EPA's response to comment #316bEFR.005.034.

Please also refer to EPA's response to comments on the HRC methods (316bEFR.005.035) and the SRP methods (316bEFR.005.006); the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003); and to EPA’s Guidelines for Preparing Economic Analyses (EPA 240-R-00-003).

Organization PSEG Services Corporation, Ofc of Environmental Counsel

Subject Matter Code 10.02.04

Valuing Forage Species (incl non-use and non-landed)

For forage fish, USEPA should discard the replacement cost method and rely exclusively on the production foregone method

Forage fish can provide benefits because of the effects they have on commercial and recreational species. USEPA should base its estimate of benefits on the production foregone method and discard the alternative replacement cost method, which has no conceptual or empirical foundation as a measure of benefits.

EPA Response

EPA agrees that the production forgone method is preferable and has used it in the analysis for the final 316(b) Phase II rule.

For EPA's response to comments on the valuation of forage species, please refer to the response to comment #316bEFR.005.028.

RFC: Proposed use of restoration measures

PSEG Supports USEPA's Proposal to Allow for Restoration Measures

PSEG supports USEPA's proposal to include provisions that would allow implementation of restoration measures by a facility in lieu of or in combination with reductions in impingement mortality and entrainment in the Proposed Phase II Rules, including USEPA's Preferred Option, as well as its other options. PSEG firmly believes that at many facilities, implementation of restoration measures can provide increased ecological benefits over a purely technology-based approach.

1. The Use of Restoration Measures is a Tried and Proven Approach for Improving Aquatic Ecosystems and the Benefits of This Approach Have Been Scientifically Demonstrated.

As discussed in this and other (e.g., III.C.1) sections of PSEG's comments, PSEG is responsible for one of the Nation's largest restoration projects implemented to address concerns about potential impacts of I&E losses. Based on the wealth of information the experience from these projects has provided, PSEG offers the following comments in response to USEPA's invitation for comments on "all aspects" of its proposal to allow restoration measures "in lieu of, or in combination with reductions in impingement mortality and entrainment" (67 Fed. Reg. 17146) to satisfy § 316(b) requirements.

The scientific literature is replete with information pertaining to wetland restoration, fish ladders, artificial reefs and land preservation. A significant percentage of the literature discusses specific examples of measures including descriptions of the restoration project, monitoring programs to measure effectiveness in terms of both structure and function, and time frames in which the benefits of conservation measures were recognized. The information summarized in this comment supports the concept that conservation measures are a cost-effective alternative that should be considered alone or in combination with technology improvements as a mechanism for maintaining fish and shellfish populations in a waterbody.

a. Structure and Function Can be Restored at Wetlands

Degraded wetlands can be successfully restored where (1) conditions favoring restoration exist, (2) an appropriate design properly addressing ecological considerations is implemented, and (3) the program is monitored and managed toward the goal of achieving self-sustaining restoration. The scientific literature has many reports reviewing creation and restoration of wetlands. <FN 92> Restored wetlands can provide the same structure and function as naturally occurring wetlands and thereby enhance the health and productivity of aquatic ecosystems. (See also EPRI 2002). It is well known that salt marshes serve as important nurseries for resident and transient fishes. <FN 93> Furthermore, salt marshes function as sites for reproduction, food, and predator refuge for fishes and other animals and therefore promote growth and survival. <FN 94> Recently, fisheries biologists with the National Marine Fisheries Service published a review article titled Catching the Link Between Wetlands and Fisheries Management (Stedman and Brown 2000). The authors point out:

Fish use wetlands as nursery areas, spawning grounds, feeding areas, and refuge from predators. The wetland vegetation, the rich detritus, and the shallow water provide unique functions that benefit many fish. Approximately three–quarters of the commercial fish landings in the United States consists of species that depend on estuaries and their wetlands.

Despite the presence of state and federal wetland protection regulations, wetland losses continue to mount. <FN 95> The Department of the Interior estimated that 1.2 million acres of wetlands were lost during the ten years ending in 1995 (Natural Resource Council 2001).

PSEG's Estuary Enhancement Program ("EEP") includes one of the world's largest wetland restoration projects. The Company undertook the salt marsh restoration to address concerns about losses of certain species (i.e., "Target Species") due to Salem's CWIS operations. PSEG's EEP clearly demonstrates that wetland restoration can be successful and should be considered as an acceptable component of § 316(b) permitting decisions (PSEG 1999). As recognized by the National Oceanic and Atmospheric Administration when it honored PSEG with its Excellence in Business Leadership Award for Coastal and Ocean Resource Management, <FN 96> PSEG's wetland restoration program is an excellent example of society's efforts to balance business interests with environmental needs.

As part of the EEP, PSEG has been conducting studies that demonstrate that the restored marshes function as habitat for reproduction, feeding, and growth for numerous species of fish and other components of the indigenous Delaware Estuary. The goals of these studies are to document finfish utilization of restored wetlands by examining the distribution and seasonal abundance of Target Species, and community composition of the ichthyofauna present; and to compare Target Species' utilization of restored wetlands to Target Species utilization of reference marshes. <FN 97> These studies also characterize the relative movement and feeding habits of Target Species in tidal creeks in restored and reference marshes, thus serving to document the direct role of restored marshes in providing foraging habitats for the Target Species.

i. PSEG's EEP Provides Benefits to Fish Populations

PSEG undertook several comprehensive studies to determine whether, in fact, restored marsh successfully augments the aquatic food web, and provides habitat for reproduction, feeding, growth and refuge for numerous species of fish and other estuarine fauna. These studies conclusively demonstrated that seasonal occurrence, abundance, and size of blue crabs in restored marshes were similar to or greater than those found in natural, reference marshes within two years of the completion of restoration construction activities. Studies at several sites found that the abundance of several fish species, including Atlantic croaker, bay anchovy, spot, striped bass, weakfish, and white perch in large marsh creeks was greater than or equivalent to abundance at the reference site. Detailed analysis of the food habits of young mummichog, bay anchovy, spot, weakfish and white perch, and of adult striped bass and white perch, indicated that individuals in the restored and reference marshes ate equivalent types of food in equivalent amounts. The studies found that fish were using the restored marshes as habitat for reproduction, feeding and growth on the same basis as at the reference marshes. Indices of fish survival indicated similar function between restored and reference marshes (PSEG 1999, Appendix G-3). Thus, PSEG's studies have demonstrated the utilization of restored marshes by Atlantic croaker, weakfish, bay anchovy, striped bass, white perch, and weakfish; the same species subject to I&E at Salem.

PSEG also helped fund state-of-the-art stable isotope studies, which showed that weakfish, bay anchovy, and white perch were using food derived from Spartina marshes. The weakfish specimens included those caught at the mouth of the Delaware Bay during the fall out migration to the coastal waters, confirming that the energy generated by the Spartina marshes in the Estuary accrues to the benefit of higher-level predators in open water.

PSEG's studies also examined the detrital production at the restored marshes, which contribute to the Delaware Estuary. Monitoring of those portions of the restored sites now dominated by Spartina showed levels of biomass production indistinguishable from those at reference marshes and near the high end of the range of peak season biomass reported of Spartina in salt marshes along the Atlantic coast (Mitsch and Gosselink 1992; PSE&G 1999, Appendix G-2).

The studies completed by PSEG have been well-documented and reviewed by recognized experts in the fields of marsh ecology and fisheries management. EEP's Monitoring Advisory Committee, comprised of independent scientists with expertise in marsh-related fisheries, and regulatory scientists from federal, state and interstate resource protection agencies, have reviewed the Biological Monitoring Work Plan for the project and the results of that program since the establishment of the EEP. Furthermore, technical papers have been published and subject to peer review describing the findings of these studies and the methods used to evaluate those findings. <FN 98>

The evidence collected by the PSEG program clearly demonstrates that marsh restoration programs make measurable and demonstrable contributions to the ecological processes that produce fish and invertebrates in the Delaware Bay system, including those species affected by the operation of Salem's CWIS. Almost from the inception of the restoration activities, PSEG restoration sites have been producing benefits for fish production that are equal to or even greater than those provided by nearby natural Spartina wetlands used as reference sites. The studies show that the restored marshes are providing food to important species, including weakfish caught in the open Delaware Estuary. The studies conducted in the restored wetland sites confirm, in the specific context of the Delaware Estuary, the important and widely recognized benefits provided by wetlands, including restored wetlands, to fish production. PSEG's EEP clearly demonstrates that wetland restoration can be successful and should be considered as an acceptable component of Section 316(b) permitting decisions (PSEG 1999, Schoenbaum and Stewart 2000).

96 PSEG received NOAA's Excellence in Business Leadership Award for Coastal and Ocean Resource Management in October 3, 2001. The Excellence in Business Leadership award recognizes one business that has made significant contributions to improve or protect the coastal or ocean environment and that demonstrates the ability to balance business interests with environmental needs. PSEG's Estuary Enhancement Program was cited as an innovative solution to an environmental issue that balances the needs of natural resources and the community's need for safe, dependable economic power.

97 Reference marshes are naturally incurring marshes that PSEG selected to use as benchmarks for tracking the return of structure and functions at its restoration sites.

EPA Response

EPA does not believe restoration measures are necessarily more cost-effective than design and construction technologies or operational measures. However, by providing additional options, restoration measures increase the number of potential solutions as permit applicants seek a cost-effective solution.

For a discussion of the benefits from restoration, see EPA’s responses to comments 316bEFR.075.017 and 316bEFR.032.011.

EPA believes that restored wetlands have been shown to match some of the structures and functions of naturally occurring wetlands, but that wetland science has not advanced to the point where it is able to define and measure all structures and functions of either naturally occurring or restored wetlands.

EPA encourages the use of the peer review process to bring current expertise to bear on the design, implementation, and assessment of restoration measures.

For a discussion of existing restoration programs, see EPA's responses to comments 316bEFR.307.046 and 316bEFR.034.032.

RFC: Consideration of additional env. Benefits

PSEG's EEP Provides Other Environmental Benefits

The benefits of wetland restoration are not limited to increased fish and detrital production. Coastal wetlands are enormously valuable for their role in linking aquatic and terrestrial ecosystems. <FN 99> The water quality benefits associated with wetlands are well documented. Coastal wetlands also buffer the coastline from severe storms and intercept nutrients and sediments (USEPA 1998). In the case of PSEG's restoration project, the restored marshes along the Delaware Estuary provide new habitat for bird populations that use the Estuary in the course of their migration between South America and Canada. Among the beneficiaries are a large concentration of shore and wading birds, more than 30 species, which forage in freshwater and salt marshes in the Estuary during their spring migration. In addition, the design of the restoration sites accounted for critical habitat of threatened and endangered species, increasing available habitat which otherwise would not be present. Public access to the waterfront and the restoration sites in the form of boat launches, towers, nature trails, and boardwalks provide educational opportunities for the public at large.

The wetlands restored by PSEG also contribute to an area of significant ecological value, as recognized by "The Convention on Wetlands of International Importance especially as Waterfowl Habitat" (commonly referred to as the Ramsar Convention). Selection for the Ramsar List is based on significance in terms of ecology, botany, zoology, limnology, or hydrology. The Delaware Estuary and all wetlands lying therein comprise one of the seventeen sites that meet the critical and stringent Ramsar Convention guidelines and is designated as an internationally important wetland. All of the PSEG wetland restoration sites are included within the Ramsar Convention Delaware Estuary "List of Wetlands of International Importance" wetland site.

The marshes of the Delaware bayshore are also identified as a "Last Great Place" by The Nature Conservancy's ("TNC") Last Great Places Alliance for People and Nature campaign. The objective of this campaign is the protection, through partnerships, community outreach, and land preservation, of the best remaining examples of important and unique ecosystems. By designating the marshes of the Delaware bayshore, a Last Great Place, TNC also has recognized the value of the ecosystem to which the PSEG wetland restoration sites will contribute for the long term.

Fish Ladders Can be Used to Restore Migratory Runs

Since colonial times, many tributary streams and rivers utilized by river herring and other species have been dammed or otherwise blocked for industrial, irrigation, recreational, and flood control purposes, leading to a decline in anadromous fish stocks (PSE&G 1993; ASMFC 1985). Fish ladders are a proven technology for enabling fish to pass upstream over natural and manmade barriers in rivers and streams (EPRI 2002).

In Delaware, the Wagamons Pond fishway recorded 1,814 river herring ascending the ladder in 1998 (University of Maryland, 1998). <FN 100> Connecticut has an extensive program for enhancing and restoring river herring populations; it includes activities associated with upstream and downstream fish passage, juvenile monitoring, and adult stocking. There are at least 25 fishways installed on Connecticut rivers and streams for the purpose of passing anadromous fish upstream. The Connecticut Department of Environmental Protection ("CDEP") has been pleased with the effectiveness of these types of ladders to pass river herring upstream, given that the ladders are properly installed and operated at appropriate sites (i.e., dams that meet engineering criteria for effective application). <FN 101> The CDEP considers fish ladders to be a proven technique for restoring river herring runs and supports their continued installation at dams where no upstream passages are present.

In Rhode Island, steeppass ladders have been used to restore runs of river herring. In some cases, these ladders have performed so well that they had to be replaced by larger Denil ladders in order to pass the increased number of fish arriving at the ladder sites. <FN 102> Alaska steeppass ladders have been installed at several locations in Maine. Information that was obtained on four steeppass ladders indicates that they are effective. <FN 103> Thousands of adult alewife (more than 10,000 at one ladder) use the ladders each year.

Alaska steeppass ladders also have been constructed for passing river herring at several locations in New Jersey. <FN 104> A ladder at Shenandoah Lake (south branch of the Metedeconk River) has passed alewives into the lake since 1973. On the basis of the success of past and ongoing restoration efforts, it can be concluded that the fish ladder - and specifically the Alaska steeppass ladder - is a demonstrated technology for allowing river herring to migrate past barriers to upstream spawning habitats.

PSEG has installed eight fish ladders in the Delaware Bay area and will install an additional four ladders over the term of its 2001 NJPDES Permit. <FN 105> A total of 733 acres of additional lacustrine habitat and 118 miles of riverine habitat have been made available by the eight already-installed ladders. In addition to producing substantial numbers of additional adult river herring that will return to the Estuary, the newly accessible impoundments will also produce substantial additional forage for the predator species in the Estuary (i.e., weakfish and striped bass). The estimated potential juvenile production ranges from 736,665 to 4,194,959 fish.

PSEG studies and others referenced above have demonstrated a direct link between establishment of fish ladders and benefits to species, which may be impacted by the CWIS. The installation of fish ladders to restore access to spawning habitat is a viable means of enhancing the aquatic productivity of an ecosystem. A number of NPDES permits resolving § 316(b) determinations have included such requirements and PSEG strongly recommends that the Phase II Rule recognizes the installation of fish ladders as a means of achieving compliance with § 316(b).

RFC: Consideration of additional env. Benefits

Artificial Reefs Provide Shelter and Increased Forage for Fish Species of Interest

A review of the scientific literature and research indicates that the creation of artificial reefs will result in increased fisheries production in estuaries and help insure the maintenance of balanced, indigenous aquatic populations as well as foster increased production of species, which are associated with the artificial reefs (EPRI 2002).

An artificial reef is defined as the manipulation of natural aquatic habitats through the addition of man-made or natural structures, for the purpose of enhancing specific or selected fisheries resources. Historically, reefs have been constructed to foster a greater, more efficient harvest of commercially and/or recreationally desirable organisms, and more recently, for the enhancement of environmental quality in the areas of water quality and biodiversity. <FN 106> Through physical modification of habitat, artificial reefs increase shelter and cover to protect the fishes of interest and also result in a more diverse and productive forage base for predator fish (Seaman et al. 1991).

In the mid-1980s, as part of the United States Army Corps of Engineers ("USACOE") Wilmington Harbor mitigation project, the Delaware Department of Natural Resources and Environmental Control's ("DNREC") Division of Fish and Wildlife funded several studies, which included an artificial Reef Siting and Design Development Plan for Delaware Bay and Adjoining Coastal Waters. These studies were utilized in the selection of the design specifications and siting for the USACOE's Brown Shoal project. <FN 107> Subsequently, the USACOE (Philadelphia District) placed a series of artificial reefs in lower Delaware Bay as partial, out-of-kind mitigation for the loss of 239 acres of wetlands and subaqueous habitat in Wilmington Harbor South, Delaware, resulting from dredge spoil disposal. The sixteen artificial reefs were placed in four clusters on Brown Shoal in June 1989, approximately 8.5 nautical miles north of Cape Henlopen, on the State of Delaware's reef site #7. The objectives of the Brown Shoal reef were to create a highly productive habitat that would provide food and shelter for endemic species, and to increase feeding efficiency of endemic fish species. <FN 108>

The biological survey of the Brown Shoal reef is one of the more comprehensive studies of an artificial reef in a temperate climate on the East Coast. The results showed that as a result of the placement of new habitat structure, the composition of the fish community changed in response to the new habitat and abundance was potentially greater than that found on the adjacent, unstructured bottom. There also was a significant increase in the epifaunal community attached to the structures as compared to the benthic community of the surrounding bottom.

A five-year study conducted by USACOE on the reef structures measured epifaunal community biomass enhancement, that averaged 486 times the control bottom and organism abundance that averaged 211 times greater than the area without a reef structure. The study concluded that the artificial reefs is likely to have enhanced the benthic forage available to the bay fish community.

PSEG believes that the construction of artificial reefs in the Delaware Bay has and will continue to increase production of fish. When a reef is built, the epifaunal community that develops is more diverse and productive than the community associated with previously existing unstructured bottom habitat, creating a larger forage base. The enhanced forage base found on artificial reefs provides the potential for improved growth and survival of recreationally and commercially important species within the waterbody.

PSEG believes that the construction of artificial reefs, therefore, is another habitat restoration measure that should be available for consideration in § 316(b) determinations.

RFC: Habitat conservation as part of restoration

Preservation of Buffer Areas Enhance and Protect Aquatic Ecosystems

Buffers, including both upland and wetland areas adjacent to estuaries, rivers, bays are critical links to the health of these ecosystems. The literature recognizes the importance of such areas, as do many public and private organizations that fund acquisition of critical lands for ecosystem protection. For example, as discussed in Section C.1.a.ii above, TNC's Last Great Places Alliance for People and Nature specifically recognizes the role land preservation plays in ecosystem protection.

Healthy, intact, broad, upland buffers are integral components of healthy wetland landscapes. In fact, upland buffers are absolutely critical to the functional value of wetlands. <FN 109> Lack of such buffers, or lack of quality in buffers that are present, is reflected directly in reduced functional quality of adjoining wetlands (South Florida Water Management District 1997). The buffers serve as physical and biological ecotones, providing habitat diversity and assuring the functional integrity of the ecosystem at the landscape scale. <FN 110> The water quality protection functions provided by upland buffers have been encompassed in riparian and estuarine conservation programs in many places, notably in "critical areas" protection programs in Maryland and New Jersey. Water quality protection values accrue from upland buffers throughout watersheds, but are particularly important in headwaters areas, where streams are smaller, flows are lower, and pristine conditions are more likely to occur.

The benefits associated with protection of buffer areas adjacent to aquatic ecosystems include the following:

-Buffers provide more complete ecosystem mosaics, resulting in a diversity of habitats for a variety of avian and terrestrial species. Buffers provide adjunct habitats to species that depend primarily upon wetlands, link wetlands and terrestrial habitats for species that depend on both, and provide habitats for species that depend on upland forests and agricultural lands (USEPA 1998).

-Buffers provide nutrient and other chemical and physical inputs to marshes. Plant communities in marsh and estuarine systems benefit from diffuse overland flow of nutrients, sediment, organic matter and other material from adjoining lands. <FN 111>

-Upland buffers protect adjoining wetlands from anthropogenic impacts. They provide areas in which human development is controlled and so aid in wetland protection and adjacent waters from the most intrusive human impacts. <FN 112> Impacts related to land use include increased artificial lighting, noise, dust, pollution, odors, vegetation removal, microclimate change. <FN 113>

-Upland and wetland areas provide natural treatment systems that protect the quality of downstream waters. <FN 114> Buffer areas diffuse excess loadings of nutrients or other chemical constituents from plant sources by reducing their concentrations and bioavailability. <FN 115> Improved water and overall habitat qualities generally lead to increase in biodiversity and improvements in ecological functions such as nutrient cycling, trophic relationships, and predator-prey relationships.

-Buffer areas provide hydraulic and hydrologic control and storage of runoff from the upland watershed or storm surge in estuaries. <FN 116>

The importance of upland and tidal marsh preservation to the long-term sustainability of estuarine processes is becoming increasingly widely recognized. The functions of upland buffers are so important that the USACOE has recognized that preserving vegetated buffers may provide more benefits to the local aquatic environments than replacing an impacted wetland.

Given the critical links between buffer lands, wetlands and adjacent surface waters, land preservation can provide long-term contribution to ecological diversity and fish habitat and will provide these services long after the cessation of CWIS operation. Preservation of these sensitive lands through transfers to government, public trusts, or through deed restrictions provides a reliable means of protecting such lands in perpetuity.

PSEG recommends that the preservation of lands in perpetuity, including wetlands, transition areas and uplands, serving as buffers to aquatic habitats, continue to be recognized as appropriate restoration measures under the Phase II Rules.

RFC: Proposed use of restoration measures

What is the Role of Restoration Under the Three Demonstration Alternatives of USEPA's Preferred Option?

USEPA has invited comment on whether or not restoration measures should be allowed only as a supplement to technologies or operational measures, or whether restoration measures should also be allowed as stand-alone measures to address potential adverse impacts of cooling water system operations. <FN 117> PSEG believes the role of restoration under the Preferred Option requires clarification and the role may depend on which "Demonstration Alternative" specified in § 125.94 for establishing best technology available is selected by the applicant.

Under Demonstration Alternative I specified in § 125.94(a)(1), the applicant would be required to demonstrate that the existing design and construction technologies, or operational measures would meet the performance standards, and/or that the restoration measures meet that portion of the performance standards not met by the existing design and construction technologies. Under this Demonstration Alternative, whether or not restoration measures are included, as standalone measures or a supplement to technologies or operational measures to satisfy the performance standards would depend on conditions of NPDES Permits in force when the Final Rules are promulgated. The Phase II Rules should recognize existing NPDES permit conditions regarding restoration measures, i.e., restoration measures that are conditions of existing NPDES permits should be considered when determining whether the performance standards are met under Demonstration Alternative I.

An applicant using Demonstration Alternative II as set forth in proposed § 125.94(a)(2) would be required to demonstrate that the proposed design and construction technologies, operational measures, and/or restoration measures would, in combination with any existing design and construction technologies, operational measures, and/or restoration measures meet the requisite performance standards. Demonstration Alternative II would allow implementation of restoration measures by a facility in lieu of or in combination with reductions in impingement mortality and entrainment. Dependent on site-specific circumstances, implementation of restoration measures at many facilities may provide increased ecological benefits over a purely technology-based approach and the Phase II Rules should allow for flexibility on the part of the applicant preparing an Alternative II Demonstration. Given the uncertainty concerning population level effects of an individual facility, the Director may, in fact, prefer the implementation of restoration measures to address other more pressing management needs that are impacting aquatic populations within the source waterbody (e.g., wetland or habitat loss, water quality, and etc.). A restoration plan that addresses other source waterbody problems more directly impacting aquatic populations can provide immediate, long-term benefits to the ecosystem and these benefits will continue regardless of the long-term operational status of the existing CWIS.

Under Demonstration Alternative III specified in § 125.94(a)(3), a site-specific determination of best technology available may be allowed if the Director were to determine that the permittee met the requirements of either the cost-cost or cost-benefit tests. The Director is required to make a site-specific determination based on less costly design and construction technologies, operational measures, and/or restoration measures to the extent justified by the significantly greater costs. PSEG agrees that an Alternative III Demonstration should allow for the use of restoration measures either in lieu of or in combination with reductions in impingement mortality and entrainment.

USEPA's Preferred Option seems to require a cost-benefit analyses regarding any proposed restoration measures to satisfy the regulatory clause, "to the extent justified by the significantly greater cost." USEPA should clarify that the cost-benefit analyses required by § 125.94(c)(2) and (c)(3) would apply only to design and construction technologies. If the applicant chooses, after the cost-cost and cost-benefit analyses, to propose restoration measures for consideration by the Director, a cost benefit analyses for the proposed restoration measures should not be required. Subjecting restoration measures proposed by an applicant to a cost-benefit analyses is not a reasonable approach because a precise and complete quantification of the benefits may not be possible, dependent on the nature of the restoration measures that have been proposed.

The inclusion of restoration measures for any Demonstration Alternative, including an Alternative III Demonstration, should remain voluntary and at the discretion of the applicant as may be necessary to resolve uncertainty concerning potential adverse effects of a particular facility's CWIS.

Footnotes

EPA Response

For a discussion of the role of existing restoration measures, see EPA's response to comment 316bEFR.032.011.

EPA believes the requirements for restoration measures in the final rule provide permit applicants with a significant amount of flexibility.

EPA believes there are uncertainties associated with the implementation, assessment, and design of restoration measures as well. For a discussion of these uncertainties, see EPA's response to comment 316bEFR.206.055.

For a discussion of the role of state program priorities in the choice of restoration measures, see EPA's response to comment 316bEFR.099.029.

For a discussion of ancillary benefits from restoration measures, see EPA's response to comment 316bEFR.032.011.

As described in the final rule, restoration measures must be considered, as are design and construction technologies and operational measures, in any site-specific determination of performance standards.

For a discussion of the extent to which restoration measures are voluntary, see EPA's response to comment 316bEFR.060.022.

RFC: Appropriate spatial scale for restoration

USEPA Should Allow Permitting Agencies and Permittees to Determine the Spatial Scale Under Which Restoration Efforts Should be Allowed

USEPA has invited comment on the most appropriate scale under which restoration efforts would be allowed. <FN 118> As proposed by § 125.95(b)(5)(iv) of the Preferred Option, any proposed restoration measures must first be discussed with the appropriate Federal, State and Tribal fish and wildlife agencies before they are included as a provision of the restoration plan. One component of this consultation would logically include a discussion of the species populations intended to be enhanced through restoration measures. Therefore, USEPA does not need to specify a spatial scale under which restoration efforts should be allowed in the Proposed Phase II Rules.

Furthermore, as noted in the USEPA's Case Study Analysis, Chapter F5, <FN 119> restoration measures may not equally benefit all species of concern at a particular CWIS and the spatial scale for restoration measures must depend on the species to be addressed and the type of restoration measures to be implemented. The appropriate spatial restoration scale will vary between anadromous, resident, and seasonally resident populations. It will also vary between various types of restoration measures that may include restoration of submerged aquatic vegetation, restoration of tidal wetlands, the creation of artificial reefs, installation of fish ladders, or water quality improvements. Determining the best course of action, and the spatial scale, for restoring habitat to offset losses requires an understanding of the specific habitat requirements for each species. Habitat requirements may include physical habitats, water quality needs and food sources in various geographic locations. Under these conditions, the Director on a site-specific basis must make any decision regarding the appropriate spatial scale for restoration measures.

Footnotes

118 67 Fed. Reg. 17148, col. 2-3, § VI.

119 PSEG does not intend that this reference to Chapter F5 of USEPA’s CSA in any way be deemed an endorsement of the use of the Habitat Replacement Cost (“HRC”) Methodology for estimating benefits. PSEG fully endorses UWAG’s comments on the HRC as well as Dr. Devousges’s Report included as Appendix 14 to UWAG’s comments.

EPA Response

For a discussion of the appropriate scale on which to conduct restoration measures, see EPA's responses to comments 316bEFR.212.001 and 316bEFR.059.008.

RFC: Consultation with wildlife agencies

The Nature and Extent of Consultations with State, Tribal, and Federal Agencies Should be Dictated by the Nature and Scale of the Restoration Measures Under Consideration

USEPA seeks comment on the type of information that would be appropriate to include in a written request for consultation with State, Tribal, and Federal agencies. <FN 120> The required consultation with appropriate Federal, State and Tribal fish and wildlife management agencies described in proposed § 125.94(d) of USEPA's Preferred Option would provide important input to the Director to assist in determining the best course of action, the appropriate spatial scale, and the necessary margin of safety to be applied to restoration proposals. To achieve these consultation objectives, any written request for consultation by an applicant needs to include essentially the same information that the Proposed Phase II Rules (§ 125.95(b)(5)) specify for inclusion in the Restoration Plan that applicants must submit to the Director for review and approval. Information included in the consultation request, however, would be of a conceptual nature with sufficient detail to focus the consultation discussions, but without site-specific plans.

While PSEG supports the need for, and value of, consultations with Federal, State and Tribal fish and wildlife management agencies; PSEG has concerns about the timing and schedule for preparation and submission of the required components of NPDES permit renewal applications. Consultations with fish and wildlife management agencies to identify the current status of species of concern, discuss potential threats to species of concern, identify appropriate restoration measures, and determine monitoring requirements for assessing the effectiveness of the proposed restoration project will require numerous and extensive meetings with agency personnel and it would likely take from six months to a year to reach consensus among the interested parties. In order for an applicant to meet the statutory deadline for filing of the NPDES renewal application six months prior to expiration of an existing NPDES permit, this consultation process must occur prior to preparation of the Comprehensive Demonstration Study proposed in § 125.95(b) of the USEPA's Preferred Option because the Comprehensive Demonstration Study must include the necessary information to support the proposed restoration measures. <FN 121>

Footnotes

120 67 Fed. Reg. 17146.

121 See PSEG Comments section IV. The schedule for preparation of Comprehensive Demonstration Studies and § 316(b) applications should be site-specific and subject to approval by the applicable state regulator (see § III.F).

EPA Response

For a discussion of the role of authorities other than the permitting authority, see EPA's response to comment 316bEFR.320.007.

The final rule contains provisions that EPA believes will provide facilities with sufficient time to develop the materials associated with restoration measures.

RFC: Performance/effectiveness of restoration

There are Valid Means of Demonstrating the “Substantially Similar Performance” of Restoration Measures

USEPA has correctly recognized that although restoration measures can provide benefits to aquatic ecosystems that are commensurate with benefits from technological alternative, it may not be feasible to quantify those benefits:

If it is not possible to demonstrate quantitatively that restoration measures such as creation of new habitats to serve as spawning or nursery areas or establishment of riparian buffers will achieve comparable performance, you may make a qualitative demonstration that such measures will maintain fish and shellfish in the waterbody at a level substantially similar to that which would be achieved under Sec. 125.94. <FN 122>

PSEG wholeheartedly endorses this provision in USEPA’s Preferred Option and offers the following comments in response to USEPA’s request for comments on how to measure “substantially similar.”

USEPA should allow flexibility in the Final Phase II Rules for application of multiple approaches to demonstrate "substantial similar performance" of restoration measures <FN 123> and should allow the Director to determine on a case-by-case basis what data and methodologies are sufficient to demonstrate that restoration measures will maintain fish and shellfish at a level comparable to that which would be achieved through satisfaction of the performance standards through the implementation of technologies. (§ 125.95(b)(5)).

Demonstrating "substantially similar performance" for habitat restoration measures where it is not scientifically possible to fully quantify the number or biomass of aquatic organisms expected to be produced, through implementation of the restoration measures can be difficult, but should not preclude application of these restoration measures. Fully quantifying the increased aquatic production from habitat restoration measures that result in water quality improvements, provide new aquatic habitat (e.g. opening impounded tidal marsh), or improve existing aquatic habitat (e.g. wetland restoration, artificial reef construction, re-establishment of submerged aquatic vegetation, wetland buffer conservation, and etc.) may not be possible, but suitable techniques are available to demonstrate "substantially similar performance."

Efforts to demonstrate "substantially similar performance" for restoration measures must address the potential conflicts between the species-specific approach used to calculate CWIS losses and the habitat-based benefits resulting from restoration measures. The final Phase II Rules should allow for an ecosystem approach to demonstrating the general ecological benefits provided by restoration measures. Habitat restoration measures may not be species-specific and, although the particular restoration measures proposed are designed to benefit certain species of interest, the restoration measures will benefit all species that use the particular type of habitat undergoing restoration. Dependent on the type of restoration measures proposed, applicants will be able to demonstrate to the

Director that the reduction in I&E due to CWIS technologies combined with restoration efforts will maintain the fish and shellfish in the waterbody at a comparable or substantially similar level to that which would be achieved through proposed § 125.94(b) and (c).

Although USEPA has rightly recognized the difficulties in quantifying benefits associated with restoration measures, this does not mean that permittees would be unable to quantify portions of the benefits derived from restoration measures. There are a number of methods of varying sophistication that can be applied, including bioenergetics and ECOPATH modeling. Mathematical modeling techniques can be used to quantify a portion of the fishery benefits that will result from implementation of most restoration measures. For restoration measures involving the stocking of hatchery-reared species, numbers or biomass of CWIS losses can be compared to the numbers or biomass of hatchery-reared organisms to be stocked. If the primary concern relates to the potential secondary effects on predator species of recreational or commercial fishery importance due to CWIS losses of a forage species (e.g. bay anchovies, Atlantic silverside, Atlantic menhaden, alewife, blueback herring); the level of stocking of predator species required can be determined through bioenergetic models which calculate the predator biomass that would be expected to result from consumption of the lost forage. <FN 124>

Similarly, the increased biomass of predator species of recreational or commercial importance attributable to the production of forage fish that results from restoration measures can be quantified through use of bio-energetic modeling. PSEG has applied this approach to estimate the increased biomass of striped bass and weakfish in the Delaware Estuary from the production of river herring in the new habitat created through the installation of fish ladders on impoundments within the Delaware Estuary. <FN 125>

Mathematical modeling techniques such as bioenergetics modeling can be used for most restoration measures for which the number or biomass of forage or predator species expected to result from implementation of the restoration measures can be estimated. It is not necessary to conduct extensive monitoring to determine precisely the number of organisms or biomass produced as a result of the restoration measures. In most instances, sufficient scientific literature exists upon which to base credible estimates. The appropriate margin of safety for particular restoration measures can be determined by the Director on a case-by-case basis; and the required consultation with appropriate Federal, State and Tribal fish and wildlife management agencies specified by § 125.94(d) of the Preferred Option would provide sufficient input to the regulatory authority to ensure that an appropriate safety margin is applied.

Comprehensive ecosystem modeling using ECOPATH, or a similar type of model that tracks energy flow through an ecosystem is an approach that may be available in some instances (Christensen and Pauly, 1992; 1993; ECOPATH 2000). The ECOPATH model presents a mass balance of trophic exchanges for an entire ecosystem. It works by using estimates of biomass for each major species or their aggregation in functional groups representing trophic levels, then uses principles of energetics and trophic transfer to estimate the flux of energy from one level to another. This creates a steady-state solution that requires an input-output budget to balance for the ecosystem as a whole, and then calculates the rate of energy transfer required to balance that budget. ECOPATH has been used to describe the structure of food webs in 56 different ecosystems (Pauly and Christensen, 1995), and its applications have grown rapidly in the recent past to the point that there are now ECOPATH models for more than 90 different ecosystems (ECOPATH, 2000). However, for most ecosystems subject to proposed or ongoing restoration measures, the data and scientific understanding of ecosystem processes necessary to quantify the subtle shifts in ecosystem energy flow resulting from restoration measures may not presently exist.

PSEG has explored various approaches for quantifying the increased fisheries production resulting from the extensive and ongoing salt marsh restoration program in Delaware Bay (PSEG 1999, Appendix G-4) that have application for other types of habitat restoration efforts. PSEG's efforts indicate that biomass should be the common metric of assessment because biomass can be directly measured and compared across all levels of the food chain. <FN 126> Biomass can also be aggregated by trophic level for comparison to CWIS losses to capture the habitat-based benefits to multiple species resulting from restoration measures. Biomass is also the most suitable metric when the age or length-class of organisms lost at a CWIS are different than the age or length-class of organisms benefiting from a habitat restoration effort.

In the case of PSEG's marsh restoration, field data from monitoring studies on fish abundance in weirs (marsh plain habitat) and otter trawls and push trawls (marsh channel habitat) have been used to estimate the abundance and biomass of fish in the restored and reference marshes and to quantify a portion of the production in these marshes (PSEG 1999, Appendix G-4). Production estimates based upon the capture of organisms in the marshes tend to be underestimates of true production because they only account for fish actually captured within the marshes or produced by predators feeding on fish produced in the salt marsh, and do not include production from detrital food webs associated with export of organic matter from the restored salt marshes; however, these type of production estimates can be used to demonstrate "substantially similar performance."

RFC: Performance/effectiveness of restoration

PSEG's Wetland Restoration Process Provides a Model for Addressing Uncertainty in Restoration Projects

USEPA expressed concern regarding uncertainties that can affect restoration projects and reduce benefits from those projects (67 Fed. Reg. 17147):

"Under today's Preferred Option, restoration planners would take care to incorporate allowances in their plans for the uncertainties stemming from incomplete knowledge of the dynamics underlying aquatic organism survival and habitat creation. Plans would include provisions for monitoring and evaluating the performance of restoration measures over the lifetime of the measures. Provisions would also be made for mid-course corrections as necessary."

In this regard, USEPA invited comments on "methods that can be used to reduce the uncertainty of restoration activities" (67 Fed Reg. 17147). PSEG believes this wetland restoration process it has developed and implemented provides a model for addressing uncertainty in restoration projects, and offers the following comments.

As noted in Section IV.A below, PSEG has successfully implemented large scale wetlands restoration measures in the Delaware Estuary pursuant to the NJPDES permit for Salem. In planning and implementing these restoration measures, PSEG and the NJDEP were well aware of the presence of uncertainties that could affect the performance of the restoration measures. Accordingly, PSEG and NJDEP put in place a process that explicitly addressed uncertainties to ensure that the benefits from the restoration measures would address any potential adverse impacts caused by the I&E losses at Salem. The process included the involvement of the necessary Federal, State and local stakeholders; the definition of appropriate conservation measures; the definition of acceptable safety margins; the determination of the necessary monitoring requirements; and the implementation of the agreed upon conservation measures. <FN 127>

Salem Station's 1994 NJPDES Permit required the formation of two advisory committees comprised of Federal and State resource managers, academic scientists with relevant expertise in wetlands science and restoration, marsh fisheries and fisheries science, and local community representatives who assisted with the development and implementation of the restoration and monitoring programs. These advisory committees further assisted with reviewing monitoring results on an annual basis to ensure that the restoration measures were performing as intended. USEPA's Final Phase II Rules should provide sufficient flexibility with regard to the required "consultation with Federal, State and Tribal management agencies" to allow for advisory committees of this type to serve similar purposes.

PSEG's restoration measure plans included provisions for monitoring and evaluation of the performance of the restoration measures consistent with USEPA's Preferred Option. <FN 128> Well-designed monitoring and, as appropriate, modeling programs, provide strong assurance regarding the benefits of conservation measures consistent with USEPA's Preferred Options.

Furthermore, PSEG's conservation plans included provisions for mid-course corrections to the restoration actions if natural forces altered the direction of a restoration project. The "adaptive management" process has been followed to monitor, guide, and respond to the temporal process of restoration for habitat restoration sites (PSEG 1999, Attachment G-2). Adaptive management is a framework for identifying and meeting environmental management goals by an iterative process of monitoring and engineering response. <FN 129> Given the level of complexity in the ecology of tidal wetlands and other types of potential restoration projects, and the inability to completely understand the details of the functioning of these systems; adaptive management is an appropriate framework under which a successful large-scale environmental restoration can be conducted. <FN 130>

Well-designed monitoring programs and adaptive management provisions help to reduce the uncertainty of restoration activities. PSEG concurs with USEPA's recommendation that restoration planners further reduce uncertainty by creating habitat that replicates as closely as possible the natural habitats in which the aquatic organisms of interest naturally occur (67 Fed. Reg. 17148, col.2, § VI). This is exactly what PSEG did in designing and implementing its restoration program. Monitoring programs that compare the ecological functioning of restored habitats to naturally occurring habitat for the aquatic species of interest, can provide strong assurances that the restored habitats are serving the intended function. <FN 131>

These types of monitoring programs are particularly important where the current state of ecological understanding precludes the absolute monitoring of increased aquatic production necessary for quantitative comparisons with cooling water intake losses. PSEG has demonstrated the value of these types of comparative monitoring programs for its tidal marsh restoration program in the Delaware Estuary (PSEG 1999, Attachment G-2, Attachment G-3). PSEG's monitoring programs have compared vegetative cover, macrophyte production, and geomorphological features to demonstrate that the restored wetlands have the appropriate habitat structure to support the naturally occurring aquatic populations of interest. Monitoring programs focused on the abundance of aquatic organisms, feeding habitats, movement, and reproduction of fish species have demonstrated that these restored habitats are performing as intended. <FN 132> Similar types of monitoring programs can be designed for other types of restoration programs to satisfy regulatory agencies that restoration plans are providing "substantially similar performance" without a requirement for a purely quantitative demonstration.

Regulatory agencies can further assure the performance of conservation measures by requiring the inclusion of safety margins within the restoration plans submitted by operators of cooling water intakes pursuant to § 125.95(5), of the Preferred Option. In determining the scale of PSEG's wetlands restoration, PSEG and the NJDEP took into account the need for a margin of safety and increased the planned acreage of wetlands to be restored to exceed what modeling studies indicated would be needed. The appropriate margin of safety for particular conservation measures should be determined by the Director on a site-specific basis. The margin of safety appropriate for a particular restoration measure should depend on the circumstances under which they are proposed. Factors such as: the degree of uncertainty concerning the adverse impact of CWIS operations (e.g., whether or not the aquatic populations demonstrate long-term trends of increasing abundance); the scientific understanding of the ecological benefits of the proposed conservation measures; the ability to monitor and quantify the ecological benefits of the proposed conservation measures; and the intended lifetime duration of CWIS should all be factored into decisions concerning the appropriate margin of safety to be applied. The required consultation <FN 133> with appropriate Federal, State and Tribal fish and wildlife management agencies specified by § 125.94(d) of USEPA's Preferred Option would provide sufficient input to the regulatory authority to ensure that an appropriate margin of safety is defined.

133 The conservation measures proposed by operators of the CWIS may also likely require the issuance of permits involving these same Federal, State and Tribal fish and wildlife management agencies. The Director or NPDES permitting authority can facilitate the necessary dialog between the interested regulatory parties who all become stakeholders in any proposed conservation measures to ensure that the outcome satisfies the differing objectives and requirements of all involved parties.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

EPA believes well-designed monitoring and adaptive management is important and has included requirements for these activities in the final rule.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

EPA believes the requirements for restoration measures in the final rule are written with a significant amount of flexibility.

RFC: Proposed use of restoration measures

Alternative Restoration Approaches Considered by USEPA

USEPA's Preferred Option proposes use of restoration measures as one means for satisfying the compliance requirements for any of the three demonstration alternatives described in proposed § 125.94(a). USEPA has also invited comment on three other restoration approaches it is considering: discretionary restoration approaches, mandatory restoration approaches, and restoration banking. PSEG supports allowing voluntary implementation of restoration measures by a facility in lieu of or in combination with implementation of technological measures which reduce impingement mortality and entrainment, concurs with UWAG's comments regarding mandatory implementation of restoration and endorses the banking of restoration credits for purposes if § 316(b) compliance.

EPA Response

For a discussion of the extent to which restoration measures are voluntary, see EPA's response to comment 316bEFR.060.022.

For a discussion of trading programs, see EPA's response to comment 316bEFR.074.020.

Subject Matter Code 11.1

RFC: Discretionary restoration approach

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

The Discretionary Approach

As Proposed by USEPA, 67 Fed. Reg. 17169, col. 3, § VI, a discretionary restoration approach would allow the Director to specify appropriate restoration measures under § 316(b), but would not require that he or she do so. USEPA cites several NPDES permits that include restoration measures as being consistent with this alternate approach (e.g., John Sevier, Crystal River, Chalk Point, Salem). In each of these permit proceedings, the permittee volunteered the restoration measure to resolve a then-ongoing controversy with the Director. The Director incorporated as terms and conditions requiring the implementation of the restoration measures into the facilities' NPDES permits, but only after the permittees volunteered to implement these measures.

The Discretionary Restoration Approach being considered by USEPA appears to authorize the Director to mandate the implementation of restoration measures; however, this calls into question the use of the word “Discretionary”. As stated in the Preamble, <FN 134> "EPA would provide the Director with the discretion to specify appropriate restoration under § 316(b)." If the intent is to authorize the Director to mandate implementation of restoration measures, the CWA gives no statutory authority for requiring restoration. <FN 135> USEPA should clarify its intent with regard to Discretionary Restoration Approaches before further consideration of this regulatory approach. The approach outlined in USEPA’s Preferred Option for restoration measures is already discretionary in that the permittee can volunteer to implement restoration measures if he or she so choose. PSEG supports this approach. PSEG also supports the approach to restoration measures in the various site-specific options. (See Section II.A above.)

RFC: Mandatory restoration approach

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

The Mandatory Approach

Under USEPA's Mandatory Restoration Approach, restoration would be required to compensate for organisms that were not protected following a facility's installation of control technologies. Phase II existing facilities would be required to implement some form of restoration measures in addition to implementing direct control technologies. <FN 136> As stated by UWAG, § 316(b) does not authorize mandatory restoration, and restoration measures can not be required as part of intake structure "design", according to USEPA's own interpretation of that statutory term. USEPA should eliminate the "Mandatory Restoration Approach" from further consideration and promulgate final Phase II Rules that allow regulators to include restoration measures a part of a § 316(b) compliance demonstration if volunteered by the permittee.

RFC: Restoration banking

Restoration Banking

USEPA indicates that it is also considering an alternate restoration approach that could include provisions for banking of restoration credits similar to the approach used under the § 404 program. <FN 137> PSEG supports inclusion of a restoration banking program § 316(b). Banking would facilitate using restoration measures, since restoration credits could then be purchased. PSEG's experience indicates that using restoration measure requires long-lead times to develop and implement an appropriate plan for each type of "restoration" and also requires a substantial commitment of specially trained and highly qualified personnel.

PSEG assumes that the reference to a § 404 banking program was not intended to limit the banking program to wetlands restoration credits. A Restoration Banking Approach should not be limited to use of wetland mitigation banks. Other types of habitat restoration can potentially be implemented to create "CWIS mitigation credits" and any USEPA CWIS restoration banking program should be flexible enough to allow for their implementation and use.

The use of wetland mitigation banks under CWA § 404 is well established and the use of banking under section § 316(b) would provide similar enhancements for fish populations and their invertebrate food base, and result in effective compensation of losses from CWIS impacts. The restoration of a large area of degraded wetlands, as through a wetland bank, may result in greater success than small, individual wetland restoration projects. Following successful project completion, and approvals for use by applicable state and federal agencies, areas of the wetland bank become available as "credits." Credits in an existing wetland bank could be purchased to provide the wetland area required to compensate for CWIS impacts. Similarly, wetlands restoration projects for § 316(b) compliance, if relatively small, could be more efficiently accomplished in combination with other wetland restoration efforts.

CWIS mitigation banks for other types of credits could easily be established in the future once a market for this type of service would be created. A CWIS facility that is proposing to raise fish in a hatchery may have extra capacity to create CWIS mitigation credits. Facilities that are proposing other types of habitat restoration, such as eel grass beds, artificial reefs, or enhancements to migratory runs by installing fish ladders may choose to enlarge the size of a particular project to create banking credits.

As rightly indicated by USEPA, a § 316(b) restoration banking program could effectively facilitate compliance, reduce the burden on permit applicants, allow for rapid fulfillment of compensation requirements for CWIS impacts, and potentially enhance the ecological effectiveness of restoration activities.

RFC: Should EPA include impingement trading?

USEPA Wisely Identified that Trading may be Applicable to a § 316(B) Determination

PSEG agrees with USEPA's promotion of the voluntary use of trading as an innovative way to develop common sense and cost-effective solution for a variety of environmental issues. <FN 138> USEPA is continuing its efforts to develop and implement market-based trading programs under the Clean Water Act. For example, EPA issued an Effluent Trading in Watersheds Policy <FN 139> and Draft Framework for Watershed-Based Trading in 1996. <FN 140> On May 15, 2002, USEPA proposed for comment a policy for trading water quality credits <FN 141> as an "incentive based approach to more efficiently protect and restore the nations waters" [emphasis supplied] that could save the public hundreds of millions of dollars by advancing more effective, efficient partnerships to clean up and protect watersheds. <FN 142> USEPA also stated that the trading policy would encourage "incentives to maintain high water quality where it exists as well as restoring impaired waters. <FN 143> USEPA can, likewise, achieve the objective protecting aquatic life by authorizing trading under § 316(b).

Footnotes

138 Experience with emissions trading provides ample evidence of the advantages of providing trading flexibility. These advantages include reduced costs of meeting environmental objectives and greater assurance that environmental objectives are achieved. RFC: Should EPA include impingement trading?

Limiting the Scope of Trading to Entrainment Losses in Unnecessarily Restrictive.

PSEG strongly supports the voluntary use of trading as an alternative for meeting the I&E performance standards proposed in USEPA's Preferred Option trading should also be included if USEPA were to promulgate Final Phase II Rules based on a site-specific option.

USEPA proposes that trading be limited to entrainment <FN 144> because "impingement reduction technologies are relatively inexpensive compared to entrainment reduction alternatives". <FN 145> PSEG believes that any trading program should include both impingement and entrainment losses because this would afford maximum flexibility and provide enhanced environmental benefits under § 316(b) – two critical aspects of trading programs. <FN 146> USEPA states that "impingement reduction technologies are relatively inexpensive compared to entrainment reduction alternatives". <FN 147> However, the impingement reduction technologies can cost millions of dollars per facility since all Phase II facilities, including "peaking" and "load-following" facilities are required to meet the performance standard for impingement under the USEPA's Preferred Option, costs such as these could result in a substantial economic burden on the permittee, with potentially minimal benefits to the fishery. USEPA has not provided adequate justification for limiting a trading program to entrainment losses.

From the perspective of maintaining the health of aquatic populations, PSEG believes that CWIS effects on post-compensation life history stages such as juvenile and adult fish (i.e., reducing fish potentially affected by impingement) as well as eggs and larvae (i.e., fish potentially affected by entrainment) need to be considered. Natural mortality rates are very high for entrained organisms (pre-compensation early life history stages), <FN 148> therefore, protecting the more mature fish is also important to maintaining and propagating aquatic populations. The impingeable sized fish have a much greater chance of reaching maturity and reproducing.

In summary, the resource that is being protected by the Proposed Phase II Rules are entrained and impinged organisms and, thus, the trading program should not be unnecessarily limited to entrainment; it should allow trading to occur for entrainment, for impingement or for both.

RFC: Potential trading units/ credits

Establishing the Appropriate Trading Units of Measure is Critical to the Success of the Program.

USEPA correctly states that a trading option requires a definition of the trading commodity and the unit, or credit that would be traded <FN 149> and requested comment on the appropriate unit. <FN 150> USEPA's preferred approach for trading is based on the density of entrained species life stages per unit of flow. <FN 151> First, as discussed above, PSEG believes it is unwise to limit the trading program to entrainable organisms. Therefore, PSEG believes that the Agency is being too prescriptive; it is inappropriate to prescribe the commodity for trading on a national basis, since the factors that should determine the appropriate commodity differ from site to site (e.g., waterbody types, fish species and life stages).

USEPA suggests establishing as the trading commodity, the density of entrained species life stages (eggs, larvae, juvenile and small fish for all fish and shellfish species) per unit of flow through a facility. <FN 152> USEPA does not favor the use of species counts because of the significant expenditure of time and resources to identify entrained organisms by life stage and size classes. <FN 153> USEPA also rejects species counts because the number of species entrained by a facility can vary substantially each year for many reasons, including facility outages, or extreme weather events. PSEG's experience suggests that any of the trading units (i.e., density, counts, biomass) suggested by USEPA will be subject to seasonal and inter-annual variability because the naturally occurring temporal variability in organism abundance in the source water directly affects density, counts and biomass at a facility's intake.

USEPA should provide that trading units be decided on a site-specific basis via a trading plan that would be submitted to the appropriate regulatory agencies for review and approval. PSEG, however, believes that in most instances biomass would be the most appropriate and workable "commodity" because it is a metric that can be easily measured in regard to I&E losses and then can be directly compared to biomass produced from other power plants. Biomass would also be applicable to the benefits associated with various restoration measures and may be a more appropriate commodity for evaluating community structure and function as proposed in §125.95(b)(5)(iii) of the Preferred Option. However, there may be other circumstances where trading would be applicable and another metric would be more appropriate. For example, if a stocking program were being used, a metric based on counts of the specific species being stocked species-specific may be a more appropriate metric.

150 67 Fed. Reg. 17171 (Col. 2).

151 67 Fed. Reg. 17171.

152 Compare or contrast this with the base line calculation and the approaches USEPA is considering for this component.

153 67 Fed. Reg. 17171.

EPA Response

Please see response to comment 316bEFR.077.052 for the discussion on the appropriate unit for trading. EPA disagrees that trading units should be decided on a site-specific basis via a trading plan submitted to regulatory agencies. In order for trading to occur in compliance with today's rule, the requirements of § 125.90(c) must be met. EPA expects that the units of trade from different facilities would need to be equivalent; thus, a trading unit selected needs to be decided for an entire State or Tribe by the permit director. For waterbodies that cross political boundaries, there will need to be coordination between permit directors.

RFC: Challenges of implementation of trading

In Establishing a Trading Program USEPA Must Provide Clear Direction Requiring Interstate Cooperation Since the Waterbodies and Organisms Are Often Subject to Regulation by Multiple Jurisdictions.

PSEG agrees with USEPA that instituting a national trading program may be difficult because of the inherent natural variability that exists between sites located through out the United States. <FN 154> In addition, from a regulatory implementation perspective, most major lakes, rivers, estuaries and the oceans border multiple states. Unique or conflicting state regulations for trading could thwart any trading program from being implemented.

USEPA has authorized and sought to encourage trading of effluent discharges among point sources of water pollution and between point and non-point dischargers as a means of achieving ambient water quality standards. To this end, the Agency has developed strong policies, <FN 155> frameworks, <FN 156> and incentives <FN 157> for states to develop consistent trading policies for pollutants under the Clean Water Act. These have allowed the states to implement relatively consistent pollutant trading programs. Similar policies, frameworks, and incentives will be required to make voluntary trading viable under § 316(b).

USEPA should also provide guidance on how to insure the enforceability of any “trades” under § 316(b). Since entrainment and impingement credits will probably not be traded on a public market, trades will normally occur between two facilities. Unlike the sulfur trading program under the Clean Air Act, trades under § 316(b) must, to be of any value, extend for the term of each facility’s NPDES permit. This will require what will amount to long-term contracts between the trading facilities. The USEPA framework must provide that States acknowledge and accept these contractual provisions within their permitting process. Moreover, these contracts must account for the likelihood that the trading facilities will have NPDES permits with differing terms, e.g., facility A’s permit is under review and will have a five year term; facility B’s permit is in the second year of its five year term.

Footnotes

154 67 Fed. Reg. 17172. PSEG notes, however, that USEPA relied on just such an approach for the calculation of the benefits associated with this rule.

155 See, e.g., Effluent Trading in Watersheds Policy, (hereinafter “1996 Policy Statement”).

156 See, e.g., Draft Framework for Watershed-Based Trading (hereinafter “1996 Framework”).

157 For example, the TMDL program provides incentives for states to develop and implement alternative means of achieving the TMDL, including the trading of pollutants.

RFC: Should EPA include impingement trading?

EPA's Determination to Allow Permittees to Consider Improvements Associated with Prior Station-Specific CWIS Improvements Should Also Apply to the Trading Component of the Rule

Under USEPA's Preferred Option, permittees would be allowed to "capture" reductions associated with prior CWIS improvements in determining compliance with the performance standards. <FN 158> Site-specific improvements that exceed the performance standards or surpass the best technology available to minimize adverse environmental impact should be available for trading credit. The trading program can not operate if states "ratchet down" impingement and entrainment limitations on facilities that are able to achieve a reduction that exceeds those required by the regulations, effectively taking back the opportunity to recover some of the costs of that reduction. The USEPA framework should discourage affected states from imposing I&E requirements, which exceeds the minimum performance standards.

For example, if a facility were to install dry cooling and a state then adopted performance standard commensurate with that technology, it would be impossible to establish a trading market. Similarly, if a facility has been retrofitted to operate with a closed cycle system with wet towers, but does not have a CWIS (i.e., the facility uses an alternate source for cooling tower make-up, such as ground water or reclaimed water), the utility should be able to capture and trade the reductions in I&E losses. These reductions would be the difference between the maximum I&E losses that would meet the performance standard (based on the baseline calculation for the original once-through system) and the actual I&E losses at the facility (in this example no I&E losses). The excess between the baseline calculation and the performance standard for the dry cooling facility should be available to trade.

To increase opportunities for trading and allow flexibility in the program, PSEG suggests that trading not be limited to just the Phase II existing facilities <FN 159> but be applicable to Phase I and Phase III facilities as well as other types of programs that could affect the aquatic species at issue.

Spatial scale for entrainment trading

The Spatial Range for Trading Should be the Ecosystem Which Supports the Organisms

USEPA has requested comment on the appropriate spatial range for trading and suggested limiting trading to a watershed. <FN 160> PSEG concurs with USEPA in advocating trades between facilities sited in waterbodies that share similar ecological characteristics (i.e., potentially affect similar species and life stages, but not necessarily the same). PSEG, however, believes that trading should not be limited to the watershed level because of the relatively small areas encompassed by specific watersheds as compared to the large spatial areas covered by the natural distribution of a number of potentially affected species (e.g., striped bass, weakfish, herrings). Moreover, there may be instances for which trading may be appropriate on a much broader scale, e.g., a coastally migrant, single-stock species such as weakfish. For instance, a purchase fish excluder devices for shrimp boats to protect over-wintering age 1 weakfish instead of installing costly technological measures at the CWIS.

If the USEPA adopts PSEG's recommendation and allows the specifics of trading to be established by the local Director, then issues such as spatial scale, based on ecological facts, should also be resolved by the Director. PSEG supports trading because it allows the regulated facilities to meet the goals of the Clean Water Act while providing flexibility to the regulated community in maximizing ecological improvements.

RFC: Should EPA include impingement trading?

Examples of How Trading Could be Implemented

The PSEG system provides examples of situations where trading could be successfully implemented. For example, the Bergen Generating Station ("Bergen") located adjacent to the Hackensack River had operated as a steam electric facility with a once through cooling system for many years prior to the Company's decision to repower Bergen to operate as a combined cycle facility. These units withdrew up to 633.6 MGD for cooling purposes. To address environmental issues associated with the withdrawal and discharge of non-contact cooling water, PSEG decided in 1994 to modify the design for the repowered units to include a closed-cycle cooling system, and entered into a contract with the local sewerage authority to purchase reclaimed water for cooling tower make-up, thereby eliminating any withdrawal of surface water. Similarly, PSEG is presently building a new1100 MWe combined cycle plant at its Linden Generating Station. Like the repowered Bergen units, the new Linden units will use reclaimed water, again completely eliminating the withdrawal of water from the Arthur Kill. PSEG believes these conversions equate to 100% reductions in I&E losses and provides "credits" that should be available for trading by other facilities (e.g., Hudson or Sewaren).

Several PSEG's stations on the Delaware River may also have "credits" that could be traded. PSEG's Hope Creek Generating Station ("Hope Creek") operates with a closed cycle system. When PSEG built a new combined cycle unit at its Burlington Generating Station ("Burlington") site, it designed Unit 10 with closed cycle cooling. In addition, PSEG improved the Salem CWIS with modified Ristroph screens that increased the survival of various species of impinged fish and shellfish and it operates under a NJPDES permit restriction on the amount of cooling water it can withdraw. Similarly, PSEG will have installed 12 fish ladders on tributaries to the Delaware to increase production of river herring. Salem's I&E losses of river herring are very small. Depending upon how PSEG and NJDEP apply the increased production fromthese fish ladder sites, trading "credits" may be available. The difference between the performance standard applicable to that waterbody and the reductions in entrainment and impingement losses compared to the baseline calculation should be available for trading among estuarine facilities impacting similar species of concern.

PSEG believes these examples at its Bergen, Linden, Burlington, Hope Creek and Salem Stations present the types of reductions in entrainment and/or impingement losses that would produce "credits" under a § 316(b) trading program. If such a program were in existence, it would provide added incentives for other companies to implement similar measures at Phase II facilities and would be protective of the resource while providing flexibility to permittees to achieve compliance in a cost-effective manner.

EPA Response

RFC: Use of previous demonstration studies

USEPA's Final Rule Should Specify That Prior §316(b) Determinations Meet the Performance Standards

USEPA has requested comment on whether the final rule should allow permittees to rely on previous § 316(b) demonstrations for determining whether there is an adverse environmental impact and the best technology for minimizing adverse environmental impact. <FN 161> PSEG strongly believes USEPA's final rule should provide that if a facility had received a reasoned BTA determination based on still valid scientific, technical and engineering information, no additional actions should be required. For example, if the BTA determination had been based on a prior demonstration that had been conducted in accordance with USEPA's prior guidance, then that determination should be renewed. <FN 162>

USEPA and delegated state NPDES permitting authorities have been interpreting and implementing the requirements of § 316(b) for almost 30 years. Many facilities have developed comprehensive § 316(b) demonstration studies, installed expensive intake technology, and demonstrated that their specific intake provides the best technology available for minimizing adverse environmental impact. <FN 163> These studies and technologies have been implemented in conjunction with the permitting agencies, and frequently with other resource agencies, to ensure the intake structures reflect the BTA for minimizing adverse environmental impact. Absent substantial justification, these permit determinations should stand.

USEPA has expressed concern with the burden on permitting agency to comply with § 316(b) throughout the preamble. <FN 164> Requiring the permitting agencies that have already expended the resources to make § 316(b) determinations for a facility to start all over again would create the exact type of drain on the resources that USEPA states it is trying to eliminate.

In summary, facilities should be able to rely on and permitting agencies should be able to base decisions under the Final Phase II Rules on prior BTA decisions, assuming no changes in operating conditions that would affect entrainment and impingement, changes in available technologies or the costs associated with their implementation, or adverse changes in the affected fisheries that are attributable to the facility's CWIS operation.

Footnotes

161 67 Fed. Reg. 17165.

162 As PSEG suggested in sample regulatory language submitted to USEPA in January 2002, permittees could be required to submit information verifying that there have been no material changes that could require an alternative finding.

Comprehensive demonstration study (7 parts)

Author Name Maureen F. Vaskis & Mark F. Strickland

Organization PSEG Services Corporation, Ofc of Environmental Counsel

Permit Requirements Must Allow for the Time Needed to Collect, Analyze, and Report the Data, Needed for a Comprehensive Demonstration Study.

USEPA (67 Fed. Reg. 171, Col 2) has requested comments on whether it should specify a particular time frame for the collection, analysis, and reporting of data required for a Comprehensive Demonstration Study. Based on its experience at a number of facilities, PSEG believes that the design, implementation, and completion of a Comprehensive Demonstration Study that is scientifically credible, that reflects sound engineering and economics, and that has had appropriate stakeholder (e.g., regulatory agency <FN 165>) input will take a minimum of four years to complete.

For example, relatively straightforward § 316(b) Demonstrations for PSEG's Mercer and Hudson stations started with the development and submission of work plans for regulatory review, which took approximately six months to complete. The performance of impingement, entrainment and river survey programs took two years, drafting, reviewing, and submission of final reports required approximately six months to complete. Analysis of the results of the monitoring and preparation of a comprehensive demonstration could take up to 12 months. A more complex § 316(b) Demonstration, as was required by the NJPDES permit for Salem <FN 166> took five years to perform the same tasks.

PSEG believes that adequate time must be allowed to perform the study properly and endorses UWAG comments on this issue. However, PSEG believes that each site is unique and that the actual schedule should be determined on a case-by-case basis by the applicable state regulatory agency.

USEPA has also requested comment on the role of fish and wildlife management agencies in a site-specific approach. PSEG realizes that involving these agencies in § 316(b) could create potential burdens to fish and wildlife management agencies. However, it is these very agencies that are looked to by the general public and other third party groups as the stewards of the resources. As such, these agencies can provide valuable insight into the status of the resources and provide guidance with respect to what constitutes adequate levels of protection.

Footnotes

165 Fish and wildlife agencies should have an interest in the § 316(b) proceedings in that the agencies will be direct beneficiaries of the waterbody studies that will be conducted as part of the demonstration and any restoration-related monitoring.

166 The September 1994 NJPDES Permit for Salem required, among other matters, a comprehensive biological monitoring program, the development of work plans, the installation of the CWIS technologies, the implementation of post- installation verification monitoring programs, the review and assessment of all of this data, and the submission of a comprehensive Section 316(b) Demonstration with the 1999 renewal application. PSEG proceeded at risk to develop the initial work and monitoring plans based on the draft permit prior to the September/ effective date in order to be in a position to complete all of the work.

EPA Response

EPA recognizes that in some cases, the Comprehensive Demonstration Study may take longer than one year to complete. If a facility foresees that he or she will need additional time to complete the studies, he or she should immediately bring this issue to the attention of the permitting Director.

Subject Matter Code 21.08

Burden on permitting agencies (general)

The Burden On Permitting Agencies For Implementing § 316(B) Is Reasonable And Recoverable By The Agencies And Can Be Reduced By USEPA Action

EPA has invited comment on the burden associated with implementing § 316(b) on a site-specific basis. <FN 167> As the Agency, itself, has stated in the very context of the instant rulemaking, expedience should not be valued above quality and accuracy. Moreover, PSEG believes the burden on permitting agencies is not, in the vast majority of permitting proceedings, unreasonable. In any event, the costs associated with such reviews are recoverable, and the time required for decision-making can be reduced if USEPA establishes clear Phase II rules and provides definitive guidance for assessing § 316(b) demonstrations, and, as PSEG and UWAG have urged, if USEPA accepts the re-validation of prior § 316(b) determinations.

The costs to permitting agencies to evaluate adverse environmental impact and to determine if the best technology available for minimizing that impact are not trivial. However, permitting agencies have the ability to fund their NPDES permitting program through general revenues or through permit fee structures. For example, the New Jersey CWA statute provides for fees that are based on the NJDEP's costs for administering the program. <FN 168> PSEG's Slaem Generating Station has been assessed a fee to defray the cost of technical reviews performed by NJDEP's consultant. <FN 169> Permitting agencies could enact regulatory provisions to authorize the imppositon of fees to defray some of the additional burden experienced for application review.

Furthermore, there are steps within USEPA's sole control that would reduce the burden on and costs to permitting agencies. Clear, accurate, and concise regulations that provide guidance to the permitting agencies would minimize the uncertainty associated with § 316(b) determinations, especially for the "high profile" permits. When dealing with "high profile permits" permittees and regulators a like, are, in the absence of regulations or guidance, forced to prepare and review each aspect of a demonstration under the threat of litigation. Among other topics, USEPA should provide further clarification on: methodologies for assessing impacts on fisheries, the suite of generally accepted analytical methods or models; the types of technologies generally available; and how to conducteconomic analysis. Such regulations and/or guidance would facilitate efficient evaluations of § 316(b) compliance while allowing for the necessary and appropriate consideration of the unique characteristics of each facility and the ecosystem with which it interacts.

USEPA cites the backlog of NPDES permit issuance as a concern regarding the burden on permitting agencies. <FN 170> Since the implementation of the NPDES permitting program, there has been a backlog in issuing permits. This backlog does not consist solely of permits for facilities operating with a CWIS. The USEPA Fact Sheet on NPDES Permit Backlog Reduction <FN 171> indicates the backlog is primarily attributable to a reduction in resources at permitting agencies and a shift in the focus of the agencies. Moreover, the actual NPDES permit backlog was reduced approximately 50% between November 1998 and January 2002, <FN 172> a significant accomplishment in these resource-limited times.

Footnotes

167 67 Fed. Reg. 17167 (Col 1) and 67 Fed. Reg. 17153 (Col 1).

168 N.J.S.A. 58:10A-9. 172 EPA, National Trend Charts for Individual NPDES Permits, available at http://www.epa.gov/npdes/pubs/natall.pdf (last viewed July 18, 2002)

EPA Response

In today's final rule, EPA has preserved the site-specific determination of BTA option for facilities whose costs of compliance with the final rule may be significantly greater than the costs estimated by EPA, or whose costs may be significantly greater than the benefits of complying with the national performance requirements in 125.94(a). In addition, EPA has added four other compliance alternatives to provide flexibility for streamlining the permitting process (e.g., the pre-approved technology alternative at 125.94(b)(4) and compliance using a Technology Installation and Operation Plan at 125.94(e)). EPA believes that this approach will provide the combined benefit of addressing site-specific concerns and also ensuring that permits are finalized in a timely manner.

EPA plans to provide guidance for implementing requirements of the final rule; Directors have been given discretion to determine parameters for all required studies.

Today's final rule allows for the use of historical data provided it is reflective of current conditions at the facility. However, EPA is not allowing the use of historical BTA determinations as discussed in the response to comment 316bEFR.040.001.

Implications for nuclear facilities

Unique Issues Associated with Existing Nuclear Power Plants Must be Considered

As USEPA has correctly noted, implementation of § 316(b) at existing nuclear power plants must be conducted in a manner that does not jeopardize the safety of the nuclear power plant. <FN 173> PSEG supports the comments submitted by NEI. <FN 174> Since 20% of the nation's electricity is generated by nuclear power plants, specific considerations related to nuclear safety and the requirements of the USNRC must be considered in this rulemaking.

The additional costs associated with implementation of the various alternatives proposed by USEPA for nuclear power plants can be significant. The analyses used by the USEPA when drafting the proposed Phase II rule significantly underestimates the time and capital outlays required to retrofit an existing nuclear unit with impingement/entrainment reduction technologies, particularly a closed-cycle cooling system. As discussed in § II.C above, PSEG has analyzed in considerable detail the engineering for and costs of retrofitting Salem to operate with closed cycle cooling. Detailed risk assessments and multi-system harmonization studies must be conducted during the design stage of such a retrofit, and these analyses are unique to or significantly more rigorous for a nuclear plant. This process would increase design costs and lead times. After the analysis is complete, the nuclear industry estimates it would take two prolonged outages to retrofit a closed-cycle system. Because of their length, these outages could overlap either winter or summer peak electricity demand seasons, which could put electricity reliability at risk and increase costs to consumers.

The Palisades Nuclear Generating Plant was used by USEPA to evaluate costs at a nuclear plant. As NEI identifies, <FN 175> this case study is not a valid representation of a closed-cycle retrofit at a nuclear plant today, nor does it appear to support USEPA's conclusions about the extent of a likely outage associated with retrofitting a nuclear plant. For example, in calculating the capital cost of adding closed-cycle cooling systems to nuclear units with once-through cooling in the EBA, USEPA used estimates below all actual cost estimates of the Palisades retrofit in the early 1970's without considering the subsequent significant regulatory changes imposed on the nuclear energy industry in the 1970's and 1980's. For example, Appendix B quality assurance requirements, which require safety-grade equipment for systems critical to reactor safety, like service water flow, went into effect in 1970. Similarly, the emergency core cooling system regulation (10 CFR 50.46), which the CWIS changes would affect, was implemented in 1974. Neither of these regulations affected Palisades, which was granted its construction permit in 1967. Because of the significant changes in USNRC regulations that have been implemented since, it would be much more costly to make changes to an existing nuclear unit today than it was in 1973 when Palisades built and connected its closed-cycle cooling system. In addition, USEPA's EBA also misrepresents the outage time required to retrofit a closed-cycle system. The EBA suggests a plant would require a four-month outage to tie in a new cooling system, less than half that experienced at Palisades. Also, NEI notes that the capital and operating costs of retrofitting a closed-cycle cooling system on an existing nuclear facility have been underestimated and the average mean annual and summer peak energy penalties calculated by USEPA for use in estimating future operating costs are lower than those USEPA calculated for Palisades and significantly lower than those USNRC and Consumers Energy (owner of Palisades) calculated.

Nuclear plants are required to evaluate design changes against existing plant configurations under 10 CFR 50.59 and assess any potential impact on nuclear safety. Prior approval of the USNRC is required for certain changes in the plant. Significant changes to balance-of-plant systems could trigger technical considerations as yet unknown to the nuclear plant operators, USNRC or USEPA. Specifically, the USEPA should be sensitive to the unintended consequences of prescribing any retrofit technology, especially new or immature technology that would be imposed on a proven integrated power generation system. Circumstances could exist under which the USEPA rule would unintentionally reduce the margin of reactor safety. The USEPA can obviate this consequence by providing flexibility in the rule for nuclear plant operators.

Although PSEG supports USEPA's acknowledgement that the USNRC must be involved in assuring nuclear safety is not compromised for installation of any § 316(b) technology, USEPA must consider the unique requirements that nuclear power plants must address, which would result in significant increases in estimated costs of retrofitting nuclear plants.

Footnotes

173 67 Fed. Reg. 17222, § 125.94(f).

174 Nuclear Energy Institute, "Comments on Part II 40 CFR Parts 9, et al., Phase II proposed rule for cooling water intake structures under the Clean Water Act § 316(b); 67 Fed. Reg. 17,122; April 9, 2002", (August 7, 2002).

175 Id. At 4.

EPA Response

Today's final rule allows for a site-specific determination of best technology available if requirements conflict with Nuclear Regulatory Commission safety requirements (see § 125.94(f)). The five compliance alternatives are also available to these facilities.

See response to comment 316b.EFR.029.027.

The Agency does not base the requirements of the final rule on cooling tower retrofit technology.

The Agency extended the assumption for cooling tower connection outages for nuclear facilities in the NODA in response to the late-received data from the Palisades case noted by the commenter. The Agency recognizes that lengthy connection outages due to cooling tower retrofit activities are possible. The uncertainty related to their reliable prediction influenced, in part, the Agency's decision to not include the technology as a basis of the final rule.

EPA's legal authority to:

Under § 316(b) of the Clean Water Act USEPA Cannot Require Operational Modificiations

USEPA in the preamble states that the cost benefit estimates use one or more of the seven technologies with operational controls in some cases. PSEG interprets the term operational controls to mean cooling water withdrawal flow reduction (and the possible resulting reduction in electrical output). Flow reduction does not fall within any of the CIWS characteristic location, design, construction or capacity regulated pursuant to §.316(b).

When there is substantial reduction in the amount of cooling water flowing through a power plant's condenser, less steam is condensed and backpressure in the turbine increases. As the backpressure increases, the power plant produces less electricity until the backpressure becomes so great that the power plant must be shut down.

In addition, reduced cooling water flow results in a higher temperature of the cooling water that is discharged from the power plant. This has the potential of causing an exceedance of a permit thermal effluent limit. Moreover, it can also result in substantial increases in entrainment mortality due to the higher temperatures and longer transit times through the cooling water system. Finally, PSEG has evaluated the costs and benefits that would be associated with various flow reduction scenarios at Salem. Estimates ranged from $33.7 million for a 10% flow reduction to $864.8 million for a 45% flow reduction scenario that retained effluent temperatures within NJPDES permit limits by reducing power levels at the Station.

Fish Population Modeling

USEPA Has Failed To Properly Account for the Effects of Density-Dependent Compensation

As noted in Chapter A6 of the EBA, USEPA chose to ignore the effects of density-dependent compensation on fish populations in its estimates of the benefits from reductions in I&E losses (EBA, page A6-7):

"EPA has implemented several density independent models to conservatively estimate potential consequences for fishery harvests and ecosystem production, as described in detail in Chapter A5. These density independent models do not assume any compensatory response to CWIS losses. While relationships between CWIS losses, fish stocks, and fishery yields are unlikely to be strictly linear, as these models assume, EPA believes that the many uncertainties associated with modeling stock-recruitment relationships and potential compensation justify this approach, in keeping with a precautionary approach to environmental decision-making."

USEPA justified its decision to ignore the effects of density-dependent compensation in its loss estimates for all fish species in all locations as being a response to its perception that many fish stocks are at risk (EBA, page A6-6):

"A recent report by the National Marine Fisheries Service concludes that nearly a third of the 283 fish stocks under U.S. jurisdiction are currently below their maximum sustainable yield (NMFS, 1999b). For another third, the maximum sustainable yield remains uncertain. EPA notes that many of these stocks are also subject to impingement and entrainment losses. Given that many fish stocks are at risk, EPA has adopted a "precautionary approach" in evaluating CWIS impacts because of the many uncertainties associated with modeling compensation and stock-recruitment relationships."

Based on this statement, it appears that USEPA had no basis for ignoring the effects of density-dependent compensation in over one third of the managed stocks it cited. PSEG agrees that for some stocks (e.g. stocks in jeopardy of being unable to sustain themselves), a "precautionary approach" may be warranted; however, that does not justify the application of such an approach to all species in all locations. USEPA's refusal to account for the effects of density-dependent compensation in any stocks is unjustified scientifically and ignores relevant data on affected stocks.

PSEG believes that the selection of methods for assessing CWIS effects on fish populations (including whether or not to account for the effects of density-dependent compensation) should be made on a species-specific and site-specific basis, based on the current state of knowledge for the species and site. For example (as discussed below), there is ample evidence that density-dependent compensation affects the stock-recruitment relationships of striped bass and weakfish, two important species subject to I&E at Salem.

In its discussion of uncertainty in stock-recruitment models (another part of USEPA's argument to ignore density-dependent compensation), USEPA claimed (EBA Chapter A6, page A6-6) that two major sources of uncertainty in stock-recruitment relationships are:

“variation in the physical environment due to fluctuations in climate and other natural conditions (Cushing, 1982; Fogarty et al., 1991) and interactions with other species (Boreman, 2000).”

And that:

“Competition and predation can interact in complex ways with other sources of mortality to alter stock-recruitment relationships.”

PSEG acknowledges that uncertainty exists in stock-recruitment relationships that may introduce errors into stock-recruitment models. However, most of these sources of uncertainty affect USEPA’s linear stock-recruitment models as well as density-dependent stock-recruitment models. Accordingly, PSEG questions the validity of USEPA’s argument that due to these uncertainties, it is better to use a linear stock-recruitment model.

Another part of USEPA’s argument to ignore the effects of density-dependent compensation was USEPA’s assertion that estimating compensatory responses of fish stock can be problematic (EBA Chapter A6, page A6-5):

“Although many fish species appear to show the potential for a compensatory response to changes in population size, in other cased a statistically significant density dependent relationship cannot be detected because of significant variability in the available population data (Shepherd and Cushing, 1990; Fogarty et al., 1991).”

However, as noted in Appendix I of the Application, recent developments in Meta-analysis methods provide a means for quantifying compensation based on historical fisheries data:

“Meta-analysis refers to the process of combining and assessing the findings from several separate research studies that bear upon a common scientific problem (Hedges and Olkin 1985; Hedges 1989). The use of statistical methods of meta-analysis for research synthesis is now the standard accepted method for making crucial decisions in medical treatment, drug evaluations, and issues in public health and social policy (Peto 1987; Louis et al. 1985). Recently, it has become a standard approach used to evaluate the critical population parameters needed to understand fisheries dynamics (Mace and Sissenwine 1993; Myers and Barrowman 1996; Liermann and Hilborn 1997; Punt and Hilborn 1997; Myers 1997; Myers et al. 1997 and Myers and Mertz 1998).”

Table 1 of Appendix I of Salem’s 1999 Renewal Application contained estimates (derived using Meta-analysis) of compensatory reserve for 55 species of fish, includinge alewife, American shad, Atlantic menhaden, blueback herring, and striped bass (species affected by I&E at Salem). Therefore, the difficulties with estimation that USEPA cited are not sufficient to prevent the use of stock-recruitment models that account for density-dependent compensation.

In summary, PSEG believes that USEPA did not provide a reasoned basis for ignoring the effects of density-dependent compensation in its assessment of the potential benefits of reducing I&E losses. In this regard, PSEG supports the critique by Barnthouse (2002) of USEPA’s rationale for assuming no biological compensation. PSEG agrees with the critique’s conclusion that USEPA’s estimates contain a consistent bias toward overestimation of benefits because USEPA ignored the effects of density-dependent compensation in all of its estimates of the benefits of reducing I&E losses. Furthermore, PSEG believes that the decision of whether or not to account for the potential effects of density-dependent mortality should be made on a species- and site-specific basis using up-to-date information.

The following sections describe current species- and site-specific information that provide strong support for the hypothesis that density-dependent compensation helps to ameliorate I&E losses of striped bass and weakfish at Salem.

1. Compensation in Delaware Estuary Striped Bass Population

According to the ASMFC stock assessment for striped bass (ASMFC, 1999), the abundance of the east-coast stock of striped bass has increased since 1989 (Figure IV.A-1). During this period of increasing abundance, the first-year survival rate of striped bass has been decreasing. The decrease in first-year survival rate is indicated by a pronounced decline in the ratio of the number of recruits (i.e., age 1 fish) to the spawning stock biomass ("SSB") (i.e., the total weight of spawning-aged fish in the population). This decline in first year survival rate in response to the increase in SSB (Figure IV.A-2) is characteristic of the presence of strong density-dependent mortality. At the current level of female SSB (15,000 tons), the survival index is at its minimum level. With a female SSB below 9,000 tons, the index of survival about doubles, compensating for the reduced SSB.

The Hudson River striped bass population has been studied intensively for over two decades by the Hudson River utility companies and the New York State Department of Environmental Conservation ("NYSDEC"). These studies were synthesized in a Draft Environmental Impact Statement ("DEIS") prepared to support renewal of the State Pollutant Discharge Elimination System Permits for the Indian Point, Bowline Point, and Roseton generating stations (Central Hudson Gas & Electric Corp, et al., 1999). The data summarized in the DEIS reflect 24 consecutive years of sampling, covering the entire estuary from the Battery to the Federal Dam at Troy, using methods that sample every life stage of striped bass from egg to adult. In addition to data collected by the utility companies, the DEIS synthesizes information obtained from several monitoring programs conducted by the NYSDEC.

These studies indicate that the abundance of the adult component of the Hudson River striped bass population has grown substantially since 1980, while the operation of three large power plants located in the principal nursery area utilized by early life stages continued. The large year classes produced since 1980 were not heavily fished, resulting in a large increase in the size of the spawning stock by the early 1990's. As the size of the spawning stock increased (due to controls on fishing mortality), the densities of striped bass early life stages in the estuary also increased. However, the average abundance of juvenile striped bass, as reflected in the annual NYSDEC beach seine index, did not increase. This is because the relative productivity or index of pre-recruit survival (recruits, "r", divided by spawning stock biomass, "ssb", that produced it) decreases as the spawning stock biomass increases. The lack of correlation between early life stage abundance and subsequent year-class strength was noted previously (Pace et al. 1993).

Data for recent years, presented in the DEIS, confirm this pattern. The abundance of early life stages of striped bass in the Hudson River estuary has continued to increase with spawning stock size, but juvenile abundance has not increased. Recruitment production is equal to the relative productivity multiplied by the spawning stock biomass. When recruitment remains stable as spawning stock biomass increases then the decrease in relative productivity just offsets the increase in spawning stock biomass. The increase in abundance of adults, eggs, and larvae, coupled with stable production of juveniles, provides strong evidence for density-dependent mortality of early life stages of striped bass in the Hudson River estuary.

The above data were used to develop a stock-recruitment model of the Hudson River striped bass population (Appendix VI-4 of the DEIS). Analysis of the model indicated that reproductive success in striped bass is highly density-dependent or compensatory in nature. Density-dependent mortality is so strong that annual conditional mortality rates as high as 20% on fish less than age 1 would result in only an approximate 1% reduction in average annual recruitment (assuming a fishing mortality rate of $F<0.5$, and a 28 inch size limit).

Based on an assessment of available data on striped bass in the Delaware Estuary, the Delaware Department of Natural Resources and Environmental Control (Kahn, et.al., 1998) concluded that:

“[F]rom 1980 through 1995, the Delaware River YOY index followed a trajectory very similar to a classic exponential rate of increase. Since 1993, the index has fluctuated without trend.”

This result is similar to the result presented in the Report of the 26th Northeast Regional Stock Assessment Workshop (NMFS 1998), the Stock Assessment Review Committee (“SARC”), which stated that the Delaware River striped bass population had “grown exponentially” from the mid-1980s through the mid-1990s, and grew faster than the coastal stock as a whole.

In reference to striped bass population trends in Delaware Estuary during the late 1990’s, Kahn, et.al. (1998) further concluded that:

“The failure to maintain an upward trajectory suggests the possibility that the stock may have reached a rough upper bound.”

This interpretation is in agreement with the position of the ASMFC, which in 1998 concluded that the Delaware striped bass stock was restored to “historical population levels” (ASMFC, 1998).

The combination of (1) the strong evidence for density-dependent compensation in the east coast stock as a whole and in the Hudson River population striped bass, and (2) the resource agencies’ conclusions that Delaware River population of striped bass has reached a “rough upper bound” and has been restored to “historical population levels”, and (3) the fact that the Delaware stock rebuilt during a period in which Salem was fully operational, support the hypothesis that compensatory mechanisms in the Delaware Estuary striped bass population have largely ameliorated the effects of I&E at Salem. Therefore, by ignoring the effects of density-dependent compensation, USEPA has greatly overestimated the benefits of reductions in I&E losses of striped bass at Salem.

2. Compensation in Weakfish Population Inhabiting Delaware Bay

The 30th Stock Assessment Review Committee (“SARC”) Report (NMFS, 2000) documents increases in the abundance of the east coast stock of weakfish since the early 1990’s (Figure IV.A-3). The abundance of juvenile weakfish within Delaware estuary increased during that period also (see Appendices J and H of Salem’s 1999 Renewal Application). As was the case for striped bass, the first-year survival rate of weakfish (as measured by the ratio of the number of recruits to the spawning stock biomass) declined sharply while the spawning stock biomass increased (Figure IV.A-4). Again, this pattern is characteristic of the presence of strong density-dependent mortality. In the 30th SARC report, the authors stated that “the rapid rebuilding of the stock reflected high estimated compensatory reserve.”

Fishery management measures reduced fishing mortality on adult fish (NMFS 2000), and the stock responded with increases in spawning stock biomass. In response to the increased abundance of fish, first-year survival has declined, as would be expected in stocks that regulate their abundance through compensatory mortality. For weakfish the first-year survival rate in earlier years (again, when the stock had lower and more stable abundance) was over two times higher that it is under current conditions.

The combination of (1) the strong evidence for density-dependent compensation in the east coast stock of weakfish as a whole, and (2) the fact that the weakfish stock in the Delaware Estuary has increased in abundance concurrently with the east coast stock, and (3) the fact that the Delaware stock rebuilt during a period in which Salem was fully operational, support the hypothesis that compensatory mechanisms in the population of weakfish that inhabit Delaware Estuary have largely ameliorated the effects of I&E at Salem. Therefore (as is the case with striped bass), by ignoring the effects of density-dependent compensation, USEPA has greatly overestimated the benefits of reductions in I&E losses of weakfish at Salem.

Figure IV.A-1. Trend in spawning stock biomass of the east-coast stock of striped bass, showing increasing abundance since 1989. Data are from the Virtual Population Analysis presented in the August 1999 stock assessment report on striped bass prepared by the Atlantic States Marine Fisheries Commission (ASMFC, 1999).

Figure IV.A-2. Ratio of number of striped bass recruits (age-1 fish in January) to the spawning stock biomass (SSB) of striped bass that generated the recruits (i.e., SSB from the previous calendar year) as an index of first-year survival. Data are from the Virtual Population Analysis presented in the August 1999 stock assessment report on striped bass prepared by the Atlantic States Marine Fisheries Commission (ASMFC, 1999).

Figure IV.A-3. Trend in spawning stock biomass of the east-coast stock of weakfish, showing increasing abundance since the early 1990’s. Data are from the Virtual Population Analysis presented in the 30th Stock Assessment Review Committee report (NMFS, 2000).

Figure IV.A-4. Ratio of number of weakfish recruits (age-1 fish in January) to the spawning stock biomass (SSB) of weakfish that generated the recruits (i.e., SSB from the previous calendar year) as an index of first-year survival. Data are from the Virtual Population Analysis presented in the 30th Stock Assessment Review Committee report (NMFS, 2000)

[see hard copy for figures]

EPA Response

This comment refers to Chapter A6 of the Case Study Document (DCN #6-0003) presented at proposal. This material was not included in EPA's final analysis. Nonetheless, EPA has responded to respond to the issues raised by the commenter in responses to Comment 316bEFR.005.009 on fish population modeling, Comment 316bEFR.025.015 on compensation, and Comment 316bEFR.005.026 on the term "precautionary approach." EPA notes that even if there is indisputable evidence for compensation in striped bass and weakfish stocks, these are only two of the hundreds of species that are impinged and entrained nation-wide. EPA reminds the commenter that the goal of EPA's analysis was to develop an estimate of the magnitude of I&E throughout the country, not just for a few managed fish stocks. Moreover, EPA notes that managed fish stocks account for less than 2 percent of impinged and entrained species.

Monitoring requirements

USEPA Has Substantially Underestimated The Costs Associated With Its Proposed Monitoring And Application Requirements Based On Site-Specific Work PSEG Has Conducted

Under USEPA's Preferred Option, an owner/operator of a Phase II existing facility would be required to provide substantial information when applying for renewal of a NPDES permit. <FN 176> USEPA provides estimated costs for the sequence of requirements in its "Economic and Benefits Analysis for the Proposed Section 316(b) Phase II Rule". The stated "costs of initial post-promulgation NPDES Permit application activities" for estuaries and tidal rivers is $1,363,863 (Table B1-2); the "cost of NPDES renewal application activities" is $51,054 (Table B1-3); and, the stated "cost of annual monitoring, record keeping, and reporting activities" is $109,734 (Table B1-4) or $78,300. <FN 177> While USEPA has made laudable attempts to revise program cost elements from its initial estimates in the "National Pollution Discharge Elimination System; Cooling Water Intake Structures for New Facilities; Proposed Rules" <FN 178> the above costs should be considered a minimum. Moreover, if there is a potential that the permit would be adjudicated, it is certain that the costs would be substantially higher.

177 TDD Section 2.3

178 65 Fed. Reg. 49060

EPA Response

EPA believes that the cost estimates are representative and have not been "substantially underestimated." Cost details and assumptions have been provided with all estimates. EPA recognizes that overall actual costs may be higher or lower that those estimates presented based on particular local circumstances, and also recognizes that adjudication of a permit may result in cost increases.

Monitoring requirements

The applicant, under proposed Section 125.95 would be required to provide a “comprehensive demonstration study” which “…must be appropriate for a quantitative survey…” for impingement, entrainment, and the source waterbody. In addition, the study must include the “…collection of a sufficient number of years of data to characterize annual, seasonal, and diel variations…”. Also, the studies would have to be designed to compile data for eggs, larvae, post larvae, juveniles, and adults for both fish and shellfish. Finally, USEPA stresses throughout the preamble the need for adequate QA/QC for permit-associated programs. <FN 179> Implementation of these program requirements can be quite costly but are necessary if one wants to have a scientifically credible and defensible program.

USEPA appropriately acknowledges the site-specific nature of Section 316(b) studies as detailed in the “facility examples” <FN 180> and the Case Studies. However, difficulties in trying to utilize data from studies conducted in the 1970s and 1980s (due to inconsistencies among sites) for developing a national rule are also discussed. Regardless, it is stated that “…[r]ecent advances in environmental assessment techniques provide new and in some cases better tools for monitoring impingement and entrainment and detecting impacts associated with the operation of cooling water intake structures…” <FN 181>. These very “advances” contribute greatly to the program costs.

In circumstances where existing data are not sufficient and new or additional sampling must be done, the sampling program must be tailored to the site. In tidal rivers and estuaries complex hydrodynamics and water quality conditions might require more intensive sampling to characterize aquatic organisms likely to be in the vicinity of the intake. USEPA, of course, could promote a consistent process for such studies through guidance.

Source water physical data

Author Name Maureen F. Vaskis & Mark F. Strickland
Organization PSEG Services Corporation, Ofc of Environmental Counsel

Considerations Regarding Source Water Sampling in the Vicinity of the Facility

According to the Proposed Rule, information on occurrence, abundance, and types of organisms in the vicinity of the facility must be provided on (1) fish eggs, larvae, and post-larvae; (2) juvenile and adult fish; and (3) shellfish. This section discusses complexities and difficulties of collecting such data by life stage.

a. Eggs, Larvae and Post-Larvae

As acknowledged in the Preamble <FN 182> any assessment of the vulnerability of eggs, larvae, or post-larvae will depend on the duration of occurrence (i.e., how long are they at risk) and their abundance in the intake area (i.e., how many are at risk). Thus, to cover the duration of occurrence for most estuarine and freshwater species ichthyoplankton studies would need to last a minimum of three months (often May, June, and July), and more likely five (April through August).

The Proposed Rule suggests that sampling be performed in the vicinity of the CWIS without providing any perspective on what "in the vicinity of the CWIS" means. <FN 183> In circumstances where there is significant spatial variability of aquatic organisms, however, such an approach is shortsighted. The applicant and the permitting agency need to know whether the data collected near the CWIS are representative and whether any post-operational changes in abundance are due to the intake and not other factors. In fact, eggs and larvae at a particular location may have originated a considerable distance away and been transported to the intake by the flow of the river, or by near-shore currents or tides in estuarine and marine environments (PSEG 1999, Attachments C-1 to C-14). This transport of eggs and larvae must also be assessed if the desire is to accurately predict entrainment impacts. For example, the Empirical Transport Model ("ETM"), often used in CWIS impact assessments, employs this approach. In any case, it is clear that multiple locations are needed, not a single location near the intake as USEPA suggests. Larval abundance varies tremendously, with multiple peaks (usually corresponding to different species or cohorts) occurring over the course of the spawning period. Frequent sampling is necessary lest these peaks be missed and the abundance of key species (taxa) being seriously under- or over-estimated.

Finally, egg and larval density often vary horizontally (e.g., from one bank to the other or upstream and downstream), vertically (i.e., by depth in the water column), and on a diel (day/night) basis. If sampling is not stratified to account for these variables, the estimates of abundance, occurrence, and distribution may be erroneous.

b. Juvenile and Adult Fish

Movement of fish into or within a waterbody is common. Much of this movement is associated with spawning (e.g., striped bass, American shad, blueback herring), but movement related to water fluctuations, salinity, temperature preferences, and/or to overwintering locations is also common (e.g., white perch, Atlantic croaker, salmonids, shiners). Thus, any survey designed to assess the vulnerability of fishes to impingement must be conducted at least seasonally. Multiple sets of sampling gear would be needed to sample the target fish populations adequately.

The Proposed Rule would require that quantitative data be collected. However, information about species population size is rarely available. Without such estimates, it would be difficult to assess AEI or design well-calibrated BTA technologies that are not simply over-conservative. Thus, intensive sampling programs may be necessary to estimate population size and the level of effort would increase considerably above what USEPA has estimated.

c. Shellfish

In the Delaware Estuary, decapods (e.g., blue crabs) and other shellfish have seasonal migrations that can bring them near cooling water intakes. Thus sampling may need to be expanded to include appropriate methods for capturing adult or larval movements.

183 67 Fed. Reg. 17175 § VII A

EPA Response

EPA recognizes the inherent complexities of source water sampling. Specific study parameters may be proposed by the facility in the Proposal for Information Collection for review and approval by the Director. However, the Director will have the final determination on all study parameters including defining the phrases "in the vicinity of" and "the hydrological zone of influence" as necessary to ensure that potentially impacted species are adequately represented.

Today's final rule requires that monitoring be conducted in accordance with the verification monitoring plan (125.95(b)(7), the Technology Installation and Operation Plan (125.95(b)(4)(ii)), if selected, and, if applicable, the Restoration Plan required at 125.95(b)(5). The Director may consider additional monitoring requirements as well.

Monitoring requirements

USEPA's Proposed Minimum Sampling Frequencies and Spatio-Temporal Extents of Monitoring Are Likely To Be Unacceptable And Suggest Unrealistically Low Monitoring Costs

The accuracy of the data will be critical, since they will be used to determine compliance with performance standards under USEPA's Preferred Option or to calculate the potential for AEI and whether further mitigative measures or technologies must be used. The data will also be the benchmark against which future performance is measured, and they may serve as the mechanism for approving or denying a permit, either initially or during a later renewal period. The need for increased precision and accuracy will lead to significant costs.

USEPA has expressed concern with the review of applications being too burdensome for regulatory staff <FN 184> and the cost of litigation being too high. <FN 185> However, PSEG believes that any proposed "Comprehensive Demonstration Study" that does not adequately sample impingement, entrainment, and the populations of fish and shellfish in the source water will result in increased regulatory burden and increased costs associated with litigation.

Given the importance of the data in determining initial and potentially future permit requirements, facility owners will likely feel that a bare minimum program would not be adequate to protect against an erroneous decision regarding adverse environmental impact. Biological populations do not exist in a time and space vacuum. USEPA's approach of looking at a single location near the proposed CWIS will be, in most cases, inadequate to establish a proper baseline. Because of the need to assess more locations, often at greater frequency than suggested, the cost of doing a NPDES Phase II I&E Study that characterizes the "species of fish and shellfish and life stages, including a description of the abundance and temporal /spatial characteristics in the vicinity of the CWIS…" <FN 186> could be much larger than USEPA supposes.

It is important when setting monitoring requirements that the monitoring study be intensive enough to provide useful information, yet not so intensive that the program is unnecessarily costly or time-consuming. The sampling frequencies of once monthly for impingement and biweekly for entrainment during specified periods (Section B1-1.3.c. - EBA) may not, in certain locations, provide enough data for comparing entrainment and impingement levels across years or for determining whether AEI is occurring under a site-specific approach. For example, at the Salem Station the minimum program required to produce useful data for a Comprehensive Demonstration Study <FN 187> is weekly (with seasonally variable within-week frequencies, i.e. number of days/week and number of samples/day) for both entrainment and impingement monitoring. Thus the USEPA estimate of the cost to conduct monitoring of entrainment and impingement is extremely low for estuaries based on PSEG's experience in the Delaware, Arthur Kill, and Hackensack River.

An accurate estimate for costs to conduct the proposed monitoring can be obtained by reviewing costs for on-going monitoring programs. PSEG has conducted monitoring on estuaries for more than 30 years. PSEG believes that the proposed costs and scope of monitoring severely underestimate the effort necessary to adequately represent the potential losses and the associated portions of the populations within an estuary. Two recently completed Section 316(b) Demonstrations for two fossil-powered facilities cost about $650,000 to $750,000 for the development, implementation, and reporting associated with the reports. The following table is a summary of the scope of different monitoring components and associated costs for estuarine monitoring conducted between 1998 and 2000:

SUMMARY OF PSEG'S ESTUARINE MONITORING COSTS <FN 188>
[see hard copy for table]

PSEG believes that the data quality objectives and the nature of the monitoring programs, as well as application requirements, will be highly site-specific based on the experience of performing similar programs in the Delaware Estuary, the Arthur Kill, and Hackensack River over the past 30 years. To adequately characterize the uncertainty associated with the cost of monitoring, PSEG suggests that USEPA consider a range of costs in assessing this component of the Proposed Phase II Rule.

EPA Response

In the Comprehensive Demonstration Study, the facility owner or operator will: characterize the impingement mortality and entrainment due to the cooling water intake structure; describe the nature and operation of the intake structure; and describe the nature and performance levels of the existing technologies, operational measures, and restoration measures for mitigating impingement and entrainment impacts.
For a discussion of monitoring and compliance, see EPA's response to comment 316b.EFR.074.023. EPA
recognizes that increased frequencies and duration of sampling may be necessary in some regions to fulfill the data requirements of the demonstration study. EPA agrees with the comment that, "It is important when setting monitoring requirements that the monitoring study be intensive enough to provide useful information, yet not so intensive that the program is unnecessarily costly or time-consuming." EPA does not agree that the cost estimates presented for monitoring are "unrealistically low." The cost estimates are representative, and cost details and assumptions have been provided with all estimates. EPA recognizes that overall actual costs may be higher or lower that those estimates presented based on particular local circumstances, and the availability of existing data (i.e., existing data that adequately reflects current conditions at the facility and in the source waterbody).

Source water physical data

The Need For Source-Water Monitoring Is Inconsistent With USEPA's Proposed Performance Standards

USEPA has proposed to rely on criteria utilizing percentage reductions of impingement survival and numbers of entrained organisms. If this is the benchmark to be met to receive a determination that an intake qualifies as BTA, permittees should only be required to conduct those studies that directly measure the efficiencies of any intake modification. There is no reason therefore to provide a comprehensive demonstration study that would characterize the source waterbody. The permittee would only need to characterize the base case I&E losses and those losses that result from improved intake technology. In fact, if one wished to follow this through to conclusion, once a demonstration of the efficiency of the reduction of impingement mortality and numbers of entrained organisms has been made, no further monitoring should be required.

EPA Response

EPA disagrees that there is no need to characterize the source waterbody, conduct monitoring, and prepare a comprehensive demonstration study (CDS). These data are needed by the Director to evaluate the type of waterbody and species potentially affected by the cooling water intake structure and determine the appropriate performance requirements. Certainly, not all facilities will need to conduct all components of the CDS (e.g., the approved technology option only requires that the verification monitoring plan be submitted and facilities that have reduced flow commensurate with closed cycle cooling systems are exempt from CDS requirements entirely). Monitoring is required to ensure that the installed design and construction technology, operational measure, and/or restoration measure is (are) effective. Monitoring requirements may be reduced at the discretion of the Director as well as CDS requirements based on the use of existing relevant data. In some cases, the Director may deem that no further monitoring is required if a demonstration has been made that the technology is effective and successfully reducing impingement mortality and entrainment.

Documented facility examples of CWIS impacts

USEPA's Preamble Includes Errors or Inaccuracies Concerning PSEG'S Salem Station

PSEG believes the USEPA should correct the following errors or inaccuracies in the Proposed Phase II Rule as it relates to PSEG facilities.

1. The Information Concerning Modifications to the Salem CWIS are Inaccurate and Should be Corrected

The preamble of the Proposed Phase II Rule describes PSEG's Salem Generating Station as follows:

Salem Generating Station. A 2381 MW facility (nameplate, nuclear), Salem is located on the Delaware River in Lower Alloways Creek Township, New Jersey. The facility has two generating units, both of which use once-through cooling and began operations in 1977. In 1995, the facility installed modified Ristroph screens and a low-pressure spray wash with a fish return system. The facility also redesigned the fish return troughs to reduce fish trauma. <FN 189>

The Salem Units 1 and 2 each have a nameplate rating of 1162 MW for a total of 2324 MW. Salem Unit 1 began operation in 1977 and Salem Unit 2 began operation in 1981. Unit 1 was retrofitted to incorporate Ristroph vertical traveling screens in 1979 and Unit 2 became operational with Ristroph vertical traveling screens installed. These Ristroph vertical traveling screens were supported by a low-pressure spray wash system and a fish return system. In 1995, the CWIS was improved with redesigned Ristroph vertical traveling screens and an enhanced spray wash system, and the fish return troughs were redesigned to improve fish survivability. PSEG requests USEPA note the corrected information in its Response to Comments.

2. The Information Concerning the Timeline for Salem's Permit Renewal are Inaccurate and Should be Corrected and the NJDEP Burden was not Disproportionate for Reviewing the Salem Permit Application

The preamble states that PSEG's Salem Generating Station filed its application for a CWA permit in 1994 and the NJDEP made its decision in 2001. <FN 190> This information is inaccurate. PSEG filed a supplemental application for the renewal of Salem's NJPDES Permit in March 1993. NJDEP issued as draft permit in June of that year. At the request of interested third parties, including an affected state, the comment period was extended until mid-January of 1994. The NJDEP issued a permit effective September 1, 1994 to Salem Generating Station. On March 4, 1999, PSEG filed a renewal application for the 1994 permit as required. The NJDEP hired a consultant to review the application and issued a draft permit on December 8, 2000, with a public comment period extending through mid-March 2001. On June 29, 2001, NJDEP issued a renewal permit with an effective date of August 1, 2001.

USEPA did not provide a burden estimate for the NJDEP to review the 1999 application but requested comment. In addition to the normal fees paid in accordance with the NJDEP regulations, <FN 191> PSEG paid an additional $200,000 to defray the costs of the contractor NJDEP hired. The activities conducted by PSEG during the permit period (1994 - 1999) and the results of those activities were explained in the application that was reviewed by NJDEP and their contractor. Those activities and the monitoring of their results were performed by PSEG at a cost in excess of $100 million dollars. The burden on NJDEP to review those activities and the results of those activities, to ensure the societal and environmental needs were being met, could only be a small fraction of the burden on PSEG.

Salem

PSEG COMMENTS ON USEPA'S DELAWARE ESTUARY CASE STUDY ANALYSIS

A. Introduction

PSEG's comments on USEPA's Delaware Estuary Case Study Analysis ("CSA") focuses on information regarding PSEG's Salem Generating Station ("Salem"), which formed the bases for the CSA. The loss portion of the CSA was prepared by Stratus Consulting ("Stratus") and the economic evaluation of these losses was prepared by ABT Associates, Inc. ("ABT") (collectively, the "CSA Consultants"). PSEG's comments are organized into seven sections. Section B addresses PSEG's concern that the CSA Chapter B3 contains misleading information on Salem's I&E estimates. Section C contains a summary of PSEG's critique (see Attachment 3, report by D.G. Heimbuch, Ph.D.) of the CSA Consultants' I&E loss estimates for Salem. Section D contains a summary of PSEG's critique (see Attachment 4, report by D. Harrison, Ph.D.) of the CSA Consultants' estimates of the economic value of Salem's I&E losses. Section E addresses PSEG's concern that the CSA Consultants' characterization of biases and uncertainties (in the CSA Consultants' estimates of benefits from reducing I&E losses) is biased and misleading. Section F identifies some factual errors regarding Salem in the CSA. Section G addresses PSEG's concern that the CSA ignored critical information. Section H addresses PSEG's concern that comments made by the CSA Consultants in the CSA and EBA regarding I&E loss estimates in general are not applicable to Salem.

B. USEPA's Discussion of Salem's I&E Data (CSA Chapter B3) is Misleading

In Sections B3-3.1 and B3-3.2, CSA Consultants provided objective summaries of Salem I&E loss estimation methods. However, the CSA Consultants' comments on the quality of PSEG's I&E estimates, which are presented in section B3-3.3, are inaccurate, misleading and one-sided.

In section B3-3.3 ("Potential Biases and Uncertainties in PSEG's I&E Estimates") of CSA, the CSA Consultants alleged that PSEG's I&E loss estimates for Salem were biased. The CSA Consultants supported their claim by referring to the review of the 1999 Application that was conducted by ESSA Technologies LTD ("ESSA") under contract to NJDEP. PSEG refutes the CSA Consultants claim that PSEG's I&E estimates are biased, and notes that the CSA Consultants presented one-sided and misleading summaries of parts of ESSA's report and chose not to refer to PSEG's response to ESSA's report on several important topics, although PSEG provided it to USEPA in April 2001.

On page B3-25, the CSA Consultants stated that:

"ESSA Technologies (2000) identified several aspects of PSEG's sampling program that increased data uncertainties and introduced bias in PSEG's I&E estimates, and USEPA shares these concerns." (page B3-25)

This statement is incomplete and therefore very misleading. The CSA Consultants failed to acknowledge ESSA's general conclusion regarding PSEG's use of the data from its sampling programs (which, as the CSA Consultants did correctly note on page B3-21, have created "one of the most comprehensive I&E data sets in the nation"):

"The methods employed for interpolation / extrapolation of data are reasonable and generally conservative. Weaknesses in the data are explicitly acknowledged and various adjustments or correction coefficients have been developed and applied to attempt to correct for known biases." (ESSA 2000, Section 2.1.1. Sampling and Estimation of Entrainment Losses).

On page B3-26, the CSA Consultants continued the misleading characterizations of PSEG's I&E loss estimates:

"ESSA Technologies (2000) expressed concern that the sampling changes necessitated the use of numerous adjustment factors that may have biased I&E estimates. Many adjustments appeared to be biased low, which would result in an underestimate of losses. For example, ESSA Technologies argued that PSEG may have underestimated the latent screen mortality of impinged organisms because they did not consider the high velocity and turbulence of exit flume waters in their estimate."

ESSA did not argue that flume turbulence and velocity caused estimates of latent impingement mortality to be underestimated. Rather, ESSA concluded that it could not determine whether PSEG's estimates were too high, accurate or too low:

"The central issue here is that the initial and latent mortality rates estimated via the sampling pool and holding tanks are quite likely not representative of the actual mortality rates of fish after they have been returned to the Delaware River. It is possible that the mortality rates measured using the sampling pool overestimate actual impingement mortality. It is also possible that actual mortality rates of fish after returning to the Delaware River are equivalent or even higher than those estimated via the sampling pool." (ESSA, 2000, Section 2.2.2.3 Impingement Mortality).

Therefore using USEPA's definitions of uncertainty and bias ("Bias refers to a potential error in which the direction of error is known (i.e., an under- or overestimate), whereas uncertainty refers to a potential error with no known directional bias"), ESSA's conclusion was that PSEG's impingement mortality rate estimates contained uncertainty, not that the impingement mortality rates were biased.

The CSA Consultants continued their misleading references to the ESSA report when on page B3-26 they addressed entrainment survival rates used in the PSEG entrainment estimates:

"ESSA Technologies (2000) also found that PSEG may have substantially underestimated entrainment mortality by assuming only moderate rates of mortality as organisms pass through the plant."

and on page B3-33 it stated:

"As discussed in Section B3-3.3, an independent review of Salem's 1999 Application by scientists with ESSA Technologies, Ltd (2000) concluded that Salem's entrainment rates were most likely underestimated by PSEG because their entrainment calculations assumed substantial through-plant survival of entrained organisms. USEPA concurs with ESSA that Salem's 1999 Applications provides inadequate justification of PSEG's assumptions about through-plant survival, and therefore, USEPA recalculated Salem's entrainment without the thermal and mechanical mortality factors used by PSEG for its calculations (see Appendix B1 for the species-specific thermal and mechanical mortality factors used by PSEG)."

As shown in the following quote, ESSA did not conclude that "Salem's entrainment rates were most likely underestimated by PSEG", nor did ESSA conclude that "Salem's 1999 Applications provides inadequate justification" as alleged by the CSA Consultants. Rather ESSA recommended that a 100% entrainment mortality rate be used as an upper bound together with PSEG's estimates in an uncertainty analysis:

"The approach taken to the estimation of losses separates through-station mortality into thermal, chemical and mechanical components. Estimates of mechanical mortality are based on studies in which larvae were held either in jars or aquaria. The detailed description of the protocol is given in Appendix F Attachment 1 Section II.C Survival. While the study protocol provides information on the survival of larvae due to mechanical damage alone, i.e., the physical damage, which alone is sufficient to cause death, the in vitro environment does not reflect the rigors faced by the larvae on exiting the discharge. Consequently it is difficult, if not impossible, to know if the station has an incremental effect on post-discharge mortality beyond that strictly attributable to death from direct mechanical damage observed in the in vitro study environment. A conservative approach to addressing this uncertainty would be to conduct the analysis with an assumed 100% mortality rate for all life stages and use this as an upper bound together with the current estimates in an uncertainty analysis of station effects." (ESSA 2.1.1 Sampling and Estimation of Entrainment Losses).

The CSA Consultants also cited (page B3-26) an untested hypothesis from ESSA (which, as noted below PSEG has completely refuted) as being additional support for the CSA Consultants claim that PSEG's entrainment estimates are biased:

"In addition, certain geographic features near Salem may have caused a large back eddy which would cause different flow dynamics depending on tidal cycle, and result in episodic entrainment patterns that might not have been captured by the sampling program."

PSEG refuted this speculation by ESSA in PSEG's response to ESSA's report (PSEG, 2001). In its response, PSEG cited four hydrodynamic studies, the data and analyses from which disproved ESSA's hypothesis. It is not clear why the CSA Consultants ignored this information in their discussion of the ESSA hypothesis, since USEPA was aware of this information. In fact, USEPA listed PSEG's response to ESSA's report in its list of references to the CSA reports, and cites portions of PSEG's response to the ESSA report elsewhere in Chapter B3 of the CSA.

In addition, PSEG recently submitted to NJDEP (as part of its 2001 Permit requirements) a report entitled "Study of the Hydrodynamics at the Intake of the Station" (PSEG, 2002) which concluded:

"In summary, PSEG has completed extensive field data collection and modeling related to hydrodynamics in the vicinity of the Station, including the intake basin and Sunken Ship Cove. PSEG has found that the circulation patterns in this region are highly complex, including large-scale, dynamic, eddy-type motions during the change of the tide as well as small-scale turbulent fluctuations. Analysis has shown that the concept of a strong back eddy being formed within Sunken

Ship Cove on the ebb tide is not possible. The prevailing tidal conditions in the Estuary are too dynamic, and they cause a near constant change in the flow patterns. Finally, the larger scale eddies that can occur during the change of the tides south of the Station are generally swept offshore, and do not interact directly with the CWIS."

In reference to the natural mortality rates used by PSEG in its estimates of age-1 equivalents and yield-per-recruit, the CSA Consultants incorrectly stated (page B3-26) that:

"Relative to published values, PSEG's adjusted rates are higher for 10 species, lower for 11 species, and within the range of measured values for 7 species (PSEG, 2001 b, c)."

In fact, in PSEG's response to the ESSA report (PSEG, 2001) it was noted that of 28 natural mortality rates (for multiple life stages of 9 species, not 28 species) 11 rates were lower, 10 were higher and 7 were within the reported range. Furthermore, in the next sentence of PSEG's report, it is noted that ESSA conducted a sensitivity analysis and concluded that in most cases substituting the un-adjusted rates for PSEG's adjusted rates decreased the estimates of yield lost to the fishery.

In section B3-5 (Salem's Annual Entrainment), the CSA Consultants commented on the degree of inter-annual variability in entrainment losses at Salem, and by innuendo, speculated that high CWIS flow rates at Salem in 1998 were the likely cause of unusually high entrainment losses (page B3-33):

"In 1998, exceptionally high numbers of alewife were entrained, over 16 million, compared to a mean of about 1.2 million for the period. In 1995 and 1998, unusually high entrainment of Atlantic menhaden occurred, reaching about 180 million compared to a mean of 20.8 million. Similarly, in 1998 blueback herring entrainment was over 66 million compared to a mean of about 5.2 million, striped bass entrainment was about 537 million compared to a mean of 39.7 million, and white perch entrainment was nearly 416 million compared to at mean of 42.6 million. Of note is that Salem's intake flow in 1998 was substantially higher than other years and close to the level of use projected by the facility over the next permit cycle."

The CSA Consultants failed to mention that freshwater flow in the Delaware River in May and June of 1998 was unusually high. The U.S. Geological Survey (http://waterdata.usgs.gov/nwis/) reported the average (over 89 years of data) daily flow rate for the Delaware River at Trenton, N.J. for days in May to range from 12,400 cfs to 15,930 cfs, and for days in June to range from 7,255 cfs to 12,200 cfs. In contrast, reported daily flow rates for 1998 exceeded 65,000 cfs in May, and exceeded 35,000 cfs in June.

High freshwater flow rates in the Delaware River have the potential to increase the entrainment vulnerability of some fish species that spawn upriver of Salem. As noted in Appendices C and H of the Application (listed in USEPA's references) alewife, blueback herring, striped bass, and white perch all spawn upriver of Salem (typically in May and June). Furthermore, entrainment of eggs and larvae of these species at Salem in 1998 occurred between late April and late June. Therefore, the unusually high freshwater flow events in late spring of 1998 likely transported entrainable life stages of alewife, blueback herring, striped bass, and white perch downriver towards Salem.

If the CSA Consultants needed to identify a cause for the unusually high entrainment losses in 1998, they should have considered a range of plausible alternatives (e.g., including hydrodynamic conditions) and discussed each. Instead, by mentioning only one possibility (i.e., Salem intake flows), the CSA Consultants implied that Salem intake flows were the cause of the unusually high entrainment losses in 1998. This assertion has no scientific basis and ignores the relevant facts.

C. USEPA's I&E Loss Estimates for Salem are Flawed

This section of PSEG's comments contains a summary of PSEG's report (prepared by D.G. Heimbuch, Ph.D.) that critiques the CSA Consultants' estimates of I&E losses at Salem (see Attachment 3). Because the CSA Consultants attributed over 98% of the estimate of economic losses due to I&E losses at Salem to the effects of entrainment, PSEG's critique of the CSA Consultants I&E loss estimates for Salem focuses on entrainment losses.

1. Background

Estimates of economic losses due to entrainment that are presented in CSA Table B4-16 are the sum of estimates of economic losses to the commercial fishery, the recreational fishery, and estimates of economic losses attributable to the loss of non-use values and to lost forage (see CSA Table B4-15). The CSA Consultants estimates of the economic losses to the commercial fishery are based on these estimates of the yield lost to the commercial fishery (in pounds) and the commercial value of a pound of fish (see CSA Table B4-9). The CSA Consultants estimates of the economic losses to the recreational fishery are based on their estimates of the reduction in recreational catch and the recreational value of the catch of an additional fish (see CSA Table B4-7). The CSA Consultants' estimates of the loss of non-use values are based on their estimates of the economic losses to the recreational fishery (and hence on its estimates of the reduction in recreational catch). The CSA Consultants' estimates of the economic losses attributable to lost forage are based on their estimates of (1) forage production foregone (in pounds) and (2) the economic value ($ per pound) of forage(see CSA Table B4-12 and B4-14). <FN 192>

The biological parameters that the CSA Consultants used as direct inputs to its economic assessment for Salem were its estimates of yield lost to the fishery (see CSA Table B4-3 and Table B3-16, reduction in catch (see CSA Table B4-3), and production foregone (see CSA Table B3-17). based its estimates of reduction in catch on its estimates of yield lost to the fishery and the average weight of fish caught by the fishery. The CSA Consultants' estimates of yield lost to the fishery are the product of its estimates of age-1 equivalents (see CSA Table B3-15) and its estimates of yield per recruit (i.e., yield per age-1 fish).

For these reasons, PSEG's review of Stratus' loss estimates focused on Stratus' methods and estimates of age-1 equivalents, yield per recruit, and production foregone.

2. Summary of Findings from PSEG's Review

This review of Stratus' methods for estimating yield foregone and production foregone due to entrainment at Salem identified several serious errors in these methods that cause USEPA's estimates to be biased high.

a. USEPA's Estimates of Yield Lost to the Fishery are Biased High

Stratus' estimates of yield foregone (which is the product of the number of age-1 equivalent fish and the yield per recruit) are flawed because they (1) incorrectly omitted the effects of entrainment survival on life stage-specific loss estimates and (2) used overestimates of juvenile survival (from the date of entrainment to the end of the juvenile life stage) in its estimates of age-1 equivalents.

Stratus' justification for omitting the effects of entrainment survival was that: "Salem's entrainment survival factors were eliminated for all analyses (Tables B37 through B3-10) because USEPA found insufficient justification in Salem's 1999 Application for their use." (CSA page B3-27) By incorrectly assuming no entrained fish survive (see EPRI [2000] for a review of many studies that demonstrated the presence of entrainment survival), Stratus overestimated entrainment losses at Salem. Stratus also incorrectly assumed that juvenile entrainment occurs in the middle of the juvenile lifestage; whereas entrainment data indicate that juvenile entrainment generally occurs at the beginning of the lifestage. By assuming entrainment occurs later than it actually does, Stratus overestimated the survival rate from the date of entrainment to age-1, and thereby overestimated the number of age-1 equivalents.

The cumulative effect of these errors generally was to cause Stratus' estimates of age-1 equivalents (and hence yield foregone) to be biased high. For weakfish, striped bass, Atlantic croaker and spot (the four species examined in the Application that had the highest estimates of yield foregone), Stratus' estimates were 54%, 119%, 454% and 536%, respectively, higher than PSEG's estimates (which accounted for entrainment survival and the fact that juvenile entrainment generally occurs early in the life stage <FN 193>).

b. USEPA's Estimates of Production Foregone are Biased High

Stratus' estimates of production foregone are flawed because their (1) incorrectly applied the formula for computing production foregone (from Rago, 1984), (2) used invalid estimates (based on its extrapolation method) of average life stage–specific weights of age-0 fish, (3) incorrectly applied the formula for computing growth rates from initial weights of fish in successive life stages, and (4) derived invalid estimates of growth rates based on its invalid estimates of average lifestage-specific weights of age-0 fish.

Stratus attempted to use the method developed by Rago (1984) to estimate production foregone. However, Stratusmisapplied Rago's mathematical formulations (by using the average weight for each lifestage rather than the initial weight of each lifestage) which caused its estimates to be biased high. Stratus also extrapolated the average weight of fish at age-1 to produce its lifestage-specific estimates of average weight of age-0 fish. Its extrapolation method was not biologically meaningful and produced estimates of average fish weights that were unrealistically high. Then they estimated lifestage-specific growth rates for age-0 fish (required inputs to the production foregone model) based on its invalid extrapolated average weight estimates. The resulting growth rate estimates were invalid because (1) initial weights for each lifestage were required (rather than average weights) for the method Stratus employed and (2) Stratus used its invalid extrapolated average weights as inputs.

The cumulative effect of these errors for bay anchovy and non-RIS forage species was to cause Stratus' estimates of production foregone to be biased high. For bay anchovy, Stratus' estimate was 1016% higher that it would have been without these errors, and for non-RIS forage, USEPA's estimate was 1297% higher than it would have been.

D. USEPA's Assessment of the Economic Value of I&E Losses at Salem is Flawed

This section of PSEG's comments contains a summary of PSEG's report (prepared by D. Harrison, Ph.D.) that critiques USEPA's estimates of the economic value of I&E losses (see Attachment 4). Section 1 below provides an overview of PSEG's review. Sections 2 through 5 address the methods the CSA Consultants used in the economic assessment of losses to the commercial fishery, losses to the recreational fishery, non-use value, and production foregone, respectively. Section 6 provides summary recommendations.

1. Overview

Although the CSA Consultants' overall economic approach to benefit estimation is sound - they use an "effect by effect" approach that develops total benefits as the sum of individual components - many of the methodologies and data the CSA Consultants uses to develop the individual components have major flaws that make them inadequate bases for national benefit estimates and inadequate guides for evaluating individual benefit-cost assessments. Many of the methodologies and applications are inconsistent with USEPA's recent guidelines for preparing economic analyses (USEPA 2000), with the Office of Management and Budget's ("OMB") guidelines for economic assessments (OMB 2000), and with basic economic textbooks on environmental benefit assessment (e.g., Freeman 1993).

To summarize, we find the following:

1. The CSA Consultants' commercial benefit estimates are substantially overstated because of mischaracterizations of the empirical studies used in the assessment.

2. The CSA Consultants' recreational benefit estimates are suspect because of use of an overly simple benefit transfer method and a flawed Random Utility Model ("RUM") study.

3. The CSA Consultants' nonuse benefits have no conceptual or empirical support.

4. The CSA Consultants' forage fish benefits are overstated by including a flawed methodology - the replacement cost approach - as one of the two methods.

The CSA Consultants' estimate of commercial losses account for a substantial majority of the overall estimated economic losses from I&E, representing about 64 percent of the total. Recreational losses are the next largest category, at 24 percent. Forage fish losses account for a very small percentage (0.1 percent) of total losses, and nonuse losses account for the remainder of the CSA Consultants' estimate.

2. USEPA's Commercial Benefit Estimates Are Substantially Overstated Because of Mischaracterizations of the Empirical Studies Used in the Assessment

Benefits due to projected increases in commercial catch represent the largest of the four categories, accounting for about 64 percent of overall benefits in the Delaware Case Study. The CSA Consultants' calculates commercial benefits by first using ex vessel prices and added catch for the various commercial species to determine the added gross revenues to commercial fishermen. Citing various empirical studies, the CSA Consultants then argue that the added producer surplus represents 40 percent to 70 percent of gross revenues; using this approach, the mid-range value is 55 percent (i.e., gross revenues are multiplied by 0.55). Citing two other studies as well as a personal communication, the CSA Consultants claim that producer surplus represents 22 percent of the total "multi-market" welfare - including producers, wholesalers, processors, retailers and consumers - and thus that the producer surplus estimates should be multiplied by 4.5 to obtain an estimate of "total surplus." The net result is that the CSA Consultants' estimate of commercial fishing benefits is equal to about 2.5 times the added gross revenues to commercial fishermen (0.55 x 4.5 = 2.48).

a. USEPA's ex vessel commercial fish values can be confirmed

The CSA Consultants' estimates of the ex vessel values appear to be reliable. The values, which range from $0.11 per pound for Alewife to $3.18 per pound for Striped Bass, appear to be accurate estimates of the average values for ex vessel prices in New Jersey and Delaware. Although the range of certain species suggests that affected fish would be caught in other areas, these state values are representative. Note that this use of prevailing ex vessel prices assumes that I&E at Salem - and the other in-scope facilities - does not affect the market prices of commercial fish. This assumption seems sensible in light of the large overall market for fish; note however, that the CSA Consultants' use of the 4.5 multiplier contradicts this assumption by implying a substantial change in price.

b. USEPA's estimates of producer surplus benefits (mid-range equal to 55 percent of gross fishing revenues) are not supported in the literature that USEPA cites; this literature suggests a mid-range value of at most 15 percent of gross fishing revenues and likely one that would "tend toward zero"

The literature that the CSA Consultants cites does not support its estimates that Delaware fishermen would gain between 40 percent and 70 percent of the gross fishing revenues as additional producer surplus in the long run. It is well established in the economic literature (see, e.g., Freeman 1993) that in open access fisheries, there is a tendency for producer surplus to be driven to zero. This "tragedy of the commons" means that commercial fishermen would not receive any additional producer surplus from reduced I&E at Salem; all of the potential gains would be dissipated by additional fishing effort.

The studies that the CSA Consultants cites show substantial gains to fishermen, but these studies relate primarily to short-term gains that do not take into account the long-term factors that operate in commercial fisheries. Moreover, to the extent that the studies indicate some special circumstances that might mitigate these effects - such as entry restrictions - they relate to West Coast and Great Lakes fisheries rather than the East Coast. Indeed, the study that USEPA relies on for the "4.5 multiplier" (Norton et al. 1983) points out that producer surplus was in fact zero for fishermen in the southern part of the Atlantic fishery - net costs were equal to net revenues. Strand (2002), who is also one of the co-authors of Norton et al. (1983), notes that the study found the overall producer surplus for East Coast striped bass fishermen to be about 15 percent of gross revenues.

c. The studies cited by USEPA do not support the "multi-market" multiplier (4.5) used by USEPA to translate changes in producer surplus to fishermen into changes in total producer and consumer surplus

The "multi-market" multiplier of 4.5 is not supported in the studies cited. The only East Coast study cited is Norton et al. (1983), which reports information on the total surplus to retailers and consumers as well as the total surplus to commercial fishermen in the striped bass fishery. Although the ratio of these two values is 4.5, there is no indication in the report that it would be valid to use that ratio to estimate additional consumer and retailer surplus for changes in the fishery. Indeed, as Strand - one of the authors of the study - notes, this is "an extraordinarily odd procedure indeed," (Strand 2002).

The CSA Consultants claims that the multiplier of 4.5 also is derived from empirical work by Richard Bishop and others on the Great Lakes, including a draft report that is not available for distribution. The study that is available does not appear to include the specific empirical results cited by the CSA Consultants. In any event, these studies relate to the Great Lakes and thus are not relevant to the East Coast.

d. USEPA provides no evidence to support a claim that consumers would benefit from the changes in commercial catch through lower prices

Consumers could in theory gain from additional commercial fish made available through reduced I&E at Salem, but only if the changes were sufficient to affect the market price. The CSA Consultants has presented no information on the relevant market for commercial fish and the relative importance of I&E losses. Changes in I&E at Salem seem small relative to the volume of commercial fish in the East Coast fish markets, suggesting that there will not be a change in the market price and thus no consumer surplus gains from I&E changes.

e. Overall, the evidence suggests that mid-range commercial benefits are equal to 15 percent or less of gross fishing revenues, indicating that USEPA overstates the likely long-run economic benefits by at least a factor of 16

The available evidence on conditions in the East Coast suggests that the economic benefits - measured as producer and consumer surplus gains - will be small due to reduced I&E at Salem. Certainly, there is no conceptual or substantial empirical support for the claim that benefits would be equal to almost 2.5 times the value of the gross increase in revenues to fishermen. If gains to fishermen were 15 percent of the gross increase - as suggested by the one East Coast study noted by the CSA Consultants in their discussion of commercial benefits - the long-run benefits would be less than one-sixteenth of the value reported by USEPA in the Delaware Case Study.

3. USEPA's Recreational Benefit Estimates Are Suspect Because They Rely on an Overly Simple Benefit Transfer Method and a Flawed RUM Study

The CSA Consultants applied a benefit transfer approach to estimate recreational losses from several "representative important species" due to I&E at Salem and other in-scope and out-of-scope facilities in the Delaware Estuary. The CSA Consultants also developed a random utility model ("RUM") analysis of recreational fishing benefits from reduced I&E to estimate recreational losses associated with two species - weakfish and striped bass. The CSA Consultants comprehensive benefit estimate adopts the RUM estimates for weakfish and striped bass and the benefit transfer estimates for the other species.

a. USEPA's use of benefit transfer to value recreational fishing benefits is sound

Benefit transfer is an appropriate methodology for developing estimates of the potential recreational fishing benefits from changes in I&E at Salem or any other CWIS. As the USEPA Guidelines note,

"[t]he advantages of benefit transfer are clear. Original studies are time consuming and expensive; benefit transfer can reduce both the time and financial resources needed to develop benefit estimates" (U.S. USEPA 2000, p. 86).

Although the Delaware Case Study is not clear on precisely why the studies used for the benefit transfer were chosen or why others were not used, the four studies provide values for similar areas and species; all four studies relate to species affected by Salem I&E and to recreational fishing along the Atlantic coast.

b. USEPA uses an overly simple application of the benefit transfer method

Although the CSA Consultants' decision to use benefit transfer itself is sound, the technique the CSA Consultants' uses to transfer the benefits is not one that is recommended by USEPA Guidelines. The CSA Consultants' analysis for the Delaware Estuary Case Study applies a point estimation approach to transfer a range of values developed in the studies used in the policy case. The CSA Consultants uses this approach to develop a low and high estimate for each fish species.

The point estimation approach is not recommended by USEPA's Guidelines. As noted above, the Guidelines state, "As it is rare that a policy case and study case will be identical, this approach is not generally recommended." Despite the fact that this approach is not recommended, theDelaware Estuary Case Study fails to explain why it was selected, and whether other approaches were considered.

c. USEPA's RUM study has major flaws

The RUM method is well established as a methodology for evaluating recreational fishing benefits. Such models allow one to estimate the benefits of improving conditions in one fishery relative to other alternatives. It is important, however, that the studies use valid data on the nature of the choices, particularly on the differences in the travel costs to the alternative sites anglers might choose.

The RUM model developed by the CSA Consultants for the Delaware Case Study has substantial inadequacies that suggest that its results are not reliable estimates of the willingness to pay of recreational anglers for I&E changes at Salem. These inadequacies include the following:

-Employing unweighted intercept (angler) data. Over-representation of avid anglers results in biased estimates of the average value of improved fishing opportunities.

-Incorrectly calculating trip costs. Several assumptions bias trip costs upward and thus bias estimates of the value of improved fishing opportunities.

-Inappropriate modeling decisions. Modeling trips in a sequential manner - first the decision to recreate and then the selection of the recreation site - is inferior to modeling these as simultaneous choices.

4. USEPA's Nonuse Benefits Have No Conceptual or Empirical Support

Nonuse benefits represent potential benefits not associated with any direct use by individuals or humankind of the Delaware Estuary resources affected by Salem I&E. These benefits are sometimes referred to as passive use values or bequest values if they relate to future generations.

The CSA does not include an independent assessment of the potential nonuse benefits affected by Salem I&E. Instead, the CSA Consultants applied a "rule of thumb" that nonuse benefits would be equivalent to 50 percent of estimated recreational benefits. The CSA Consultants claims that this is a "long-standing" benefit transfer approach.

a. USEPA's 50 percent "rule of thumb" has no basis in the USEPA Guidelines or in the economic literature

This rule of thumb has neither conceptual nor empirical support as a valid measure of the willingness to pay of individuals for nonuse effects of I&E at Salem.

-The author of the original article discussing the "rule of thumb" refers to it as a "tenuous empirical basis from which to estimate national nonuser benefits" (Freeman 1979, p. 171). This author does not include the method in his comprehensive treatise on benefit assessment (Freeman 1993).

-Other authors have voiced similar criticisms. Fisher and Raucher (1984), for example, note that "[t]he proportional relationship [the 50 percent rule] is not in the least robust." (p. 47).

-Although some studies have calculated both use and nonuse values and compared the totals, these studies do not evaluate situations that are at all comparable to I&E in the Delaware.

Thus, the 50 percent rule is not appropriate as a benefit transfer approach to evaluating nonuser benefits for the CSA. <FN 194>

b. USEPA provides no empirical basis for a claim that changes in I&E at Delaware facilities would lead to any nonuse benefits

The CSA Consultants provides no information whatsoever on nonuser benefits that might be relevant for I&E on the Delaware. Indeed, the total discussion of nonuser benefits in the CSA (p. B4-11) is only one paragraph. This one-paragraph description is used to explain and justify annual benefits ranging from about $800,000 to $2.7 million per year.

c. Extensive empirical information on the status of the Delaware fishery suggests that there are no nonuse benefits

Although the CSA Consultants do not present any information related to nonuse benefits, there is extensive information on the environmental status of the Delaware Estuary that provides insight into the likely importance of this category. The existing literature on nonuse benefits suggests that nonuse values are likely to be significant under two conditions:

1. The resource is unique (e.g., the Grand Canyon); and

2. The losses to the resource are substantial and irreversible (e.g., damming the Grand Canyon).

Detailed studies on the status of the Delaware Estuary and the effects of I&E at Salem indicate that these conditions are not likely to be met for I&E at Salem:

-Historical data indicate a consistent and significant improving trend for growth in the stock of the major species affected by Salem I&E.

-Salem I&E has a negligible effect on the few fish species whose stocks have been declining recently.

-Even the declining stocks are not threatened to fall below key biological reference points.

-Any effects of Salem I&E could be reversed by various measures (e.g., curtailing commercial or recreational fishing).

This information suggests that the nonuse benefits associated with I&E at Salem are not significant. Any positive estimate for nonuse benefits should be based on an acceptable study of nonuse effects, consistent with USEPA's Guidelines (2000) and on current economic methods (e.g. Freeman 1993), rather than on a crude and inappropriate rule of thumb.

5. USEPA's Forage Fish Benefits are Overstated by Including a Flawed Methodology—the Replacement Cost Approach—as One of Two Methods

Forage fish refer to species that are not commercially or recreationally fished. These fish represent prey for other species that are commercially or recreationally fished, and thus provide potential indirect benefits if they increase the numbers of those fish. The CSA Consultants developed values for forage fish losses at Salem based on two approaches:

1. Production foregone value. The CSA Consultants estimated the value of the recreational and commercial species whose production would be changed as a result of changes in forage fish populations.

2. Replacement cost. The CSA Consultants estimated the cost of raising fish for stocking to replace the forage fish affected by I&E.

The values are somewhat higher using the replacement cost approach.

a. Additional forage fish lead to benefits to the extent that they increase commercial and recreational catch

Changes in forage fish populations can lead to benefits - in the form of additional consumer and producer surplus - if they increase the numbers of commercial and recreational fish. Thus, this is a valid benefit category for the Delaware Case Study. Forage fish represent an example of indirect ecosystem benefits - they provide services that do not directly benefit individuals but rather provide biological services required for services that do benefit individuals.

b. The production foregone method in theory could lead to valid benefit estimates

The production foregone method provides a valid methodology for evaluating the potential indirect benefits of forage fish changes. The validity of the calculations of course depends upon the accuracy of the scientific assessments of the linkages between changes in forage fish and changes in the populations of commercial and recreational species.

c. In contrast, the replacement cost method is not an economically valid benefit methodology

Replacement cost is not a valid method of assessing the benefits of changes in I&E at Salem (or anywhere else). The USEPA Guidelines provide an extensive list of acceptable benefit assessment methodologies; replacement cost is not among these methodologies, and for good reason.

Hatchery costs provide a measure of the costs of one potential alternative for improving fish populations - stocking additional forage fish. Such stocking may be a worthwhile exercise. But the costs do not provide a measure of the benefits. Indeed, accepting such an approach would make a mockery of benefit-cost analysis. If costs were used as a measure of benefits, the benefit-cost analysis would suggest all projects had a net benefit of zero.

E. USEPA's Characterization of Omissions, Biases and Uncertainties Contains Omissions and Is Biased

In CSA Chapter B7 (page B7-2) the CSA Consultants concluded that:

"Thus, on the whole, USEPA believes the estimates developed here underestimate the economic benefits of reducing I&E."

PSEG categorically disagrees with this conclusion and contends (as discussed below) that the CSA Consultants have not provided the justification for this conclusion. Rather, the CSA Consultants apparently selectively chose and interpreted factors (that could have introduced bias or uncertainty) in a manner that supported the CSA Consultants' belief that it underestimated benefits.

1. USEPA's Summary

In section Chapter B6, B6-3, the CSA Consultants presented a summary (Table B6-7) of what it considered to be the omissions, biases and uncertainties in PSEG's estimates of the economic value of I&E losses (referred to by USEPA as benefit estimates). For each identified issue, the CSA Consultants decided whether the effect of the issue was to overestimate benefits, or to underestimate benefits, or whether USEPA could not determine the direction of the potential error (i.e., the issue introduced uncertainty but not bias).

The CSA Consultants identified eight issues. Surprisingly, of the eight issues identified, the CSA Consultants concluded that four would have caused underestimation and four would have simply introduced uncertainty. PSEG disagrees with the CSA Consultants' conclusions that four of the issues have resulted in underestimates. Furthermore, PSEG notes that USEPA's list is very incomplete, and that many issues USEPA failed to consider or chose to ignore have caused USEPA's estimates to be biased high.

a. Unjustified Claims of Underestimation of Benefits

EPA claimed that if the “(e)ffect of interaction with other environmental stressors” (Table B6-7) had been considered, benefits would have been greater than those estimated. The Agency justified its conclusion by claiming that “yearly reductions in fish may make the stock more vulnerable to other stressors.” USEPA provided no scientific evidence for this speculation. The Agency also claimed that “as water quality improves over time due to other watershed activities, the number of fish impacted by I&E may increase.” Although the number of fish lost to I&E may increase as populations of fish increase in abundance due to improvements in water quality, it is also likely that the value per fish will decrease as fish abundance increases. USEPA’s determination regarding this issue appears to be one-sided speculation without any documented scientific basis.

EPA claimed that because “(b)oating, bird-watching, and other in-stream or near-water activities are omitted” benefits were underestimated. However, USEPA provided no evidence that I&E losses at Salem would in any way affect boating, bird-watching or other activities, nor did it demonstrate any likely linkages between I&E losses and those activities. Furthermore, as noted in Appendices J and H of the 1999 Salem Application, almost all (RIS) fish stocks in Delaware Estuary have shown increases in abundance during the period of Salem operation. Therefore, it is not reasonable to hypothesize that I&E losses lead to declines in fish abundance which somehow affected boating, bird-watching and related activities. USEPA’s claim appears to be another example of USEPA ignoring the facts in favor of biased speculation.

b. Omitted and Ignored Issues That Cause Overestimates

As discussed above, USEPA omitted the following issues (all of which caused USEPA’s estimates to be biased high) that were identified in PSEG’s reviews of USEPA’s methods and estimates of biological and economic losses (see Attachments 3 and 4):

-EPA’s erroneous assumption that juvenile entrainment occurs in the middle of the juvenile lifestage

-EPA’s misuse of the production foregone formulation from Rago (1984)

-EPA’s erroneous method for estimating weights of age-0 fish by extrapolation from weight at age-1

-EPA’s erroneous estimates of economic value of commercial landings

-EPA’s flawed RUM estimates for recreational value

-EPA’s erroneous application of its “50% rule of thumb” for non-use values.

In addition, USEPA chose to ignore, as issues that could introduce bias or uncertainty, the following (all of which caused USEPA’s estimates to be biased high):

-EPA’s decision to ignore the effects of density-dependent mortality and growth

-EPA’s assumption of no entrainment survival

-Alternative energy pathways that allow food not eaten by fish lost to I&E to be available for new growth by other species (e.g. see Section VII.B.2.b in PSEG's response to the ESSA report (PSEG, 2001)).

2. USEPA's Characterization of Bias in Valuation of Fish Not Caught by the Fishery is Misleading

In CSA Chapter B6, USEPA presented two pie charts: one that depicts the "Salem: Distribution of Impingement Losses by Species Category and Associated Economic Values" (Figure B6-2), and one that depicts "Salem: Distribution of Entrainment Losses by Species Category and Associated Economic Values" (Figure B6-3). Each chart shows the proportion of the total number of age-1 equivalents (the sum of individual fish, regardless of species) that are in each of three categories: (1) forage fish, (2) commercial and recreational fish that are harvested, and (3) commercial and recreational fish that are not harvested.

These charts are highly misleading. Despite USEPA's characterization, the age-1 equivalents of different species are not equivalent (in terms of biomass, ecologic function, economic value or otherwise) and the sum of individual fish with different ecological and economic values is not a meaningful quantity. For example, the CSA Consultants' estimate of the average weight of an age-1 bay anchovy is 0.00381 pounds (CSA, Appendix B2, Table B2-5), whereas the CSA Consultants' estimate of the average weight of an age-1 striped bass is 0.485 pounds (CSA, Appendix B2, Table B2-5), over 125 times the weight of a bay anchovy. Furthermore, bay anchovy are forage (consumed by the billions by predatory fish) and striped bass are predatory fish. Although the CSA Consultants apportions these losses into categories, implicit in the use of a pie chart is the assumption that what is being compared is in equal units. The CSA Consultants' chart therefore cannot account for these differences and erroneously implies that an individual bay anchovy is just as important as an individual striped bass, which is clearly not the case (ecologically or economically). Since the sum of individual fish (over all species) is not a meaningful quantity, the apportionment of that sum into categories (defined by the ultimate fate of each fish) does not produce meaningful percentages.

Furthermore, the CSA Consultants' characterization of commercial and recreational fish that are not harvested as being "UNVALUED" is extremely misleading. The difference between commercial and recreational fish that are harvested and those that are not harvested (based on the methods of estimation as described in CSA, Chapter A5) is that fish that don't get harvested die from natural causes. Apparently this is the reason the CSA Consultants originally decided to assign an economic value of $0 to the commercial and recreational fish that are not harvested, i.e., those fish die from natural causes. If the CSA Consultants believed an economic value other than $0 should have been applied, then the CSA Consultants should have used that alternative value from the start of its analysis. At the end of its case study, to claim those fish were "UNVALUED" creates the misleading impression that its benefit estimates are biased low.

Similarly, the CSA Consultants' characterization of forage fish as being "UNDERVALUED" is extremely misleading. The CSA Consultants presented no scientific justification for the conclusion that its method for assessing the economic value of forage production foregone would lead to underestimates. To the contrary, it is likely that the presence of alternative energy pathways in the Delaware Estuary ecosystem allow surviving fish to grow faster by consuming the food left behind by the forage fish lost to I&E (e.g., see PSEG's response to the ESSA report (PSEG, 2001)). the CSA

Consultants' methods for estimating production foregone do not account for such alternative energy pathways. Therefore, the CSA Consultants estimates of the value of forage production foregone are likely to be biased high.

Simply put, these charts are not scientifically valid and are extremely misleading. One can only surmise that the purpose of these charts is to create the erroneous impression the CSA Consultants benefit estimates for Salem are biased low.

F. USEPA's Delaware Estuary Case Study Contains Factual Errors Regarding Salem

In section B3-7, the CSA Consultants incorrectly stated that the modified Ristroph intake screens at Salem have been in service since 1995:

"Current impingement at Salem was estimated by considering only the years since 1995, when Salem's Ristroph screens were modified with improved fish handling systems that increased the survival of impinged organisms." (CSA, Chapter B3, page B3-40).

And, the CSA Consultants incorrectly averaged impingement loss data from the years 1995, 1997 and 1998 to represent current conditions with the modified Ristroph screens in place, when in fact, the modified screens were not fully in place until the beginning of 1997.

G. USEPA Ignored Substantial Amounts of Information Provided by PSEG

The Case Study Analysis of the Delaware Estuary Watershed ("Delaware Case Study", EPA-821-R-02-002, Part B) does not consider all relevant information in the record concerning the effects of Salem on fisheries resources, does not consider prior analyses on the long-term trends of key species in the Delaware; and does not consider the cumulative assessment of Salem's effect on the key fisheries populations in the Delaware.

The CSA Consultants discuss thermal discharges and associated environmental impacts (CSA Chapter B1, page B1-10) but never references the Salem § 316(a) variance determination by NJDEP or the independent review by Versar (1989). Both of these independent reviews discuss the small and localized nature of Salem's thermal plume. In addition, PSEG's § 316(a) Demonstration (1999, Appendix E, Volume 10) provides evidence from both retrospective and predictive studies that support the position that the balanced indigenous populations/communities ("BIP"/"BIC") in the Delaware are protected and not adversely impacted by Salem's thermal discharge.

On page B3-1 the CSA Consultants stated that: "[b]ecause of the lack of I&E data on these species, the CSA Consultants was unable to evaluate potential CWIS impacts on them." In this instance, the CSA Consultants are discussing several threatened and endangered ("T&E") species that are occasionally impinged at Salem and other facilities. However, Salem's Section 316(b) Demonstration (PSEG 1999, Appendix F, Volume 14) Section V.B.2.c.v does address threatened and endangered species and states that Salem's operations are not having adverse effects on these T&E species and the conclusion is confirmed by numerous NMFS-issued "no jeopardy" decisions under the Endangered Species Act. NMFS is the federal agency charged with making these decisions for the T&E species potentially involved at Salem. Therefore, PSEG believes that very definitive statements have been made and are supported by regulatory agency documentation that Salem is not jeopardizing nor will not jeopardize the continued existence of these T&E species or result in the destruction or adverse modification of their habitat (USNRC 1980, NMFS 1991, 1992, 1993, 1999). USEPA should accept these decisions by its sister Agency and not erroneously state that CWIS impacts on T&E species cannot be addressed.

Section VII.B of the Salem § 316(b) Demonstration (PSEG 1999, Appendix F, Volume14) presented a summary of PSEG's analysis of trends of relative abundance of RIS of fish and blue crab. One of the first signs of a continuing decline in population abundance is a downward trend in recruitment. Thus, the trend analyses are important and relevant in evaluating CWIS impacts. The summarized results presented in the Salem § 316(b) Demonstration and the detailed discussion presented in Appendix J of the Salem § 316(b) Demonstration (PSEG 1999, Volume 34) were not fully and properly acknowledged by the CSA Consultants in theCSA. The results of these rigorous statistical analyses are important in evaluating CWIS impacts and clearly demonstrate that there is no evidence of continuing decline in the abundance of finfish RIS and blue crab in the Delaware attributable to Salem operations. Page B3-28 of the Delaware Case Study, states "…Blueback herring and spot impingement has declined in the past decade at the same time populations of these have shown significant declines within the estuary (see Appendix J in PSEG, 1999d). However, in the case of spot the decline is in part attributable to an exceptionally strong year class in 1988, a year that showed exceptionally high spot impingement." What the CSA Consultants did not state is that the declining trend for blueback herring mirrors the coastwise decline in abundance that started in the late 1960s, which is well before Salem started operating (PSEG 1999, Appendix F, page VII-25). PSEG questions how the CSA Consultants can either ignore or mischaracterize these relevant findings in reaching its conclusions in the CSA.

The focus of the CSA Consultants' cumulative impact assessment is on the total I&E in terms of age 1 equivalents, yield lost to the fishery (in pounds) and production foregone (in pounds; Delaware Case Study, Section B3-8). However, the CSA Consultants' does not place these losses into perspective by comparing them to appropriate aquatic population and community benchmarks, even though they acknowledged the importance of providing such a context (CSA, Chapter B7, page B7-1):

"…[I]t is important to consider how I&E rates relate to the relative abundance of species in the source waterbody. Thus, low I&E does not necessarily imply low impact since it may reflect low population abundance, which can result from numerous natural and anthropogenic factors, including long-term I&E impacts of multiple CWIS. On the other hand, high population abundance in the source waterbody and associated high I&E may reflect waterbody improvements that are independent of impacts from or improvements in CWIS technologies. Or, high levels of I&E impacts on a species may indicate a high susceptibility of that given species to CWIS effects"

In contrast to the CSA approach (which raised and then ignored these considerations), PSEG performed an overall assessment of the cumulative effects of Salem on the aquatic environment (PSEG 1999, Appendix H, Volume 34) that put the I&E losses into the context of the abundance of affected species in the source waterbody. The assessment employed multiple lines of evidence from both predictive and retrospective studies. The studies showed that the Salem CWIS and other sources of stress on the relevant aquatic populations are not having an adverse environmental effect and that Salem's operations as a whole are not adversely affecting the biotic community of the Delaware Estuary. PSEG believes this approach is scientifically credible, addresses the issue of adverse environmental impact ("AEI") rather than ignoring it, and results in cost-effective solutions to complex resource issues.

The CSA Consultants incorrectly assumes AEI is occurring in the Delaware Case Study and then proceeds to economically value the losses and the benefits that would potentially accrue as a result of the proposed regulations. As noted in the proposed rules PSEG and the UWAG have offered definitions of AEI and approaches to address these issues.

H. USEPA's Claim That In General I&E Loss Estimates are Biased Low Is Not Applicable to Salem

In the Economic and Benefits Analysis (EBA; USEPA –821-R-02-001, Section C1-5, <FN 196> USEPA states that data uncertainties lead to underestimates of Case Study benefits and cite the following factors: data limitations, estimated technology effectiveness, potential cumulative impacts, recreational benefits, secondary (indirect) economic impacts, commercial benefits, forage species, nonuse benefits, and incidental benefits. PSEG believes these general statements are not valid in regard to Salem's § 316(b) Demonstration (PSEG 1999) and, in fact, believes that the USEPA's Case Study of the Delaware Estuary has ignored site-specific information and overestimated the benefits that would be attributable to I&E reductions at Salem. The following paragraphs address each of the listed uncertainties for Salem.

In regard to data limitations, the CSA Consultants state that facility-furnished data typically focus on a subset of the fish species impacted by impingement and entrainment (I&E), resulting in an underestimate of the total magnitude of losses (EBA, Section C1-5.1). In addition, the CSA Consultants state that facility-derived biological monitoring data often pertain to conditions existing many years ago <FN 197> and often is of very limited duration. <FN 198> PSEG believes these uncertainties have been adequately addressed in the Salem Section 316(b) Demonstration and inappropriately considered by the CSA Consultants in the Delaware Estuary Case Study. The Salem § 316(b) Demonstration focused on 12 RIS of fish and finfish and four T&E species (i.e., shortnose sturgeon, loggerhead turtle, Kemp's Ridley turtle, and the green sea turtle), in accordance with available § 316(b) Guidance (EPA 1977). However, PSEG provided I&E loss estimates for fish species and blue crab with data being collected almost yearly in the 1977 through 1998 time period.

The CSA Consultants states that potential losses of T&E species were not considered in Salem's 1999 Application and, therefore they were unable to evaluate potential CWIS impacts on them (Delaware Case Study, B3-1). This statement is not true because the Salem Section 316(b) Demonstration (PSEG 1999, Volume 14, Appendix F, V.B.2.c.v.) addressed T&E species and noted that PSEG had consulted with the appropriate regulatory agencies (USNRC and NMFS) in accordance with Section 7 of the Endangered Species Act. The conclusion reached by these agencies was that Salem operations have not jeopardized and will not jeopardize the continued existence of these species or result in destruction or adverse modification of their habitat (USNRC 1980, NMFS 1991, 1992, 1993, 1999).

The CSA Consultants states that the only technology effectiveness that is certain is reductions in I&E with cooling towers. <FN 199> PSEG disagrees and believes that the estimated technology effectiveness values used in the Salem Section 316(b) Demonstration for modifications to the CWIS (i.e., Ristroph screens, and fish return) actually installed at Salem are appropriate and valid because they were based on site-specific studies and considered the effects of latent impingement mortality (PSEG 1999, Volume 16, Appendix G, Exhibit G-1-2).

PSEG does not believe the benefits evaluation for Salem (presented in the Application) was underestimated because an overall assessment of the cumulative effects for the Station was performed using multiple lines of evidence from both predictive and retrospectives studies (PSEG 1999, Volume 34, Appendix H). The studies showed that the Salem intake and other sources of stress on the relevant aquatic populations are not having an adverse environmental effect and that Salem's operations as a whole are not adversely affecting the biotic community of the Delaware Estuary.

Contrary to the CSA Consultants' general assertions on the underestimates associated with commercial and recreational benefits assessments (EBA, C1-5.4 and C1-5.6, respectively) the Salem § 316(b) Demonstration followed the CSA Consultants 1983 Cost-Benefit Guidelines and identified the benefits from changes in commercial and recreational species. The commercial values per pound of fish used by the CSA Consultants (Table B4-8) and PSEG (1999, Volume 15, Appendix F, F-13 Table 1) are very similar with the CSA Consultants' values on average being approximately four cents higher per pound. Benefits were estimated in the Salem § 316(b) Demonstration for the blue crab, which is considered the most economically important commercial invertebrate species in the mid-Atlantic (Epifano 1995). In addition, PSEG estimated recreational fishing benefits using the gains from increased fishing trips as well as additional fish per trip using both Random Utility and Travel Cost Models, as appropriate, in conducting a statistical, meta-analysis of the marginal value of the increased catch (PSEG 1999, Volume 15, Appendix F, Attachment 14).

The CSA Consultants state that benefits for forage species are underestimated because the facilities focus on losses of commercial and recreational species even when the predominant share of the losses are forage species and their full ecological role is not considered (EBA, C1-5.7). The statement is not valid for the Salem Section 316(b) Demonstration where the losses to the fisheries due to the losses of forage species were estimated using the production-forgone model for the bay anchovy, a fish species that is dominant in the I&E collections at Salem, for non-RIS forage species, and for representative forage invertebrate species (opossum shrimp and scud) that frequent the collections at Salem (PSEG 1999, Volume 14, Appendix F, Attachment F-4).

To summarize, USEPA has stated that data uncertainties lead to underestimates of Case Study benefits and cite the following factors as contributing to the underestimates: data limitations, estimated technology effectiveness, potential cumulative impacts, recreational benefits, secondary (indirect) economic impacts, commercial benefits, forage species, nonuse benefits, and incidental benefits. PSEG believes these general statements are not valid in regard to the Salem § 316(b) Demonstration (PSEG 1999) and, in fact, PSEG believes the USEPA Case Study of the Delaware Estuary has ignored site-specific information and overestimated the benefits for Salem.

Footnotes

192 See Attachment 3 for PSEG's review of USEPA's methods for valuing forage production foregone.

193 However, PSEG's estimates did not account for effects of density-dependent compensation and therefore, likely were biased high, also.

194 Furthermore, it should be noted that USEPA's implementation of the 50% rule was based on flawed estimates of recreational benefits.

EPA Response

In response to PSEG's comments under B., EPA carefully considered the ESSA report and all comments by PSEG and made adjustments to its analysis of Salem's I&E data as considered appropriate for the purposes of EPA's regional analysis. Details of such changes are provided below.

Under C., EPA wishes to emphasize that the purpose of its analysis for the final rule was to develop an estimate of I&E across the entire mid-Atlantic region using available data from multiple facilities, not to conduct a detailed study of the Salem facility. EPA averaged rates across multiple facilities to develop its regional estimate, and therefore EPA believes that its I&E estimate for the mid-Atlantic is not significantly influenced by its estimates of Salem's I&E rates.

In regards to PSEG's comments on EPA's I&E methods under C.2., please see Chapter A7 of Part A of the Phase II Regional Study Document for a discussion of EPA's conclusions regarding entrainment survival.

In response to PSEG's comments under D.2. on the commercial fishing valuation methods used at proposal, please refer to the response to Comment 316bEFR.005.029 for EPA's.

In response to the comments under D.3.b, EPA notes that in the cost benefits analysis for the final Section 316b Phase II rule, EPA no longer uses a benefits transfer approach to estimate recreational fishing losses and benefits. Rather, EPA has developed a random utility model (RUM) to estimate benefits for each region. For further detail on the new methods please refer to the regional study document, Chapter A11: Estimating Benefits with a Random Utility Model (RUM). Specific results for the mid-Atlantic region are presented in Chapter D4 of Part D of the Regional Analysis Document (DCN #).

In response to Comment D.3.c., EPA believes that the National Marine Fishery Service (NMFS) has adequately corrected for sampling bias through long-established and tested survey and statistical methods. In addition, EPA does not believe that the Agency's analysis incorrectly calculates opportunity cost of time in the RUM models. EPA follows generally-accepted RUM procedures for estimating the opportunity cost of time. In regions where data were available on angler income, EPA included income for anglers who reported that they lost income by taking the fishing trip, and who reported their income. However, in all of these cases, only a minor fraction of anglers in the RUM data set provided information on household income. If anything, EPA's measure of opportunity cost of time would result in downward bias in estimates for regions where income was reported for extremely small numbers of respondents. For regions where income was estimated using median household income from the U.S. census, it is impossible to determine the direction of bias, if any, because, without collecting primary data, there is no way to compare the median income of anglers to the median income of all households in the region. EPA has followed standard, generally-accepted methods of RUM modeling. See response to comment #316bEFR.041.452 for additional details.

In response to comment D.4.a. EPA did not use the "50 percent rule of thumb" used at proposal for its final analysis.

In response to comments on replacement cost methods under D.4.c, please see the document entitled "Habitat-based Replacement Cost Method" (Docket # XX) and EPA's response to comment #316bEFR.005.035.

Under E.1., EPA stands by its statement that other environmental stressors may interact with I&E to cause further harm to aquatic organisms that are impinged and entrained. It also stands by its statement that there may also be indirect effects on birds and other organisms that feed on fish that are impinged and entrained. EPA believes that most scientists would agree with these assumptions, particularly in the absence of any data to the contrary.

In response to comments under E.1.b, please see response to Comment 316bEFR.025.015 for EPA's position on density dependence and Chapter A7 of Part A of the Phase II Regional Study Report for a discussion of EPA's conclusions regarding entrainment survival. Regarding production foregone calculations, several commenters have raised questions about the EPA calculations of production foregone, primarily with regard to the values of stage-specific fish weights. These commenters have indicated that in some cases the weight parameters used by EPA may lead to overestimation of production foregone. Some commenters have also questioned inconsistencies between values used for the same species occurring in different regions, and apparent discontinuities in weights between early life stages. Through the course of reviewing public comments on the initial case studies and later comments on the NODA, EPA has reviewed and revised many of the weight parameters. EPA relied upon numerous published records, local experts, and other resources to develop weight estimates. Following suggestions of commenters, EPA also revised some of its approximation methods, including the use of volumetric methods to improve estimates of egg weights.

Some commenters also indicated that the mathematical definition used to calculate estimates of foregone production require weights that represent the beginning and the end of each life stage. EPA acknowledges that this is true. However, such data are seldom available. In fact, the weight parameters used by EPA in its analyses include a variety of types of values, some of which are unknown because in some cases facility documents are not explicit about whether the values represent weights for the beginning, the end, or midpoints of particular stages. This issue is also complicated by the fact that some weights are determined indirectly through length-weight regression relationships. Length-at-age values found in different literature sources may also represent different parts of a lifestage.

Although such uncertainty is unfortunate, EPA believes that the practical effect on the benefits estimation is negligible. EPA disagrees with the characterizations put forth by some commenters that accuracy of these estimates are of vital importance to the benefits estimates. EPA notes that the benefits assessment does not put any direct valuation on the production foregone, per se. Production foregone estimates are used only in the context of the trophic transfer model which is used only to generate estimates of incremental foregone yield attributable to losses of forage species. The portion of the total benefits associated with the trophic transfer pathway is quite small, usually less than 2 percent of the total within any particular region. EPA believes its analysis of production foregone is reasonable. However, even if EPA's estimates of production foregone caused the trophic transfer model to overestimate foregone yield, the practical effect on the total benefits estimate would be very small.

In response to comments under E.2, EPA wishes to provide additional discussion of the basis of the pie charts that were used to summarize results. There are several “metrics” that can and are used to quantify and portray the impacts of I&E. These potential metrics (units of measurement) include numbers of organisms killed (regardless of lifestage), age 1 equivalents, mass (i.e., yield or body weight), and economic value (i.e., in monetized, dollar terms). Each potential metric has its advantages and limitations, depending on what the analysis is intended to portray. In some instances, it is possible to develop monetary estimates of impacts, as applicable in a benefit-cost analysis. In other instances, estimates of mass are needed to reflect the change in biomass harvested. There is no single right or wrong metric, and EPA does not directly compare losses across different species using its results for age 1 equivalents.

In its analysis of the 316b rule, EPA provides information using all of the above metrics as part of its assessment of the physical impacts of I&E, and of the benefits and costs of the rule. Each type of outcome metric (e.g., age 1 equivalents) is used so that readers can make their own inferences. In many instances, one type of metric is used because it feeds into the next step of the analysis (e.g., yield impacts on commercial harvests are combined with market prices per pound to develop economic measures of the impact on the commercial fishery).

Thus, in the regional analyses prepared as part of the cost benefit analysis for the final Section 316(b) Phase II rule, estimated losses of age 1 equivalent fish are reported by species/species groups in the results tables. Then they are classified as recreational, commercial, and forage species. Losses of the recreational species are valued using a random utility model, as detailed in Chapter A11 of the regional study document. Losses of the commercial species are valued using price data from the National Marine Fisheries Service, as detailed in Chapter A10 of the regional study document. Losses of forage fish are translated into foregone production among harvested species that are impinged and entrained, using an assumed trophic transfer ratio, and then translated into foregone production among these harvested species to develop an estimate of foregone yield.

The portion of forage species impacts from I&E that would have added biomass to those commercial or recreational fish landed are valued, albeit indirectly, through the direct use benefits estimated under recreational and commercial fisheries. However, the majority of forage species losses (i.e., those fish that are not converted to landed biomass) are not valued under the direct use benefits categories (i.e., for recreational or commercial fisheries), and therefore remain unvalued in EPA’s analysis of use values. Additional information on the methods EPA used to estimate forage losses is provided in the regional study document, Chapter A5. In the cost-benefits analyses, only the sums of total losses and total benefits are used in the analysis.

In terms of the pie charts for Salem (note that the same types of charts were developed for most of the other case study sites at proposal as well), EPA is simply reporting its findings, and not in any misleading manner. The use of age 1 equivalents is a suitable metric for considering and portraying the physical impact of I&E. Overall, after completing its NODA analysis, EPA found overall that 2% of the age 1 equivalent losses due to I&E would have been harvested as commercial or recreational landings. Therefore, these 2% of the impacted individual fish account for 100% of the recreational and commercial fishery benefits. Of the remaining 98% of age 1 equivalent fish (i.e., those fish not landed by recreational or commercial anglers), a large portion are forage fish. A small portion of the forage losses are indirectly reflected as increased recreational or commercial biomass, and thus this small share of the forage fish impact is captured in the direct use benefits values through the trophic transfer model. But the remaining forage fish are not captured in that analysis. In addition, any nonuse values associated with the forage fish impacts are not included. Therefore the forage losses are “undervalued” because the direct use benefits estimates pertain only to use values and only capture the small share of forage fish that end up as a contribution to the landed commercial or recreational yield This is what the pie chart communicates; and it is neither erroneous nor misleading.

Likewise, the unlanded increase in commercial and recreational fish are not assigned monetary value under the EPA’s approach to estimating direct use values. Therefore, they are “unvalued” in that context. This is what is communicated in the pie chart. The term “unvalued” does not mean that these fish truly have zero value; rather, their value is not well captured in the valuation of recreational or commercial fishery impacts. These fish have no direct use value that is captured in EPA’s analysis (although, by adding to the fishery stock, they may help sustain the increased annual yield that is harvested, and thus, indirectly, some aspect of their impact may become captured in the analysis). For further detail on EPA's response to a related comment on the fraction of unlanded and unvalued fish, please refer to comment # 316bEFR.336.009.

Under F., PSEG states that EPA incorrectly assumed that the modified Ristroph screens were first in operation in 1995, not 1997 as PSEG states. EPA regrets the error, which was inadvertent. However, EPA notes that inclusion of the 1995 did not have a significant effect on the results of EPA’s analysis, because it is based on an average across multiple years.

In response to PSEG’s comments under G., EPA notes that its analysis is concerned with 316b only, not 316a. Therefore, PSEG’s comments on potential thermal impacts have no bearing on EPA’s benefits analysis for this rule. In regards to threatened and endangered (T&E) species, EPA stands by its statement that no I&E data for these species were presented in Salem’s 1999 Permit Application. Without such data, EPA could not evaluate impacts on these species. PSEG’s statement that there are no “adverse” impacts is not pertinent to EPA’s analysis, which estimated I&E losses and the economic benefits of reducing these losses. EPA also notes that its analysis did not focus on assessing impacts on populations or communities (see responses to Comment 316bEFR.005.009 and Comment 316b.EFR.025.015. Nor did EPA describe Salem’s I&E rates as an “adverse environmental impact.” Nowhere in its analysis did EPA characterize I&E in these terms.

Finally, in response to PSEG’s comments under H., EPA notes that the referenced section of the Economic and Benefits Analysis (EBA; USEPA —821-R-02-001, Section C1-5) discusses data uncertainties and benefits estimates in general. None of this material references Salem in particular, nor is it meant to.

Option: PSEG site-specific alternative

PSEG's Proposed Language for a Site-Specific Rule

January 2002

Draft Section 316(b) Regulations for Site-Specific Permit Renewal Options for Existing Sources

Part 125—Criteria and Standards for the National Pollutant Discharge Elimination System

Subpart I—Requirements Applicable to Cooling Water Intake Structures for New Facilities Under Section 316(b) of the Act (Sections 125.80--125.89 in Final Rule, 66 Fed. Reg. 65256)

Subpart II—Requirements Applicable to Cooling Water Intake Structures for Existing Facilities Under Section 316(b) of the Act (Likely Sections 125.90-125.99)

§ 125.9? Permit Renewal Options for Existing Facilities

(a) Demonstration Options. A permittee may seek to demonstrate Section 316(b) compliance for purposes of renewing an existing source's permit with a site-specific demonstration that meets the requirements of any one of the three options provided in this section: Option I, demonstration based on a prior Section 316(b) determination; Option II, demonstration based on a site-specific evaluation of the best technologies or other measures for minimizing entrainment and impingement effects; and Option III, demonstration based on a detailed assessment to determine the presence, if any, of adverse environmental impact ("AEI").

(1) Demonstration Option I. A permittee may demonstrate Section 316(b) compliance based on a prior Section 316(b) determination of best technology available ("BTA") made in conjunction with issuance of a permit when circumstances warrant continued reliance on that determination.

(A) Necessary Components of a Demonstration under Option I. The demonstration must allow the permit writer to determine that:

(i) The CWIS has previously been determined by a permitting authority to meet the statutory requirements of BTA on the basis of a Section 316(b) demonstration that was conducted in accordance with EPA's May 1, 1977 draft "Guidance for Evaluating the Adverse Impact of Cooling Water Intake Structures on the Aquatic Environment: Section 316(b) P.L. 92-500" ("EPA's 1977 Guidance");

(ii) There have been no material changes in the key bases for the prior Section 316(b) determination, including no material change in the operation of the facility, that would substantially increase entrainment or impingement losses;

(iii) All required technological and/or restoration measures have been implemented and appropriately maintained, and are satisfactorily achieving the levels of protection contemplated by the permitting authority in its prior Section 316(b) determination.

(iv) Data and/or information show that representative important species (“RIS”) are being maintained or that any declines in those species are not attributable to the CWIS; and

(v) The results of cost-benefit analyses of available technologies for minimizing AEI remain substantially similar to those in the prior determination.

(B) Findings Necessary for Issuance of Renewal Permit under Option 1. A permitting agency may issue a renewal permit based on a prior Section 316(b) determination if it makes, and documents in the Fact Sheet required under §124.8 to accompany a draft permit, positive findings with regard to each of the demonstration components identified in section (a)(1)(A) above, and includes in the Fact Sheet:

(i) The agency’s finding of fact that the prior Section 316(b) determination was based upon a demonstration conducted in accordance with the Agency’s 1977 Guidance;

(ii) Identification of the data and information that the permittee provided in support of the re-affirmance of the prior Section 316(b) determination;

(iii) The agency’s findings in support of the proposed determination; and

(iv) The agency’s proposed Section 316(b) determination.

(2) Demonstration Option II. A permittee may demonstrate Section 316(b) compliance based on a site-specific evaluation of the best technology to minimize entrainment and impingement effects associated with a CWIS.

(A) Necessary Components of a Demonstration under Option II. A Section 316(b) demonstration under Option II must include:

(i) A report identifying the suite of technologies potentially applicable to the CWIS and/or any planned voluntary conservation measures to be implemented in conjunction with section (c) below;

(ii) An analysis describing the bases for the selection of technologies or other voluntary conservation measures applicable to the facility;

(iii) An assessment of the issues associated with retrofitting the CWIS to include each of the applicable technologies or other voluntary conservation measures and their costs;

(iv) An assessment of the reasonably likely reductions in entrainment and impingement losses that would be achieved if the CWIS were to be retrofitted to operate with the technology and/or the offset from such losses if other voluntary conservation measures were to be implemented;

(v) A cost-benefit analysis that addresses and assesses the effects of the reductions in entrainment and impingement losses achievable through the application of each technology or other measure on life stages of the species for which an economic value can be determined utilizing readily available information, such as market values of commercial species, and recreational costs based on methods determined to be appropriate by the permitting agency and the appropriate fisheries management agencies.

(B) Standards for Supporting Documentation Under Option II. In evaluating the benefits of alternative technologies under Option II:

(i) A permittee must undertake the level of analysis that is appropriate to the situation and supported by the applicable data.

(ii) If the permitting agency determines that the applicant's demonstration does not contain sufficient information to assess the CWIS' effects on one or more RIS at the population level, due to inadequate, conflicting or unclear information about declines in any RIS, or to assess whether other technologies are potentially available for application to the CWIS, the agency may require the permittee to collect additional data, conduct additional analyses, and/or to conduct an analysis of the population level effects of the CWIS's losses as described in Section 125.9__(a)(2)(A)(i)-(iii) as appropriate.

(C) Findings Necessary for Issuance of Renewal Permit under Option II. The permitting agency may issue a permit renewal under Option II if it makes, and documents in the Fact Sheet required under §124.8 to accompany a draft permit, appropriate findings with regard to the following:

(i) The alternative technologies or voluntary conservation measures that are available for addressing the CWIS's effects;

(ii) The incremental costs and benefits of alternative technologies or other voluntary conservation measures relative to the existing CWIS's operation; and

(iii) The best technology or other measures for implementation, the costs of which are not wholly disproportionate to the benefits.

(3) Demonstration Option III. A permittee may demonstrate Section 316(b) compliance based on a detailed site-specific assessment of AEI.

(A) Necessary Components of a Demonstration under Option III. The permittee must undertake an analysis of potential AEI attributable to its CWIS, including:

(i) A detailed assessment that evaluates the effects of the existing CWIS's operation;

(ii) A demonstration of the extent to which the CWIS operation may be jeopardizing the sustainability of the populations of RIS; and

(iii) An assessment of any other appropriate factors for determining AEI.

(B) Standards for Supporting Documentation under Option III. A permittee's demonstration under

Option III should provide data and information to address the assessment factors in sections (b)(1)-(6) and should also be based on guidance to be developed by EPA, as supplemented or revised from time to time. Until such time as EPA issues final guidance, implementing Section 316(b), permittees shall follow EPA's 1977 Guidance.

(C) Findings Necessary for Issuance of Renewal Permit under Option III. The permitting agency may issue a permit renewal under Option III if it makes, and documents in the Fact Sheet required under §124.8 to accompany a draft permit, appropriate findings as follows:

(i) If the permitting agency finds that the CWIS as currently designed and operated is not causing any AEI, it shall issue the permit renewal and state its finding that the existing CWIS is deemed BTA.

(ii) If the permitting agency concludes that the assessment demonstrates that the CWIS as currently designed and operated is causing some AEI that can be addressed by appropriate technology or other measures, then it shall issue a permit renewal requiring the applicant to implement the identified measures and state its finding that implementation of the required measures is BTA.

(iii) If the permitting agency concludes that the assessment demonstrates that the CWIS as currently designed and operated is causing some AEI, but is unable to assess whether implementation of technology or other measures can satisfactorily address that AEI, then the permitting agency shall require the applicant to develop a Section 316(b) demonstration under Option II for minimizing entrainment and impingement effects.

(4) Demonstration Based on Multiple Options. In appropriate circumstances, a permittee may demonstrate Section 316(b) compliance on a site-specific basis by developing a demonstration that incorporates more than one of the three demonstration options detailed in this section.

(A) Necessary Components of a Multiple Option Demonstration. For each demonstration type included in a multiple option demonstration, the demonstration type shall include the required components of that demonstration type as specified above in sections (a)(1)(A), (a)(2)(A), and/or (a)(3)(A).

(B) Standards for Supporting Documentation under a Multiple Option Demonstration. For each demonstration type included in a multiple option demonstration, the demonstration type shall meet any applicable standards for supporting documentation as specified above in sections (a)(2)(B) and (a)(3)(B).

(C) Finding Necessary for Issuance of Renewal Permit under a Multiple Option Demonstration. A permitting agency may issue a permit renewal under a multiple option demonstration if it makes, and documents in the Fact Sheet required under §124.8 to accompany a draft permit, a finding that the applicant has satisfactorily demonstrated BTA to minimize AEI.

(b) Factors for Determining Adverse Environmental Impact in Site-Specific Demonstrations. In making determinations regarding adverse environmental impact for site-specific Section 316(b) demonstrations, applicants and permitting agencies shall evaluate the factors identified below, and shall also consider any subsequent guidance published by EPA to assist in making such demonstrations.

Section 316(b) demonstrations analyzing the potential for AEI shall be assessed, considering the magnitude of both short and long term impacts with reference to the following factors, so that operation of the CWIS does not interfere with the maintenance and typical functions of the RIS populations:

(1) Absolute damage (number of fish impinged or percentage of larvae entrained on a monthly or yearly basis);

(2) Percentage damage (% of fish or larvae in existing populations, which will be impinged or entrained, respectively);

(3) Absolute and percentage damage to any endangered species;

(4) Absolute and percentage damage to any critical aquatic organism;

(5) Absolute and percentage damage to commercially valuable and/or sport fisheries yield; or

(6) Whether the impact would endanger (jeopardize) the protection and propagation of a balanced population of shellfish and fish in and on the body of water from which the cooling water is withdrawn (long term impact).

(c) Role of Voluntary Conservation Measures in Alternative Site-Specific Demonstrations. Under any of the alternative permit renewal options, voluntary restoration or conservation measures may be used, in conjunction with or instead of technologies, to demonstrate that an existing CWIS is not causing AEI. If a facility already has implemented such measures, the permitting agency will consider the benefits to the aquatic system in connection with any renewal determinations.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Option: Site-specific determination of BTA

Summary of the Legal and Regulatory Bases in Support of the Site-Specific Application of Section 316(b) of the Clean Water Act Which Defines Adverse Environmental Impact

INTRODUCTION

USEPA has invited comment on whether it should adopt regulations that would implement § 316(b) <FN 1> of the Clean Water Act ("CWA") <FN 2> on a site-specific basis <FN 3> and the appropriate decision making criteria for adverse environmental impact ("AEI"). <FN 4> USEPA provides draft regulatory language for site-specific implementation of the requirements of § 316(b) <FN 5> but decided not to provide a specific definition of AEI. <FN 6> As PSEG has long urged, USEPA should continue to implement this statutory provision on a site-specific basis and evaluate AEI at a population or community level.

USEPA's site-specific sample rule is a formal process for determining the best technology available ("BTA") for minimizing adverse environmental impact ("AEI") at a particular facility, focusing on the site-specific interactions between the cooling water intake, the affected environment and the costs of implementing controls. <FN 7> As discussed in detail in the comments <FN 8> by both UWAG <FN 9> and PSEG <FN 10> on the Agency's Proposed Phase I Rule, <FN 11> a site-specific determination must be made to achieve the objectives of the Clean Water Act and AEI must be defined consistent with the community or population level approach.

The legislative history, the language of the statute, USEPA's guidance and long standing practice, and the very essence of what is being regulated -- the interaction of an intake structure with a specific aquatic environment -- all dictate that site-specific determinations are the best approach. PSEG fully supports USEPA implementing § 316(b) on a site-specific basis and requests USEPA define AEI at the community/population level.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA has chosen not to define the term "adverse environmental impact" in the final rule. Please refer to section VIII of the preamble to the final rule for more information.

EPA elected to not adopt any of the alternative technology-based options discussed in the proposed rule (67 FR 17154-17159) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA disagrees with the commenter's statement about the historic interpretation of 316(b). Today's rule is the first major regulation for 316(b) for existing facilities; all other § 316(b) determinations for existing facilities to date have used a best professional judgment approach. The final rule does include a site-specific compliance alternative as one of the five alternatives available to facilities, creating a flexible regulatory framework. EPA believes that today's final rule will minimize adverse environmental impact associated with cooling water intake structures.

Implement a site-specific alternative

THE LEGISLATIVE HISTORY AND STATUTORY TEXT REQUIRE A SITE-SPECIFIC APPROACH TO IMPLEMENTATION OF § 316(B) AND PROVIDE THE DEFINITIONAL FOUNDATION FOR ADVERSE ENVIRONMENTAL IMPACT

The legislative history of § 316(b) is sparse but the placement of § 316(b) within the site-specific thermal discharge section of the statute indicates the intent of Congress for § 316(b) to be applied on a site-specific basis. The words of the statute, “location”, “design”, “construction”, and “capacity”, taken independently and in context, require a site-specific evaluation. These factors all support the continued implementation of §316(b) on a site-specific basis.

The substantive standard of §316(b) requires intakes to reflect "best technology available for minimizing adverse environmental impact." If there is no "adverse environmental impact," there is nothing "for minimizing," and the objective of BTA is satisfied.

A. The Statutory Language of § 316(b) Supports a Site-Specific Approach

The plain language of § 316(b) requires a site-specific approach. Section 316(b) requires “that the location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact.” <FN 12> Each of the terms “location”, “design”, “construction”, “capacity”, and “adverse environmental impact” are factors specific to the facility, the local environment, or the affected ecosystem. This is especially so with respect to an existing facility.

With most of the terms within this single sentence individually requiring a site-specific evaluation, there is no reasonable way to interpret all words of this sentence collectively to require anything but a site-specific evaluation. <FN 13> Because the plain language and the legislative intent are clear, the EPA cannot construe the requirement otherwise. <FN 14> The clear meaning of § 316(b) requires evaluations be performed on a site-specific basis.

Furthermore, adverse environmental impact refers to those environmental factors that determine the health of aquatic populations and ecosystems. Any environmental impact, whether adverse or not, can only be evaluated within the given ecosystem being affected. As discussed by Dr. Hartman <FN 15> ecosystems are distinct and unique, even ecosystems within the same waterbody. For example, the ecosystem of the Mississippi River is very different in Minnesota than the ecosystem of the Mississippi River in Louisiana.

B. The Legislative History of § 316(b) Indicates Congress Intended § 316(b) be Implemented on a Site-Specific Basis

Review of the legislative history of § 316(b) confirms the intent of the statutory language. Section 316 <FN 16> was incorporated in the CWA following a long and detailed debate to define the approach to control discharges of pollutants. The House bill <FN 17> and the Senate bill <FN 18> were forwarded to the Conference Committee containing disparate provisions for the control of thermal effluents under § 316. The Conference Report <FN 19> forged a compromise on thermal discharges between the Senate and House bills by retaining heat within the definition of a pollutant while providing a case-by-case (i.e., site-specific) variance provision if the facility could demonstrate that the thermal limits were “more stringent than necessary to assure the protection and propagation of a balanced, indigenous population of shellfish, fish, and wildlife in and on the body of water into which the discharge is to be made.” <FN 20> Thus the intent of Congress, as accepted in the Conference Report, was to retain heat as a pollutant but allow the site-specific variance provision, acknowledging consideration of the technological, environmental, and economic conditions at a particular site. The statutory focus of § 316 clearly looks to the “population” of aquatic organisms in the specific “body of water into which the discharge is made.” <FN 21> Any impact must be evaluated at this population level.

Although the legislative history of § 316(b) is sparse, Anderson <FN 22> shows that Congress clearly intended § 316(b) to be evaluated on a case-by-case basis, based on its incorporation within § 316 for which there is extensive legislative history recognizing that any effect on the environment is based on the unique characteristics at a particular site. Much of the thermal discharge discussion, especially in the House, focused on the evaluation of the discharge of heat from steam electric plants and concluded that the thermal discharges should be controlled on a site specific basis. Section 316(b) was incorporated while the bills were in the Conference Committee and Congress found it appropriate to address intake structures in the same section they addressed thermal discharges, not elsewhere in the Clean Water Act. Therefore, in 1972, the record indicates Congress understood it was preferable to address intakes at steam electric power plants on a case-by-case basis and address impacts at the population level, intending §316 to be thus applied.

Subject Matter Code 2.04.02

Apply 316(b) before a det. of impact/AEI

The Substantive Statutory Standard Under § 316(b) Requires "Adverse Environmental Impact" be Defined

The substantive standard of § 316(b) requires intakes to reflect "best technology available for minimizing adverse environmental impact." Unlike the technological standards of §§ 301 and 306, which require point sources to install technology (e.g., BAT) without regard to the specific benefit to the environment to be achieved, the plain language of § 316(b) interposes an environmental-effects standard to determine whether an intake structure reflects BTA. USEPA recently stated in the context of its current rulemaking that:

"while the technical focus of an effluent guideline regulation is on the effectiveness of various technologies in treating wastewater discharges, [Section] 316(b) states that the location, design, construction, and capacity of cooling water intake structures shall reflect the best technology available "for minimizing adverse environmental impact . . . [E]nvironmental impacts caused by cooling water intake structures are highly site specific." <FN 23>

If there is no "adverse environmental impact," then there is nothing "for minimizing," and the objective of BTA is satisfied. As the Agency stated to the court, "adverse environmental impact" is an important legal concept that needs to be addressed in the § 316(b) regulations. <FN 24> A basis for USEPA's requesting an extension to the court order mandating promulgation of these regulations was to provide a benchmark for important concepts such as "adverse environmental impact." <FN 25> USEPA should follow through on its prior intention and include a biologically meaningful definition of AEI in the Phase II Rule.

The words of the statute, which require a determination that there is an "adverse" effect on the "environment" before further actions are required to achieve BTA, must be given their full import. <FN 26> USEPA cannot eliminate these words from the statute by presuming any intake causes an adverse effect. If USEPA were to do so, it would completely ignore the mandate of Congress. <FN 27>

Apply 316(b) before a det. of impact/AEI

The Overall Statutory Scheme Of The CWA Supports PSEG's Position That AEI Must Be Determined At A Biologically Relevant Unit

When the term adverse environmental impact is viewed in the context of the objectives and goals of the CWA, AEI must refer to those environmental factors that determine the health of aquatic populations and ecosystems. <FN 28> Courts have looked to the objective of the CWA, which is "to restore and maintain the chemical, physical and biological integrity of the Nation's waters," when construing its other provisions. <FN 29> Specifically, courts have noted that Congress used the term "integrity" to "convey a concept that refers to a condition in which the natural structure and function of ecosystems is maintained." <FN 30> In other words, "any change induced by man which overtaxes the ability of nature to restore conditions to [a] "natural' or "original' [state] is an unacceptable perturbation." <FN 31> Congress' general concern under the CWA was to protect and maintain the structure and function of ecosystems themselves. To meet the intent of Congress, USEPA must define AEI based on the impacts to aquatic populations, communities, or ecosystems, unless species of special concern (i.e., threatened or endangered) are affected.

Implement a site-specific alternative

REGULATORY GUIDANCE PROVIDED BY USEPA HAS CONSISTENTLY REQUIRED A SITE-SPECIFIC APPROACH FOR IMPLEMENTING § 316(B) AND PROVIDED A CONSISTENT DEFINITION OF ADVERSE ENVIRONMENTAL IMPACT

For almost 30 years, USEPA has interpreted § 316(b) of the CWA on a site-specific basis; in its regulations, development documents, and guidance documents.

Additionally, USEPA has generally interpreted AEI to be addressed on a community or population level and that long-standing interpretation should not be changed without a reasoned basis. These interpretations have consistently required the application of § 316(b) on a site-specific basis. In December 1973, little more than one year after the FWPCA's enactment, USEPA proposed regulations to implement the requirements of § 316(b). <FN 32> The proposal languished for several years while USEPA focused on other regulations under the FWPCA, and the final rule was not published until 1976. <FN 33> The regulations were set-aside on procedural grounds, <FN 34> but the court's decision was unrelated to the substantive content of the regulations; thus they may appropriately be cited as indicative of USEPA's contemporaneous interpretation of congressional intent. Both the proposed and final versions referenced and relied upon Development Documents discussed below, which describe factors and design alternatives to consider when making a § 316(b) determination, considerations that are applicable only to a specific site. These regulations are an important source of information about the definition of "adverse environmental impact" and how permitting authorities should proceed in determining whether such impacts are present.

Early USEPA guidance recognied that adverse environmental impact should be evaluated at the population-level when making a § 316(b) determination. <FN 35> In 1975 USEPA provided the following guidance as to the meaning of the term "adverse environmental impact":

Adverse environmental impacts occur when the ecological function of the organism(s) of concern is impaired or reduced to a level which precludes maintenance of existing populations; a reduction in optimum sustained yield to sport and/or commercial fisheries results; threatened or endangered species of aquatic life are directly or indirectly involved; the magnitude of the existing or proposed damage constitutes an unmitigable loss to the aquatic system. <FN 36>

USEPA's 1976 316(b) Development Document also established a community or population-level focus of adverse environmental impact determinations:

Serious concerns are with population effects that reduce harvestable cooling water intake structures may interfere with the maintenance or establishment of optimum yields to sport or commercial fish and shellfish, decrease populations of endangered organisms, and seriously disrupt sensitive ecosystems. [sic] <FN 37>

USEPA's 1977 Draft § 316(b) Guidance began by explaining "[R]egulatory agencies should clearly recognize that some level of intake damage can be acceptable if that damage represents a minimization of environmental impact" <FN 38> and also provided that the magnitude of an adverse impact should be estimated, considering both short-term and long-term impact, with reference factors that go primarily to the health or sustainability of the population. <FN 39>

These documents require site-specific analyses and an evaluation of community or population level AEI to demonstrate compliance with § 316(b). In the Phase II Rule, USEPA relies on its guidance documents calling for § 316(b) decisions to be made on a site-specific basis. <FN 40>

In 1998, USEPA stated to the Office of Management and Budget ("OMB") that it was the magnitude of impingement and entrainment effects which were critical in determining whether an intake was having an adverse environmental impact, and that the existence of such impact must be determined on a case–by–case basis. <FN 41> USEPA further stated to OMB that the determination of adverse ecological effects under § 316(b) should be evaluated in accordance with its 1998 Guidelines for Assessing Ecological Risk. <FN 42> USEPA's Ecological Risk Guidelines rely on the development of biologically relevant endpoints, e.g., populations or communities. <FN 43>

USEPA's long-standing population-level interpretation of adverse environmental impact and the requirement to evaluate intake structures on a site-specific basis should not be changed without a reasoned basis. There is no basis in the record for deviating from the approach required by the legislative history, the statutory language of § 316(b), and the extensive guidance promulgated by USEPA.

Implement a site-specific alternative

THE CONSISTENT AND LONG-STANDING INTERPRETATION OF THE STATUTE BY USEPA AND THE COURTS SHOULD BE CONTINUED

USEPA has been interpreting § 316(b) of the CWA for almost 30 years in permitting proceedings either directly or through the delegated state permitting agencies with USEPA oversight and by the courts. The principles of deference to agency interpretations of statutes have important implications for a number of issues presented in the implementation of § 316 of the CWA. USEPA has not provided a reasoned basis for departing from their long-standing interpretation and thus should promulgate implementing regulations consistent with this interpretation.

A. Implementation of the Requirements of § 316(b) for Almost 30 Years has been on a Site-Specific Basis, Interpreting AEI on a Community or Population Level

USEPA has developed consistent and long-standing interpretations of a number of key provisions in § 316, through their own actions and through approval of state permitting agency actions. USEPA's interpretations of these provisions are consistent with the terms of the statute and have been conducted on a site-specific basis. USEPA permitting decisions have also interpreted AEI on a community or population level, not on an individual organism level. Accordingly, these interpretations are controlling and must be followed in applying § 316(b).

USEPA permitting decisions have interpreted AEI on a community or population level, not on an individual organism level. For example, in the Seabrook I case, the USEPA Administrator concluded that the combined intake entrainment mortality of 100 billion clam larvae, an estimated 4.6 percent of the population, would have "an insignificant effect on adult [clam] populations." <FN 44> In the subsequent Seabrook II decision following remand, the USEPA Administrator concluded that although "fish eggs and larvae may be expected to be subject to intake and thermal entrainment in substantial numbers," for most species "the impact of either intake entrainment or thermal discharge will be insignificant." <FN 45> As the First Circuit stated in affirmation of the USEPA Administrator's decision, "though the intake would act as an additional large predator, there are other more dangerous threats in the natural environment, which fish are able to survive because they are highly fecund." <FN 46> In discussions regarding particular species, the court strongly implied that the critical question is whether the intake "will affect the ability of the [species] to propagate and survive." <FN 47>

In a decision on a NPDES permit for Carolina Power and Light's Brunswick Station, USEPA confirmed that the first inquiry in a § 316(b) decision is whether entrainment and impingement create adverse impact. <FN 48> The factors to be considered were reiterated in the USEPA Region I Administrator's Decsion on Pilgrim Station. <FN 49> A population-based or community-based standard of adverse environmental impact is also evident in USEPA's decision in Goudey <FN 50> where USEPA was satisfied, for § 316(b) purposes, by a showing that the intake structure "has not caused any adverse effects upon a balanced indigenous fish community." <FN 51> In its Crystal

River determination, USEPA stressed that relevant adverse impact to the macroinvertebrates living in Crystal Bay was impact to communities and not individuals. <FN 52> In these decisions, USEPA applied the "adverse environmental impact" standard in a reasoned manner that indicates it does not believe damage to individuals is the proper test but rather whether these losses have impacted the relevant populations, communities, or ecosystems. Biological communities and populations are unique to a specific site and these interpretations of individual permit requirements are clearly site-specific. Agencies have also interpreted the “adverse environmental impact” standard of § 316(b) as requiring a permitting authority to carry the burden <FN 53> of demonstrating significant harm to biological communities and populations as opposed to individual losses.

Agencies have interpreted § 316 as authorizing voluntary use by permittees of conservation and mitigation measures, whose biological benefits must be considered by the permitting agency in determining whether and to what extent regulatory controls, including intake technology controls, are needed. <FN 54> These conservation and mitigation measures are specific to the permitted facility.

Agencies have also interpreted § 316(b)’s “best technology available” (“BTA”) provision to require permitting agencies to determine BTA on a case–by–case basis, taking into account the specific environmental and economic circumstances of the source in question and to evaluate intake technologies in terms of their feasibility and appropriateness for the source in question. <FN 55>

USEPA is proposing to “set performance standards for minimizing adverse environmental impact based on a relatively easy to measure and certain metric-reduction of impingement mortality and entrainment.” <FN 56> EPA has chosen this approach “to provide certainty about permitting requirements and to streamline and speed the issuance of permits.” <FN 57> In Cronin v. Browner, the court noted the USEPA’s position that “[T]he public has a significant interest in ensuring that the government does not promulgate rules via a process that emphasizes expediency over quality and accuracy.” <FN 58> USEPA rightly argued against expedience as the goal for the rulemaking process; it is inconceivable then that this could be an appropriate goal for implementation of the Final Rule. The court also noted that “[I]n this case, it is important that the regulations have a sound, scientific basis, comport with the requirements of the CWA, are compatible with other regulatory programs, and further USEPA’s broad policy goals of protecting human health and the environment.” <FN 59> USEPA is proposing to regulate intakes without a scientifically founded definition of AEI, in direct conflict with the Congressional mandate and EPA’s own statements to the court. Regulations impacting the regulated community on the order of billions of dollars should be based on sound science, not administrative expediency or convenience of the permitting agency.

Thus USEPA has consistently espoused that a population, community, or ecosystem-level assessment of the impacts is required to determine if they are “adverse”. Impacts, and any “minimization” required, can only be considered at a specific site. These have been the standards under which compliance with § 316(b) has been judged for almost 30 years. There is nothing in the record, which justifies a radical departure from this standard.

B. EPA Must Provide a Reasoned Basis for the Significant Departure from Its Interpretation of §316(b).

USEPA has invited comment on the framework proposed for implementing §316(b) in these regulations. <FN 60> Although the proposed regulations allow for site-specific evaluations as an alternative to the technology based standards, the proposal for technology based standards and the premise that all impingement and entrainment cause adverse environmental impact are significant departures from almost 30 years of USEPA policy and practical permit decision-making.

Regulatory agencies must follow judicially established administrative law requirements of decisional consistency and stare decisis. “Patently inconsistent application of agency standards to similar situations lacks rationality and is arbitrary.” <FN 61> The requirements of decisional consistency and stare decisis apply to decisions of administrative agencies as a part of the general administrative law requirement of “reasoned decision-making,” under which an agency must provide a clear and persuasive rationale and substantial support in the administrative record for change from a prior decision. <FN 62> A change in position must be justified by a “reasoned analysis” that explicitly addresses prior precedent and demonstrates a sufficient basis in the facts of record for the change. <FN 63>

Absent a clear, factually well-supported justification for changing course, an agency’s decision to depart from its prior decisions will be invalidated by the courts. <FN 64> In the specific context of § 316 of the Clean Water Act (“CWA”), the requirement of decisional consistency has been recognized in several permitting decisions. For example, USEPA has found that an applicant is entitled to renewal of a Section 316(a) variance on a showing that (1) plant operating conditions and load factors are unchanged and are expected to remain so for the life of the new permit; (2) there are no changes to plant discharges or other discharges in the vicinity; and (3) there are no material changes in the biotic community likely to be affected. <FN 65> Changes that would be considered significant include “increased discharge volumes, increased thermal loading, change to design conditions and change to stream designation or documentation.” <FN 66> USEPA Region V has also recognized that §316(a) variances should be renewed in the absence of any material change. <FN 67>

USEPA has acknowledged that the language of § 316(b) can be interpreted to allow for site-specific decision-making but has determined that the language of § 316(b) also can be interpreted to allow a technology-based approach. <FN 68> Although USEPA uses the Chevron analysis to justify its departure from 30 years of decisional consistency, the Agency does not provide a reasoned basis for this changed interpretation as required by previous judicial decisions. <FN 69> USEPA claims that absolute deference to its current interpretation is required because the Congressional mandate is ambiguous and USEPA provides judicial citations purportedly supporting that claim. <FN 70> Even if the Congressional mandate were determined to be ambiguous, the judicial citations provided by USEPA demonstrate just the opposite ¾ that agency deference is only appropriate where there is a final determination on the merits of the changed position. <FN 71> Because there is no final determination of the changed position, the proposed rulemaking is more akin to a policy statement and may be entitled to respect <FN 72> but does not rise to a level requiring deference.

Implement a site-specific alternative

THE ESTABLISHED AND LONG-STANDING INTERPRETATIONS OF SECTION 316 OF THE CLEAN WATER ACT BY USEPA ARE CONSISTENT WITH THE ACT, REASONABLE, AND ACCORDINGLY ARE CONTROLLING

Section 316(b) has been successfully implemented on a site-specific basis for almost 30 years, using the population or community metric for determining AEI. The legislative history of § 316(b) indicates the intent of Congress for § 316(b) to be applied on a site-specific basis and that impacts be evaluated on a “population” level. The statutory words, “location”, “design”, “construction”, and “capacity”, require a site-specific evaluation. The regulations, development documents, and regulatory guidance provided by USEPA have required a site-specific approach for implementation of § 316(b) and that a population, community, or ecosystem-level assessment of the impacts is required to determine if they are “adverse”. Permitting decisions, many of which have been upheld by courts, have applied the requirements of § 316(b) on these bases. The principle of stare decisis requires continuity of an interpretation absent a compelling and reasoned basis for a change. These factors all support the continued implementation of § 316(b) on a site-specific basis and a definition of AEI that requires a population, community, or ecosystem-level assessment when determining the existence of any adverse environmental impacts. PSEG supports this approach.

EPA Response

EPA disagrees. The Agency is not bound by its previous implementation of section 316(b). See also the preamble and supporting documents.

Review of EPA's Biological Loss Estimates for Salem Generating Station

presented in

U.S. EPA Case Study Analysis for the Proposed Section 316(b) Phase II Existing Facilities Rule (EPA-821-R-02-002. February 2002)

Delaware Estuary Case Study

Prepared for PSEG Services Corporation, Newark, NJ

Prepared by Douglas G. Heimbuch, Ph.D., PBS&J, Beltsville, MD

3/05/02

I. Introduction

In its report entitled "Case Study Analysis for the Proposed Section 316(b) Phase II Existing Facilities Rule", (EPA-821-R-02-002. February 2002)" ("CSA" report), United States Environmental Protection Agency ("EPA" or the "Agency") claimed (Table B4-16, Chapter B4) that the average annual economic losses due to impingement and entrainment ("I&E") at PSEG Nuclear LLC's ("PSEG") Salem Generating Station ("Salem") were between $13.1 million and $27.1 million. EPA based this claim on its estimates of the yield lost to the commercial fishery (pounds of fish), reduction in recreational catch (numbers of fish), production foregone, and its estimates of the economic value (dollars per pound or per fish) of commercial landings, recreational catch and production foregone. EPA attributed over 98% of its estimate of economic losses to the effects of entrainment.

This report presents a review of the methods EPA used to estimate yield lost to fisheries (in pounds of fish and in numbers of fish), and production foregone due to entrainment at Salem. The purpose of the review is to identify methods and data selected by EPA that had the potential of producing estimates of losses at Salem that were biased high. This report also compares EPA's estimates of these quantities to corresponding estimates that were presented in PSEG's 1999 Salem Permit Renewal Application ("1999 Application"), or if not presented in the Application that are consistent with methods used in the Application.

A. Overview of EPA's Methods and Estimates

The estimates of economic losses due to entrainment that are presented in CSA Table B4-16 are the sum of estimates of economic losses to the commercial fishery, the recreational fishery, and estimates of economic losses attributable to the loss of non-use values and to lost forage (see CSA Table B4-15). <FN 1> EPA's estimates of the economic losses to the commercial fishery are based on its estimates of the yield lost to the commercial fishery (in pounds) and the commercial value of a pound of fish (see CSA Table B4-9). EPA's estimates of the economic losses to the recreational fishery are based on its estimates of the reduction in recreational catch and the recreational value of the catch of an additional fish (see CSA Table B4-7). EPA's estimates of the loss of non-use values are based on its estimates of the economic losses to the recreational fishery (i.e., EPA assumed nonuse value was equal to 50% of recreational value), and hence on its estimates of the reduction in recreational catch. EPA's estimates of the economic losses attributable to lost forage are based on its estimates of production foregone (in pounds) and the economic value of a pound of production (see CSA Table B4-12 and B4-14).

In summary, the biological parameters that formed the basis of EPA's economic assessment for Salem were its estimates of yield lost to the fishery (see CSA Table B4-3 and Table B3-16, reduction in recreational catch (see CSA Table B4-3), and production foregone (see CSA Table B3-17). EPA derived its estimates of reduction in recreational catch from its estimates of yield lost to the fishery (in pounds):

Because the economic evaluation of recreational yield is based on numbers of fish rather than pounds, foregone recreational yield was converted to numbers of fish. This conversion was based on the average weight of harvestable fish of each species. (CSA page B4-2)

EPA's estimates of yield lost to the fishery are the product of its estimates of age-1 equivalents (see CSA Table B3-15) and its estimates of yield per recruit (i.e., yield per age-1 fish).

This review focuses on EPA's estimates of the parameters underlying yield lost to the fishery and reduction in recreational catch (i.e., age-1 equivalents and yield per recruit) and on EPA's estimates of production foregone.

B. Report Organization

EPA's method for estimating each of the key component biological parameters (i.e., age-1 equivalents, yield per recruit ("YPR"), and production foregone) on which the economic assessment was based is reviewed in the following sections. Section II presents a review of EPA's methods and estimates of yield foregone, and the component parameters: age-1 equivalents and YPR. Section III presents a review of EPA's methods and estimates of production foregone. Section IV presents a summary and overall conclusions.

II. Yield Foregone

A. Age-1 Equivalents

EPA based its estimates of age-1 equivalents on lifestage-specific loss estimates (see CSA Table B3-6) from Appendix L of PSEG's 1999 Application, which EPA adjusted for its assumption that no entrained fish survive (see CSA Table B3-7). EPA then estimated age-1 equivalents given its adjusted estimates of lifestage-specific losses and, for representative important species ("RIS"), lifestage-specific natural mortality rate estimates from Appendix L of the Application (see CSA

Appendix B2). For non-RIS, EPA selected lifestage-specific natural mortality rate estimates from the literature (CSA Appendix B2).

1. Lifestage-Specific Loss Estimates

a. EPA's Method

EPA's estimates of lifestage-specific losses were based on the assumption that no entrained organisms survive: "Salem's entrainment survival factors were eliminated for all analyses (Tables B37 through B3-10) because EPA found insufficient justification in Salem's 1999 Application for their use." (CSA page B3-27)

Whether or not the Application provided adequate documentation regarding entrainment survival, the existence of entrainment survival has been demonstrated by many independent studies (EPRI, 2000). EPA's assumption of no entrainment survival clearly introduces biases into its estimates of estimates of losses. Furthermore, EPA's assumption that no entrained organisms survive is inconsistent with facts noted by EPA in its Preamble to the Proposed Phase II Rule for 316(b) (Federal Register, Vol. 67, No. 68, p 17136):

The mortality rate of entrained organisms varies by species and life stage entrained. Naked goby larvae demonstrated mortality rates as low as 2 percent whereas bay anchovy larvae mortality rates were as high as 97 percent.

To produce entrainment loss estimates that reflected its assumption that no entrained organisms survive, EPA adjusted the entrainment loss estimates for Salem from Appendix L of the Application (which accounted for the effects of entrainment survival). For each species, EPA deduced the average entrainment survival rate that had been applied in PSEG's 1999 Application (memorandum dated 5/28/02 from Liz Strange and Dave Cacela, Stratus Consulting, Inc. to Lynne Tudor and Tom Wall, U.S. EPA). EPA then used its deduced survival rate estimates to adjust the loss estimates presented in Appendix L of the Application to produce estimates that assumed no survival of entrained organisms.

b. Comparison of EPA and PSEG Estimates

EPA's adjusted estimates of entrainment losses (see CSA Table B3-7) are biased high due to its erroneous assumption of no entrainment survival. The likely magnitude of the bias is depicted in Figure 1, which compares EPA's loss estimates to PSEG's loss estimates, which were based on the best available estimates of entrainment survival rates (see Appendix F, Attachment F-2, Section III.C.4 and Tables 12 and 13 of PSEG's 1999 Application).

2. Estimates of Age-1 Equivalents

a. EPA's Method

EPA computed species-specific estimates of the number of age-1 equivalents based on the lifestage-specific loss estimates for each species. For each lifestage that experienced losses at Salem, EPA estimated the equivalent number of age-1 fish (i.e., if the fish had not been lost to entrainment at Salem, how many would have survived to be 365 days old). EPA then summed the age-1 equivalents over all lifestages to produce its estimate of the age-1 equivalents of the losses for the species.

For each lifestage, EPA estimated age-1 equivalents using the following formula to translate the lifestage-specific loss into the age-1 equivalents (see CSA Chapter A5, equations 4 and 5):

[see hard copy for equation]

This formula assumes that for every lifestage, the loss occurs sometime in the middle of the lifestage. For some species and lifestages this assumption is not valid and introduces a large bias.

For example, EPA estimated the age-1 equivalent striped bass in 1993 to be 4.1 million fish (CSA Table B3-8), which were mostly due to entrainment of the juvneile-1 lifestage. EPA's method treated the losses of juvenile-1 striped bass as if they occurred sometime in the middle of that lifestage which lasts 130 days, roughly from week 25 through week 43 (roughly the last week of June through the last week of October). EPA's estimate for the fraction of striped bass that would survive the entire juvenile-1 lifestage (of 130 days) is 10.3% (see CSA Appendix B2, Table B2-10). However, since EPA assumed that the entrainment losses occurred sometime in the middle of the juvenile lifestage, EPA set the survival rate from (its assumed) time of entrainment to the end of the juvenile-1 lifestage to 18.7% (i.e., the value of   in this example) to reflect its assumption that the time spent from the date of entrainment to the end of the juvenile-1 lifestage was substantially less than the full lifestage duration of 130 days.

However, the actual entrainment data show that the losses occurred at the beginning of the juvenile-1 lifestage (Figure 2), around week 25. Therefore, the actual duration from the date of entrainment to the end of the juvenile-1 lifestage was approximately 130 days (the full lifestage duration). Therefore the survival rate for the full lifestage duration, i.e. 10.3%, should have been applied. Using the correct survival rate of 10.3% would have produced an estimate of 2.3 million age-1 equivalents (still assuming no entrainment survival). The effect of EPA's erroneous assumption was to cause its estimate (of 4.1 million age-1 equivalents) to be 1.8 times as large as it should have been.

EPA's method apparently was patterned after PSEG's approach for estimating age-1 equivalents of entrained eggs and larvae, which took into account the fact that the ages of entrained eggs and larvae are not known (Appendix F, Attachment F-2, Section III.E). However, EPA erroneously applied the method to all age-0 lifestages, including juveniles. In the Application, the entrainment loss during a juvenile lifestage was assumed to occur at the beginning of the lifestage. This assumption was made because as juvenile fish grow, their susceptibility to entrainment declines quickly. For example, the average (over all years with springtime entrainment sampling and recorded entrainment of juvenile striped bass, through 1999) midpoint week of occurrence of juvenile striped bass entrainment was week 25, and in no year were juvenile striped bass observed in entrainment samples after week 28.

b. Comparison of EPA and PSEG Estimates

The likely magnitude of the bias introduced by EPA's erroneous assumption regarding the date of entrainment of juvenile fish is depicted in Figure 3 which compares PSEG's estimates of age-1 equivalents (which are based on loss estimates that include terms for entrainment survival) to corresponding estimates of age-1 equivalents based on EPA's formula (and PSEG's loss estimates that include terms for entrainment survival).

The cumulative effects on estimates of age-1 equivalents of EPA's erroneous assumption regarding the date of entrainment of juvenile fish and EPA's erroneous assumption that no entrained fish survive, are depicted in Figure 4. Figure 4 compares PSEG's estimates of age-1 equivalents to the estimates of age-1 equivalents that EPA listed in CSA Table B3-15. EPA's estimates are severely biased high.

B. Yield per Recruit

1. EPA's Method

EPA's formula for estimating yield lost to the fishery does not explicitly include a term for YPR. However, the formula EPAused to estimate age-1 equivalents can be shown to be equivalent to the product of 1) age-1 equivalents and 2) YPR. In CSA Chapter A5, EPA lists its formula (equation 7) for estimating yield lost to the fishery as:

[see hard copy for equation]

However, this reviewer was unable to reproduce EPA's tabulated results (CSA Table B3-8) using this equation, which is not the standard equation for computing yield to a fishery (e.g., see Ricker, 1975). However, the following equation, which is the standard formulation (Ricker, 1975), does reproduce EPA's results (EPA's documentation apparently contains a typographical error):

[see hard copy for equations]

2. Comparison of EPA and PSEG Estimates

Parameter estimates (for mortality rate and average weight at age) from CSA Appendix B2 and this formula for YPR produce the YPR estimates in Table 1. Also listed in Table 1 are YPR estimates from PSEG's 1999 Application. EPA's estimates are consistent with those from the Application.

III. Production Foregone

A. EPA's Method

1. Algebraic Formulation

EPA's estimates of production foregone are based on the method by Rago (1984):

[see hard copy for equations]
[Rago's equation (3)]
[Rago's equation (4)]

On page 85 of Rago's paper, he extends his method to address lifestage-specific estimates: "By adding a subscript to P, G, Z and B, we can calculate production of a particular age or size class (i). Thus:

[see hard copy for equation]

However, EPA apparently misinterpreted Rago's formula for production foregone and applied it incorrectly to the data. EPA used the following formula (CSA Chapter A5, equation 8):

[see hard copy for equation]

EPA's error was that it used the average (over the duration of the lifestage) weight per fish for the parameter Wi. Whereas in Rago's formula, the parameter Wi (referred to as in Rago's equation (5)) represents the average (over individuals within the population) weight per fish at the beginning of the lifestage. EPA's misuse of Rago's equation produces overestimates of production foregone because the average weight for the entire lifestage is greater than the weight at the beginning of the lifestage.

2. Input Parameter Values

In addition to its misuse of Rago's formula, many input parameter values (i.e., value of Gi and Wi) that EPA used for its estimates of production foregone are seriously flawed.

a. Lifestage-specific Weights for Age-0 Fish

EPA claims to have estimated the average weight per fish for all age-0 lifestages (i.e., egg, yolk-sac larvae, post yolk-sac larvae and juveniles) by extrapolation from the weight of fish at age-1 (see CSA Appendix B2). In the CSA, EPA did not provide documentation for its method of extrapolation, however, in response to questions from this reviewer, EPA did explain its method (document entitled "RESPONSE TO UWAG QUESTIONS RE: PHASE II PROPOSAL RECORD -- Revised July 3, 2002"). EPA assumed that the difference in weight between any two successive lifestages (within the interval between eggs and age 1) was the ratio of (1) the average of the weight of an egg and the weight of an age-1 fish, and (2) the number of lifestages between egg and age 1:

[see hard copy for equation]

EPA provided no justification for this method of interpolation, which appears to have no basis in biological fact or theory.

Estimates of lifestage-specific weights based on EPA's method of extrapolation (presented in CSA Appendix B2) are simply not realistic. For example, EPA estimated the average weight of post yolk-sac larvae striped bass to be 0.194 pounds (CSA, Appendix B2 Table B2-10). It is more likely that post yolk-sac larvae striped bass weigh less than 0.0001 pounds (based on the length-weight relationship from Bason (1971) and life stage-specific entrainment lengths from Appendix L, Tab 11 of the Application).

EPA's extrapolated estimates of the average weights of age-0 fish (which EPA used in its estimates of production foregone) are not scientifically valid and generally are biased high (e.g., see Table 2).

b. Lifestage-specific Growth Rates

Although not documented in its CSA report, EPA's response (document entitled "RESPONSE TO

UWAG QUESTIONS RE: PHASE II PROPOSAL RECORD -- Revised July 3, 2002") to questions from this reviewer indicated that EPA estimated the instantaneous growth rate (Gi) using the following relationship:

[see hard copy for equation]

which is valid when Wi and Wi+1 represent the weight per fish at the beginning of lifestages i and i+1, respectively (e.g., see equation (7a) in Rago, 1985). However, EPA apparently used the average weight values listed in CSA Appendix B2, which are average weights for the lifestages (not beginning weights).

Furthermore, for age-0 lifestages, the average weights EPA used in its computation of growth rates apparently were the invalid interpolated values listed in CSA Appendix B2. Therefore, even if it had correctly computed growth rates (e.g., using a formula that relates growth rates and average weights), EPA's growth rate estimates would have been erroneous because the estimates of average weights (used as inputs) were not valid.

B. Comparison of EPA and PSEG Estimates

In PSEG's 1999 Application for Salem, estimates of production foregone were presented for bay anchovy and for non-RIS forage species using the methods described in Appendix F, Attachment F-4, Section I.E.1. The estimated production foregone (due to entrainment) for the Basecase Scenario <FN 2> for bay anchovy was estimated to be 546,000 pounds per year (Appendix F, Attachment F-4, Table 11 of the Application), and the Basecase Scenario production foregone (due to entrainment) for non-RIS forage species was estimated to be 39,000 pounds per year (Appendix F, Attachment F-4, Table 11 of the Application).

EPA's estimate of production foregone for bay anchovy (average for 1978-1995, 1997 and 1998) is 7,044,000 pounds per year (CSA Chapter B3, Table B3-17), and its estimate of production foregone for non-RIS forage species (average for 1995-1998) is 419,000 pounds per year (CSA Chapter B3, Table B3-17).

Both EPA and PSEG used natural mortality rate estimates from Appendix L, Tab 18 of the Application. Also, Both EPA and PSEG assumed that mortality rates and weights at age for non-RIS forage were the same as for bay anchovy. However, the production foregone estimates in the Application were based on estimates of weight at the beginning and end of each lifestage (Table 2), whereas EPA's estimates of production foregone were based on its estimates of average lifestage-specific weights (Table 2). For each age-0 lifestage, EPA's estimates of average weight greatly exceeds (sometimes by orders of magnitude) PSEG's estimate of the maximum weight for the lifestage.

The errors in EPA's method for estimating production foregone and its errors in input parameter values cause its estimates to be severely biased high (Figure 5). If Rago's equation is correctly applied and if reasonable beginning and ending weights for age-0 lifestages (e.g., the weights in Table 2) are used rather than EPA's extrapolated values, the estimate of production foregone for bay anchovy would be 631,000 pounds (9% of EPA's reported estimate of 7,044,000 pounds), and the estimate for non-RIS forage would be 30,000 pounds (7% of EPA's reported estimate of 419,000 pounds).

IV. Summary

This review of EPA's methods for estimating yield foregone and production foregone due to entrainment at Salem identified several serious errors in EPA's methods that cause EPA's estimates to be biased high.

EPA's estimates of yield foregone (which is the product of the number of age-1 equivalent fish and the yield per recruit) are flawed because it (1) incorrectly omitted the effects of entrainment survival on lifestage-specific loss estimates and (2) used overestimates of juvenile survival (from the date of entrainment to the end of the juvenile lifestage) in its estimates of age-1 equivalents. The cumulative effect of these errors generally was to cause EPA's estimates of age-1 equivalents (and hence yield foregone) to be biased high. For weakfish, striped bass, Atlantic croaker and spot (the four species examined in the Application that had the highest estimates of yield foregone), EPA's estimates were 54%, 119%, 454% and 536%, respectively, higher than PSEG's estimates (which accounted for entrainment survival and the fact that juvenile entrainment generally occurs early in the lifestage).

EPA's estimates of production foregone are flawed because it (1) incorrectly applied the formula for computing production foregone (from Rago, 1984), (2) used invalid estimates (based on its extrapolation method) of average lifestage–specific weights of age-0 fish, (3) incorrectly applied the formula for computing growth rates from initial weights of fish in successive lifestages, and (4) derived invalid estimates of growth rates based on its invalid estimates of average lifestage-specific weights of age-0 fish. The cumulative effect of these errors for bay anchovy and non-RIS forage species was to cause EPA's estimates of production foregone to be biased high. For bay anchovy, EPA's estimate was 1016% higher that it would have been without these errors, and for non-RIS forage, EPA's estimate was 1297% higher than it would have been.

[see hard copy for appendices/tables/figures]

Table 1. Comparison of EPA's estimates of yield per recruit ("YPR") and PSEG's estimates of YPR that were used in its estimates of pounds lost to the fishery that were presented in the Application.

Table 2. Comparison of weights at age for age-0 bay anchovy that were used in estimates of production foregone. EPA's extrapolated estimates are from CSA Appendix B2, Table B2-5. PSEG's estimates are based on a length-weight regression and average length of fish by lifestage (length-weight relationship from Derickson and Price (1973) and life stage-specific entrainment lengths from Appendix L, Tab 11 of the Application).

Figure 1. Comparison of EPA's and PSEG's estimates of average annual entrainment losses. EPA's estimates assume no entrained fish survive. PSEG's estimates are from Appendix L, Tab 9 of the Application (reproduced in CSA Table B3-6). EPA's estimates are from CSA Table B3-7. Abbreviations: Atlantic croaker (AC), American shad (AS), alewife (AW), blueback herring (BH), striped bass (SB), spot (SP), weakfish (WK), white perch (WP).

Figure 2. Observed density of juvenile 1 striped bass in entrainment samples at Salem in 1993 (the year with EPA's highest estimate of age-1 equivalents for striped bass (CSA Table B3-8)).

Figure 3. Comparison of EPA's and PSEG's methods for estimating age-1 equivalents. All estimates depicted in this figure are based on PSEG's estimates of entrainment losses (i.e., the estimates include terms for entrainment survival). The differences between the PSEG and EPA estimates are due to EPA's assumption that entrainment losses of juvenile fish occur in the middle of the juvenile lifestage. Abbreviations: Atlantic croaker (AC), American shad (AS), alewife (AW), blueback herring (BH), striped bass (SB), spot (SP), weakfish (WK), white perch (WP).

Figure 4. Comparison of EPA's and PSEG's estimates of age-1 equivalents. This figure shows the cumulative effect of EPA's erroneous assumption regarding the date of entrainment of juvenile fish and EPA's erroneous assumption that no entrained fish survive. PSEG's estimates of age-1 equivalents were computed using the methods described in Appendix F, Attachment F-4 of the Application. EPA's estimates are from CSA Table B3-15. Abbreviations: Atlantic croaker (AC), American shad (AS), alewife (AW), blueback herring (BH), striped bass (SB), spot (SP), weakfish (WK), white perch (WP).

Figure 5. Comparison of EPA's and PSEG's estimates of production foregone for bay anchovy and non-RIS forage. PSEG's estimates are from Appendix F, Attachment F-4 of the Application and represent the Basecase Scenario . EPA's estimates for bay anchovy represent an average for 1978-82, 1985-95, 97 and 98. EPA's estimates for non-RIS forage species represent an average for 1995-98. The estimates labeled "Rago Model" were computed using the formula in Rago (1984), correctly applied to PSEG's weight-at-age estimates (beginning and ending weights) for bay anchovy.

Footnotes

1 PSEG's review of EPA's assessment of economic losses and benefits valuations are addressed in a separate report prepared by NERA, Inc. under the direction of David Harrison, Ph.D.

2 In the 1999 Salem Permit Application, PSEG defined a Basecase Scenario for Salem operation. The Basecase Scenario assumed that the withdrawal rate of each of the 12 CWS pumps was 175,000 gpm during normal operation, and that during scheduled outages 7 CWS pumps ran at 175,000 gpm (Appendix F, Attachment F-4 of the Application). The average cooling water withdrawal for this scenario is roughly 3,024 mgd.

EPA Response

Regarding entrainment survival, please see Chapter A7 of Part A of the Phase II Regional Study Document (DCN #) and response to Comment 316bEFR.306.506. Salem did not provide the Agency with convincing evidence that entrainment survival occurs at Salem.

Regarding EPA's calculation of production foregone, several commenters have raised questions about the EPA calculations of production foregone, primarily with regard to the values of stage-specific fish weights. These commenters have indicated that in some cases the weight parameters used by EPA may lead to overestimation of production foregone. Some commenters have also questioned inconsistencies between values used for the same species occurring in different regions, and apparent discontinuities in weights between early life stages.

Through the course of reviewing public comments on the initial case studies and later comments on the NODA, EPA has reviewed and revised many of the weight parameters. EPA relied upon numerous published records, local experts, and other resources to develop weight estimates. Following suggestions of commenters, EPA also revised some of its approximation methods, including the use of volumetric methods to improve estimates of egg weights.

Some commenters indicated that the mathematical definition used to calculate estimates of foregone production require weights that represent the beginning and the end of each life stage. EPA acknowledges that while this is ideal, such data are seldom available. In fact, the weight parameters used by EPA in its analyses include a variety of types of values, some of which are unknown because in some cases the I&E monitoring documents are not explicit about whether the values represent weights for the beginning, the end, or midpoints of particular stages. This issue is also complicated by the fact that some weights in the monitoring documents are determined indirectly through length-weight regression relationships. Length-at-age values found in different literature sources may also represent different parts of a lifestage.

Although such uncertainty is unfortunate, EPA believes that the practical effect on the benefits estimation is negligible. EPA disagrees with the characterizations put forth by some commenters that accuracy of these estimates are of vital importance to the benefits estimates. EPA notes that the benefits assessment does not directly value production foregone, per se. Production foregone estimates are used only in the context of the trophic transfer model which is used only to generate estimates of incremental foregone yield attributable to losses of forage species. The portion of the total benefits associated with the trophic transfer pathway is quite small, usually less than 2 percent of the total within any particular region. Thus, even if the commenter was correct that the analysis inflated estimates of production foregone and caused the trophic transfer model to overestimate foregone yield, the practical effect on the total benefits estimate would be very small.

Benefit Estimation Methodology

ATTACHMENT 4

ECONOMIC EVALUATION OF THE DELAWARE ESTUARY CASE STUDY IN THE U.S. ENVIRONMENTAL PROTECTION AGENCY'S 316(B) EXISTING FACILITIES BENEFITS CASE STUDIES

Prepared for PSEG
August 2002

EXECUTIVE SUMMARY

This report reviews and evaluates economic issues in the case study prepared by Abt Associates, Inc. ("Abt") for the U.S. Environmental Protection Agency ("EPA") to measure the economic benefits of reducing impingement and entrainment ("I&E") at in-scope cooling water intake structures ("CWIS") within the Delaware Estuary (hereafter "Delaware Case Study"). <FN 1> The Delaware Case Study is significant in part because it is used as the basis for the EPA's estimates of the national benefits of its proposed requirements for existing facilities under Section 316(b) of the Clean Water Act. But the Delaware Case study—along with the other case studies—is perhaps even more important because its methodologies might provide models for preparation or review of benefit-cost assessments in individual 316(b) permit applications.

Although EPA's initial approach to benefit estimation is sound—since the approach is based upon an "effect by effect" procedure to develop total benefits as the sum of individual components—many of the specific methodologies and data EPA uses to develop the individual components have major flaws. Many of the methodologies and applications are inconsistent with EPA's recent guidelines for preparing economic analyses (U.S. EPA 2000), with the Office of Management and Budget's ("OMB") guidelines for economic assessments (OMB 2000), and with basic economic textbooks on environmental benefit assessment (e.g., Freeman 1993). Since the specific methodologies are critical to developing economically sound benefit values, these flaws in the EPA methods make the estimates in the Delaware Case Study inadequate bases for national benefit estimates and inadequate guides for evaluating individual benefit-cost assessments.

To summarize, we find the following:

1. EPA's commercial benefit estimates are substantially overstated because of mischaracterizations of the empirical studies used in the assessment.
2. EPA's recreational benefit estimates are suspect because of the use of an overly simple benefit transfer method and a flawed RUM study.
3. EPA's nonuse benefits have no conceptual or empirical support.
4. EPA's forage fish benefits are overstated by including a flawed methodology—the replacement cost approach—as one of the two methods.

The following are specific evaluations of the methodologies EPA uses for the four individual components in the Delaware Case Study. <FN 2> To provide a sense of perspective on their relative empirical importance, Figure ES- 1 shows the percentages of overall benefits at Salem accounted for by each of the four categories.

Figure ES- 1. Summary of EPA-Estimated Losses at Salem by Category
[see hard copy for figure]

A. EPA's Commercial Benefit Estimates Are Substantially Overstated Because of Mischaracterizations of the Empirical Studies Used in the Assessment

Benefits due to projected increases in commercial catch represent the largest of the four categories, accounting for about 64 percent of overall benefits in the Delaware Case Study. EPA calculates commercial benefits by first using ex vessel prices and added catch for the various commercial species to determine the added gross revenues to commercial fishermen. Citing various empirical studies, EPA then argues that the added producer surplus represents 40 percent to 70 percent of gross revenues; using EPA's approach the mid-range value is 55 percent (i.e., gross revenues are multiplied by 0.55). Then, citing two other studies as well as a personal communication, EPA claims that producer surplus represents 22 percent of the total "multi-market" welfare—including producers, wholesalers, processors, retailers and consumers — and thus that the producer surplus estimates should be multiplied by 4.5 to obtain an estimate of "total surplus." The net result is that EPA's estimate of commercial fishing benefits is equal to about 2.5 times the added gross revenues to commercial fishermen (0.55 x 4.5 = 2.48).

1. EPA's ex vessel commercial fish values can be confirmed

EPA's estimates of the ex vessel values appear to be reliable. The values, which range from $0.11 per pound for alewife to $3.18 per pound for striped bass, appear to be accurate estimates of the average values for ex vessel prices in New Jersey and Delaware. Although the range of certain species suggests that affected fish would be caught in other areas, these state values are representative. Note that EPA's use of prevailing ex vessel prices assumes that I&E at Salem—and the other in-scope facilities—does not affect the market prices of commercial fish. This assumption seems sensible in light of the large overall market for fish; note however, that EPA's use of the 4.5 multiplier contradicts this assumption by implying a substantial change in price.

2. EPA's estimates of producer surplus benefits (mid-range equal to 55 percent of gross fishing revenues) are not supported in the literature that EPA cites; this literature suggests a mid-range value of at most 15 percent of gross fishing revenues and likely one that would "tend toward zero"

The literature that EPA cites does not support its estimates that Delaware fishermen would gain between 40 percent and 70 percent of the gross fishing revenues as additional producer surplus in the long run. It is well established in the economic literature (see, e.g., Freeman 1993) that in open access fisheries, there is a tendency for producer surplus to be driven to zero. This "tragedy of the commons" means that commercial fishermen would not receive any additional producer surplus from reduced I&E at Salem; all of the potential gains would be dissipated by additional fishing effort.

The studies that EPA cites show substantial gains to fishermen, but these studies relate primarily to short-term gains that do not take into account the long-term factors that operate in commercial fisheries. Moreover, to the extent that the studies indicate some special circumstances that might mitigate these effects—such as entry restrictions—they relate to West Coast and Great Lakes fisheries rather than the East Coast. Indeed, the study that EPA relies on for the “4.5 multiplier” (Norton et al. 1983) points out that producer surplus was in fact zero for fishermen in the southern part of the Atlantic fishery—net costs were equal to net revenues. Strand (2002), who is also one of the co-authors of Norton et al. (1983), notes that the study found the overall producer surplus for East Coast striped bass fishermen to be about 15 percent of gross revenues.

3. The studies cited by EPA do not support the “multi-market” multiplier (4.5) used by EPA to translate changes in producer surplus to fishermen into changes in total producer and consumer surplus

The “multi-market” multiplier of 4.5 is not supported in the studies cited. The only East Coast study cited is Norton et al. (1983), which reports information on the total surplus to retailers and consumers as well as the total surplus to commercial fishermen in the striped bass fishery. Although the ratio of these two values is 4.5, there is no indication in the report that it would be valid to use that ratio to estimate additional consumer and retailer surplus for changes in the fishery. Indeed, as Strand—one of the authors of the study—notes, this is “an extraordinarily odd procedure indeed.” (Strand 2002). EPA claims that the multiplier of 4.5 also is derived from empirical work by Richard Bishop and others on the Great Lakes, including a draft report that is not available for distribution. The study that is available does not appear to include the specific empirical results cited by EPA. In any event, these studies relate to the Great Lakes and thus are not relevant to the East Coast.

4. EPA provides no evidence to support a claim that consumers would benefit from the changes in commercial catch through lower prices

Consumers could in theory gain from additional commercial fish made available through reduced I&E at Salem, but only if the changes were sufficient to affect the market price. EPA has presented no information on the relevant market for commercial fish and the relative importance of I&E losses. Changes in I&E at Salem seem small relative to the volume of commercial fish in the East Coast fish markets, suggesting that there will not be a change in the market price and thus no consumer surplus gains from I&E changes.

5. Overall, the evidence suggests that mid-range commercial benefits are equal to 15 percent or less of gross fishing revenues, indicating that EPA overstates the likely long-run economic benefits by at least a factor of 16

The available evidence on conditions in the East Coast suggests that the economic benefits—measured as producer and consumer surplus gains—will be small due to reduced I&E at Salem. Certainly, there is no conceptual or substantial empirical support for the claim that benefits would be equal to almost 2.5 times the value of the gross increase in revenues to fishermen. If gains to fishermen were 15 percent of the gross increase—as suggested by the one East Coast study noted by EPA in its discussion of commercial benefits—the long-run benefits would be less than one-sixteenth of the value reported by EPA in the Delaware Case Study.

B. EPA's Recreational Benefit Estimates Are Suspect Because They Rely on an Overly Simple Benefit Transfer Method and a Flawed RUM Study

EPA applied a benefit transfer approach to estimate recreational losses from several "representative important species" due to I&E at Salem and other in-scope and out-of-scope facilities in the Delaware Estuary. EPA also developed a random utility model ("RUM") analysis of recreational fishing benefits from reduced I&E to estimate recreational losses associated with two species—weakfish and striped bass. EPA's comprehensive benefit estimate adopts the RUM estimates for weakfish and striped bass and the benefit transfer estimates for the other species.

1. EPA's use of benefit transfer to value recreational fishing benefits is sound

Benefit transfer is an appropriate methodology for developing estimates of the potential recreational fishing benefits from changes in I&E at Salem or any other CWIS. As the EPA Guidelines note,

"[t]he advantages of benefit transfer are clear. Original studies are time consuming and expensive; benefit transfer can reduce both the time and financial resources needed to develop benefit estimates" (U.S. EPA 2000, p. 86).

Although the Delaware Case Study is not clear on precisely why the studies used for the benefit transfer were chosen or why others were not used, the four studies provide values for similar areas and species; all four studies relate to species affected by Salem I&E and to recreational fishing along the Atlantic coast.

2. EPA uses an overly simple application of the benefit transfer method

Although EPA's decision to use benefit transfer itself is sound, the technique EPA uses to transfer the benefits is not one that is recommended by EPA Guidelines. EPA's analysis applies a point estimation approach to transfer a range of values developed in other studies and to develop a low and high estimate for each fish species. In discussing this approach, the EPA Guidelines state, "As it is rare that a policy case and study case will be identical, this approach is not generally recommended." EPA's Delaware Estuary Case Study fails to explain why it was selected, and whether other approaches were considered.

3. EPA's RUM study has major flaws

The RUM method is well established as a methodology for evaluating recreational fishing benefits. Such models allow one to estimate the benefits of improving conditions in one fishery relative to other alternatives. It is important, however, that the studies use valid data on the nature of the choices available to anglers, particularly on the differences in the travel costs to the alternative sites anglers might choose.

The RUM model developed by EPA for the Delaware Case Study has substantial inadequacies that suggest that its results are not reliable estimates of the willingness to pay of recreational anglers for I&E changes at Salem. <FN 3> These inadequacies include the following:

-Employing unweighted intercept (angler) data. Over-representation of avid anglers results in biased estimates of the average value of improved fishing opportunities.

-Incorrectly calculating trip costs. Several assumptions bias trip costs upward and thus bias estimates of the value of improved fishing opportunities.

-Inappropriately modeling decisions. Modeling trips in a sequential manner—first the decision to recreate and then the selection of the recreation site—is inferior to modeling these as simultaneous choices.

C. EPA's Nonuse Benefits Have No Conceptual or Empirical Support

Nonuse benefits represent potential benefits not associated with any direct use by individuals or humankind of the Delaware Estuary resources affected by Salem I&E. These benefits are sometimes referred to as passive use values or bequest values if they relate to future generations.

The Delaware Case Study does not include an independent assessment of the potential nonuse benefits affected by Salem I&E. Instead, EPA applied a "rule of thumb" that nonuse benefits would be equivalent to 50 percent of estimated recreational benefits. EPA claims that this is a "long-standing" benefit transfer approach.

1. EPA's 50 percent "rule of thumb" has no basis in the EPA Guidelines or in the economic literature

This rule of thumb has neither conceptual nor empirical support as a valid measure of the willingness to pay of individuals for nonuse effects of I&E at Salem.

-The author of the original article discussing the "rule of thumb" refers to it as a "tenuous empirical basis from which to estimate national nonuser benefits" (Freeman 1979, p. 171). This author does not include the method in his comprehensive treatise on benefit assessment (Freeman 1993).

-Other authors have voiced similar criticisms. Fisher and Raucher (1984), for example, note that "[t]he proportional relationship [the 50 percent rule] is not in the least robust." (p. 47).

-Although some studies have calculated both use and nonuse values and compared the totals, these studies do not evaluate situations that are at all comparable to I&E in the Delaware Estuary.

Thus, the 50 percent rule is not appropriate as a benefit transfer approach to evaluating nonuser benefits for the Delaware Case Study.

2. EPA provides no empirical basis for a claim that changes in I&E at Delaware facilities would lead to any nonuse benefits

EPA provides no information whatsoever on nonuser benefits that might be relevant for I&E in the Delaware Estuary. Indeed, the total discussion of nonuser benefits in the Delaware Case Study (p. B4-11) is only one paragraph. This one-paragraph description is used to explain and justify annual benefits ranging from about $800,000 to $2.7 million per year.

3. Extensive empirical information on the status of the Delaware fishery suggests that there are no

nonuse benefits

Although EPA does not present any information related to nonuse benefits, there is extensive information on the environmental status of the Delaware Estuary that provides insight into the likely importance of this category. The existing literature on nonuse benefits suggests that nonuse values are likely to be significant under two conditions:

1. The resource is unique (e.g., the Grand Canyon); and

2. The losses to the resource are substantial and irreversible (e.g., damming the Grand Canyon).

Detailed studies on the status of the Delaware Estuary and the effects of I&E at Salem indicate that these conditions are not likely to be met for I&E at Salem.

-Historical data indicate a consistent and significant improving trend for growth in the stock of the major species affected by Salem I&E.
-Salem I&E has a negligible effect on the few fish species whose stocks have been declining recently.
-Even the declining stocks are not threatened to fall below key biological reference points.
-Any effects of Salem I&E could be reversed by various measures.

This information suggests that the nonuse benefits associated with I&E at Salem are not significant. Any positive estimate for nonuse benefits should be based on an acceptable study of nonuse effects, consistent with EPA's Guidelines (2000) and on current economic methods (e.g. Freeman 1993), rather than on a crude and inappropriate rule of thumb.

D. EPA's Forage Fish Benefits are Overstated by Including a Flawed Methodology—the Replacement Cost Approach—as One of Two Methods

Forage fish refer to species that are not commercially or recreationally fished. These fish represent prey for other species that are commercially or recreationally fished, and thus provide potential indirect benefits if they increase the numbers of those fish. EPA developed values for forage fish losses at

Salem based on two approaches:

1. Value of production foregone. EPA estimated the value of the recreational and commercial species whose production would be changed as a result of changes in forage fish populations.

2. Replacement cost. EPA estimated the cost of raising fish for stocking to replace the forage fish affected by I&E.

The values are higher using the replacement cost approach.

1. Additional forage fish lead to benefits to the extent that they increase commercial and recreational catch

Changes in forage fish populations can lead to benefits—in the form of additional consumer and producer surplus—if they increase the numbers of commercial and recreational fish. Thus, this is a valid benefit category for the Delaware Case Study. Forage fish represent an example of indirect ecosystem benefits—they provide services that do not directly benefit individuals but rather provide biological services required for services that do benefit individuals.

2. The production foregone method in theory could lead to valid benefit estimates

The production foregone method provides a valid methodology for evaluating the potential indirect benefits of forage fish changes. The validity of the calculations, of course, depends upon the accuracy of the scientific assessments of the linkages between changes in forage fish and changes in the populations of commercial and recreational species.

3. In contrast, the replacement cost method is not an economically valid benefit methodology

Replacement cost is not a valid method of assessing the benefits of changes in I&E at Salem (or anywhere else). The EPA Guidelines provide an extensive list of acceptable benefit assessment methodologies; replacement cost is not among these methodologies, and for good reason.

Hatchery costs provide a measure of the costs of one potential alternative for improving fish populations—stocking additional forage fish. Such stocking may be a worthwhile exercise. But the costs do not provide a measure of the benefits. Indeed, accepting such an approach would make a mockery of benefit-cost analysis. If a project's costs were also used as a measure of its benefits, benefit-cost analysis would suggest all projects had a net benefit of zero.

E. Before Issuing a Final 316(b) Rule, It Is Imperative that EPA Revise the Economic Benefit Methodologies in the Delaware Case Study and Other Case Studies to Correct Serious Deficiencies

It is important that the economic benefit methodologies in the Delaware Case Study be sound, both because they underlie estimates of the benefits of alternative 316(b) regulatory alternatives and because they are likely to be used by applicants and permit writers to evaluate specific 316(b) benefit-cost assessments.

The overall approach in the Delaware Case Study is sound—developing "effect-by-effect" estimates of the potential benefits from reduced I&E at Salem. But the methodologies used for the four effects have serious flaws that should be remedied before the final rule is promulgated.

1. For commercial fishing benefits, EPA should review the empirical foundations and revise its estimates

The commercial fishing benefits in the Delaware Case Study are overstated because they exaggerate the likely consumer and producer surplus associated with changes in the commercial catch. The values do not appropriately acknowledge the long-run tendency for producer surplus to be dissipated, which means that most additional gross ex vessel revenues will not constitute long-term benefits.

More importantly, EPA uses a "multiplier" to translate changes in producer surplus into a total "multi-market" surplus that has no theoretical justification. The validity of such a multiplier would imply substantial reductions in fish prices, but EPA has provided no information to support such a claim.

Indeed, given the relatively small effect that changes in I&E at Salem would have on overall supply, it is unlikely that consumers would receive any additional consumer surplus gains.

EPA should revise its estimated range of potential commercial fishing benefits from Salem I&E to reflect long-term effects on producer surplus (consistent with the newest time frame for the regulatory proposal) and the absence of any effects on fish prices.

2. For recreational fishing benefits, EPA should modify its application of the benefit transfer approach and revise (or ignore) its RUM study

EPA's recreational fishing benefits are based on the benefit transfer approach and a RUM study carried out by EPA. The benefit transfer study should be reevaluated to consider using a more sophisticated approach that would allow the value per fish to vary with individual circumstances. The RUM study—which is used to value two of the relevant species—either should be ignored or should be revised to eliminate (or explain) apparent methodological problems.

3. For nonuse fishing benefits, EPA should discard the estimates derived from the 50 percent rule of thumb

EPA's nonuse benefits are based upon a crude rule of thumb that has no validity and no applicability to I&E changes in the Delaware Estuary. Unless EPA has specific evidence of nonuse benefits associated with changes in I&E in the Delaware Estuary, this category should be eliminated as part of the Delaware Case
Study.

4. For forage fish, EPA should discard the replacement cost method and rely exclusively on the production foregone method

Forage fish can provide benefits because of the effects they have on commercial and recreational species. EPA should base its estimate of benefits on the production foregone method and discard the alternative replacement cost method, which has no conceptual or empirical foundation as a measure of benefits.

[comment text continued in 316bEFR.075.502]

Footnotes

1 This report focuses on economic assessments. A companion report prepared by Douglas Heimbuch, Ph.D., evaluates issues related to the biological benefits assessments in the Delaware Case Study (Heimbuch 2002).

2 Other reports provide additional economic assessments related to the proposed 316(b) regulations. See Desvougues et. Al. (2002), Stavins

3 (2002), and Strand (2002). Harrison et al. (2000) provides an overview of the general economic issues related to 316(b) benefit-cost determination. This section relies upon the analyses in Desvouges et al. (2002).

EPA Response

The comment states that the methods and data EPA employees to estimate the benefits of the regulatory options in the Delaware Estuary case study have major flaws. The comment further states that EPA's methodologies and applications are inconsistent with EPA's recent guidelines for preparing economic analyses (U.S. EPA 2000, DCN #6-1931), with the Office of Management and Budget's ("OMB") guidelines for economic assessments (OMB 2000, DCN #6-3256), and with basic economic textbooks on environmental benefit assessment (e.g., Freeman 1993, DCN #5-1265). The comment concludes that the Delaware Case Study provides "inadequate bases for national benefit estimates and inadequate guides for evaluating individual benefit-cost assessments." EPA disagrees.

EPA's approach to economic analysis of the final Section 316(b) Phase II rule is consistent with principles outlined in the EPA's Guidelines for Preparing Economic Analyses, United States EPA (EPA 240-R-00-003). Moreover, EPA's Guidelines expressly state that they "do not provide a rigid blueprint or a 'cook-book' for all policy assessments ... [and that t]he most productive and illuminating approaches for particular situations will depend on a variety of case-specific factors and will require professional judgment to apply." Id. at p. 2. The Guidelines also recognize that the choices made on how to approach the economic analysis issues in a given situation will necessarily be influenced by factors such as the nature of the issues present, the relevant statutory requirements, the availability of data, the cost and time needed to obtain data, and the need for expedition in taking regulatory actions. Id. at pp. 3, 5 (n. 2), 59, 64. Therefore, EPA's Guidelines for Preparing Economic Analysis are not legally binding and, in fact, allow EPA to use the most up to date approaches to benefit estimation, if applicable.

EPA has changed and improved many of the methods used to estimate benefits for the final Phase II 316b rule. Therefore, a number of the points made in this comment are no longer relevant. Nevertheless, specific concerns regarding EPA's approach to economic analysis of the Section 316(b) Phase II regulation are discussed below.

1. Commercial Fishing Benefits

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment 316EFR.005.029.

2. Recreational Fishing Benefits

For EPA's Response to comments on the methods used to estimate recreational fishing benefits for the proposed Phase II rule, please see the response to comment 316EFR.075.504. For the final Phase II 316b analysis, EPA has reduced its reliance on benefit transfer to estimate recreational fishing benefits. In the recreational fishing analysis, benefit transfer is used for the inland region, and benefit function transfer is used for the North Atlantic region. EPA has estimated RUM models for all other coastal regions (Mid-Atlantic, South Atlantic, Gulf of Mexico, and California), and for the Great Lakes region. Therefore, the comments on benefit transfer presented here are no longer relevant.

The Agency disagrees that its RUM methodology is flawed. EPA does follow standard and generally accepted practices for sampling methodology, calculation of trip costs, and participation modeling. Please see responses to comments #316bEFR.041.452 and #316bEFR.072.058 for details regarding EPA's application of
RUM modeling. In addition, the Agency points out that it revised its RUM analysis to include a larger geographic area as suggested by the commenter. For detail see Chapter D4, RUM Analysis, of the regional study document (DCN # 6-0003).

3. Non-use Benefits

As stated in the NODA, the rule-of-thumb approach to estimating non-use is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. EPA attempted to include non-use benefits categories for the final Section 316(b) Phase II rule analysis. However, Given the unavoidable uncertainties in estimating non-use benefits at the national level, the Agency presented a qualitative assessment of the benefits of the environmental protections at issue in the final 316(b) benefit cost analysis. See Chapters A9, Economic Benefit Categories and Valuation, and A12, Non-Use Meta-Analysis Methodology, in the regional study document prepared for the analysis for the final Phase II rule (DCN # 6-0003)

4. Using Hatchery Costs to Value Forage Species

In the analyses for the NODA and the final rule, EPA no longer uses hatchery costs to estimate impacts on forage species. Instead EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule. See Chapter A5: Methods Used to Evaluate I&E (DCN # 6-0003).

Commercial Fishing Benefits

[comment continued from 316bEFR.075.501]

I. INTRODUCTION

This report reviews the case study developed by the United States Environmental Protection Agency ("EPA") regarding the potential benefits of reducing impingement mortality and entrainment ("I&E") <FN 4> at cooling water intake structures ("CWIS") within the Delaware Estuary ("Delaware Case Study" or "Case Study"). <FN 5> NERA's focus is on the economic issues related to the benefits assessment in the Delaware Case Study. <FN 6>

A. Background

On April 9, 2002, EPA issued a proposed rule ("316(b) Phase II Proposed Rule," 67 FR 17121) that would establish requirements for CWIS for existing power producing facilities with a cooling water intake flow of 50 million gallons per day or more from rivers, streams, estuaries, and other U.S. waters. This proposed rule represents Phase II in EPA's development of regulations to implement Section 316(b) of the Clean Water Act. The proposal involves methodologies for determining the "best technology available" ("BTA") that Phase II facilities with CWIS would be required to adopt in order to minimize I&E of fish and other organisms. The proposed requirements would be implemented through National Pollutant Discharge Elimination System ("NPDES") permits.

As part of its development of the proposed rule and pursuant to the requirements of Executive Order 12866 ("Regulatory Planning and Review") and relevant statutes, EPA prepared an analysis of the benefits and costs of the proposed rule and alternatives. To inform this exercise, EPA also prepared a number of case studies examining the potential benefits of reducing I&E at CWIS in various ecosystems around the U.S. This report examines the Delaware Case Study—which evaluates the effects of I&E at CWIS within the transition zone of the Delaware Estuary and within the scope of the 316(b) Phase II Proposed Rule. The Delaware Case Study is one of several case studies developed by EPA; other case studies are the Ohio River Watershed Case Study, the Tampa Bay Watershed Case Study, San Francisco Bay/Delta Estuary Case Study, the Brayton Point Station Facility Case Study, the Seabrook and Pilgrim Facilities Case Study, the J.R. Whiting Facility Case Study, and the Monroe Facility Case Study.

The remainder of this chapter provides an overview of the Delaware Case Study results, a discussion of the specific objectives of this report, and an outline of the other chapters.

B. Overview of EPA Delaware Case Study Benefit Results

The Delaware Case Study presents results for the four in-scope facilities <FN 7> on the Delaware Estuary as well as separately for PSEG Nuclear LLC's Salem Generating Station ("Salem"). This report focuses on the results for Salem.

Table 1 summarizes the Delaware Case Study midpoint results reported in the Delaware Case Study for Salem. EPA estimates total annualized losses due to I&E at Salem at approximately $23 million per year. The vast majority of the losses (98 percent) are due to entrainment rather than impingement. Note that the values presented in Table 1 are annualized. Using a discount rate of seven percent and a retirement date of 2021 for the Salem plant, these annualized values imply that the present value of losses due to Salem I&E would be approximately $218.1 million (in 2000 dollars).

Table 1. Summary of EPA Midpoint Estimates of Damages due to I&E at Salem Facility
[see hard copy for table]

Figure 1 summarizes the results by loss category for the four categories of economic losses estimated by EPA. Commercial losses account for a substantial majority of the overall losses, representing about 64 percent of the total. Recreational losses are the next largest category, at 24 percent. Forage fish losses account for a very small proportion (0.1 percent) of total losses, and nonuse losses account for the remainder of EPA's estimate.

Figure 1. Summary of EPA-Estimated Losses at Salem by Category
[see hard copy for figure]

C. Objective of this Report

The objective of this report is to evaluate the economic methodologies used by EPA in the Delaware Case Study. <FN 8> In particular, we consider whether the analyses are based upon sound conceptual and empirical methodologies. The criteria for these judgments are based upon the economic literature as well as on recent guidelines for regulatory analyses developed by U.S. EPA (2000), and by the Office of Management and Budget ("OMB") (1996).

Evaluating the soundness of the economic methodology in the Delaware Case Study is important for at least two reasons. First, EPA uses the results of the Delaware Case Study (along with results from the other case studies) to estimate the overall national benefits of the 316(b) Phase II Proposed Rule and various regulatory alternatives. Second, the case study methodologies are likely to be used by applicants and permit writers as guidance for the implementation of benefit-cost analyses to evaluate options for individual permits.

D. Outline of the Report

The report is organized as follows. Chapter II provides a brief overview of benefit-cost analysis and the benefit assessment process, including an evaluation of the extent to which the Delaware Case Study follows EPA guidance in its basic approach. The next four chapters provide assessments of the benefit categories in the Delaware Case Study: Chapter III considers commercial fishing benefits; Chapter IV considers recreational fishing benefits; Chapter V considers nonuse benefits; and Chapter VI considers forage fish estimates. The final chapter summarizes recommendations regarding modifications EPA should make before issuing a final Phase II rule.

II. FRAMEWORK FOR BENEFITS ASSESSMENTS AND EVALUATION OF EPA BENEFITS ASSESSMENT APPROACH

This chapter considers the overall framework for carrying out a benefits assessment. The chapter reviews the general principles—emphasizing EPA's recent Guidelines for Preparing Economic Analyses (EPA 2000, subsequently "EPA Guidelines")—and evaluates the consistency of the overall approach in the Delaware Case Study with these principles. We conclude that the general "effect-by-effect" approach used by EPA in the Delaware Case Study is consistent with sound economic principles and with the EPA Guidelines. <FN 9> Moreover, the benefit categories included in the Delaware Case Study correspond well to the framework provided for ecosystem benefits in the EPA Guidelines.

A. Overview of Benefit-Cost Analysis

Benefit-cost analysis is a well-established methodology for providing information to decision makers faced with the task of determining whether a project should be undertaken, and if so, at what scale of activity (see, e.g., Nas 1996 and U.S. EPA 2000). The approach involves systematic enumeration of benefits and costs that would accrue to members of society if a particular project were undertaken. Benefit-cost analysis provides an ex ante perspective; a project is evaluated in advance to aid in deciding in what form it should be undertaken and, indeed, whether the project should be undertaken at all.

The rationale for undertaking a benefit-cost analysis of a particular decision is to allow society's resources to be put to their most valuable use. In choosing among alternatives, the basic benefit-cost principle is to select the alternative that produces the greatest net benefits (i.e., benefits minus costs). It is possible that all project alternatives produce net benefits that are negative. In that case, the higher value alternative is to "do nothing," which at least produces a net benefit of $0.

Benefit-cost analyses of the choice of Best Technology Available ("BTA") require the careful enumeration of the monetary value of different impacts resulting from various alternatives. These impacts are typically separated into costs (negative impacts) and benefits (positive effects), although the two categories may be closely related.

The costs included in cost-benefit assessments should reflect costs to society as a whole, rather than transfers from one group to another. EPA Guidelines for Preparing Economic Analyses define social cost as follows:

The total social cost of pollution control is the sum of the opportunity costs incurred by society because of a new regulatory policy; the opportunity costs are the value of the goods and services lost by society resulting from the use of resources to comply with and implement the regulation, and from reductions in output (U.S. EPA 2000, p. 113, emphasis in original).

This definition is consistent with guidelines from the Office of Management and Budget (1996) and standard economic theory as described in economic texts on benefit-cost analysis.

The benefits included in benefit-cost assessments should reflect benefits to society. Estimates of benefits associated with environmental improvements reflect social benefits when they are based on the willingness to pay ("WTP") of individuals who receive the increased environmental services (e.g., recreational fishing services). WTP represents the value of a good or service in monetary terms (i.e., the amount the individual is "willing to pay" in dollar terms). The current EPA Guidelines for preparing economic analyses explain this concept as follows:

The willingness to trade off compensation for goods or services can be measured either as willingness to pay (WTP) or willingness to accept (WTA). Economists generally express WTP and WTA in monetary terms. In the case of an environmental policy, willingness to pay is the maximum amount of money an individual would voluntarily exchange to obtain an improvement (or avoid a decrement) in the environmental effects of concern. Conversely, willingness to accept compensation is the least amount of money an individual would accept to forego the improvement (or endure the decrement) (2000, p. 60, emphasis in original).

EPA notes that: "In practice, WTP is generally used to value benefits because it is often easier to measure and estimate" (2000, p. 61).

This approach to measuring benefits is consistent with Office of Management and Budget Guidelines and standard economic texts (e.g., Tietenberg 2000).

B. EPA Guidelines for Assessing Ecosystem Benefits

The recent EPA Guidelines provide a framework for benefit assessment as well as specific guidelines for organizing assessment of ecological benefits such as those related to reduced I&E.

1. EPA Guidelines for the "Effect by Effect" Approach

The EPA Guidelines provide an overview of the "effect-by-effect" approach for valuing the benefits of an environmental program, such as the issuance of a 316(b) permit. The Guidelines note that this is the most widely used approach for estimating the benefits of a policy option. An alternative approach is to develop WTP estimates for the combined effects of the environmental program, which would eliminate the need to identify, quantify and value each effect separately. <FN 10>

The general effect-by-effect approach as laid out in the EPA Guidelines consists of three logical components:

1. The identification of physical effects.
2. The quantification of the major physical effects.
3. The estimation of the values of these physical effects.

The EPA Guidelines provide additional recommendations for these various steps and how to implement them in various circumstances, including where ecosystem benefits occur.

2. EPA Guidelines for Evaluating Ecosystem Benefits

The benefits due to reduced I&E represent ecosystem benefits because they affect the services provided by the nation's water resources. In the case of the Delaware Estuary, for example, changes in I&E at Salem affect fish populations in the Delaware Estuary and in other water bodies that the affected fish populate.

The EPA Guidelines (2000) provide a summary of the benefit categories relevant to an assessment of ecological benefits. Figure 2 outlines this classification scheme.

Figure 2. Summary of Classification Scheme from EPA Guidelines
[see hard copy for figure]

The following is a brief overview of the categories relevant to ecosystem valuation (adapted from EPA 2000), which serves as a prelude to the consideration of categories included in the Delaware Case Study.

-Market benefits. Direct market benefits relate to primary products that can be bought and sold in competitive markets. The EPA Guidelines note that examples include agricultural products, commercial fish species and timber.
-Non-market benefits. These include benefits that are experienced directly by individuals but that are not bought and sold in markets. Non-market benefits listed in the EPA Guidelines include both consumptive uses (e.g., recreation fishing and hunting) and non-consumptive uses (e.g., scenic vistas, wildlife viewing, hiking and boating).
-Indirect benefits. Ecosystems can provide services that do not directly benefit individuals but may be valued because they provide biological services required for services that are valued directly by individuals. Examples in the EPA Guidelines include wetlands, usefulness in recharging groundwater, mitigating flooding or trapping sediments.
-Non-use benefits. This category includes benefits not associated with any direct use by individuals or mankind. Also referred to as passive use values, these benefits are based upon the knowledge the resource exists in an improved state. The EPA Guidelines mention the commitment of some groups to particular animals or ecosystems as examples of nonuse benefits.

This list provides a useful template for evaluating the benefit assessments contained in the Delaware Case Study.

C. Benefit Assessment Approach in the Delaware Case Study

This section considers the consistency of the approach in the Delaware Case Study with the EPA guidelines, both the overall approach and the particular approach for ecosystem benefits.

1. Overall Approach

The Delaware Case Study follows the "effect-by-effect" approach recommended in the EPA guidelines. The following are the activities corresponding to the three-step process in the EPA guidelines contained in the Delaware Case Study.

--Identification of physical effects. EPA performed several tasks related to this step.
   -Described the physical setting in the Delaware Estuary.
   -Noted that the current CWIS at Salem involves the I&E of various aquatic species.
   -Categorized the aquatic species affected by Salem into those considered to be "representative important species"
   -Identified whether the various species are commercial, recreational or forage fish.
--Quantification of physical effects. EPA performed several tasks in this category for Salem. The

tasks include breakdowns by species.
-Estimated annual impingement.
-Estimated annual entrainment.
-Determined the splits between recreational, commercial and forage.
-Determined the numbers of age 1 equivalents.
-Determined the yield lost to fisheries and production foregone.
--Estimation of the values of these physical effects. The steps involved here are discussed in the following section.

This strategy is similar to the approach developed by PSEG in Salem's 1999 Application (PSEG 1999).

2. Benefit Valuation Approach

U.S. EPA (2002a) provides an overview of its benefit estimation for Salem in Chapter B6 that summarizes the nature of the benefit valuation. Figure 3 reproduces the basic steps.

Figure 3. Overview of EPA's Methodology for Valuing Economic Losses due to I&E at Salem
[see hard copy for figure]

This valuation approach is consistent with the general approach for ecological benefits in the EPA Guidelines, with one exception. Figure 4 reproduces the EPA Guidelines categories, adding the specific categories for Salem.

Figure 4. Application of EPA Classifications to Salem Case Study
[see hard copy for figure]

The exception between the approach in the EPA Guidelines and the approach in the Delaware Estuary Case Study is the treatment of nonuse benefits. In the EPA Guidelines, nonuse benefits are treated as a separate category from all of the use benefits. In the Delaware Case Study, the nonuse category is treated as a supplementary element of recreational benefits. As discussed in Chapter V, the treatment of nonuse benefits in the Delaware Case Study is not consistent with sound economic principles, including those reflected in the EPA Guidelines.

D. Summary

The general benefit assessment approach in the Delaware Case Study is consistent with the EPA Guidelines in following the "effect-by-effect" approach. EPA develops estimates of the effects of I&E on populations of various fish species and develops estimates of the changes in relevant fish populations. These changes in fish populations are used to develop total dollar benefit estimates for I&E based on the following benefit categories:

1. Commercial benefits;
2. Recreational benefits;
3. Forage benefits; and
4. Nonuse benefits.

The following four chapters estimate the specific methodologies used in the Delaware Case Study for these four categories.

[comment text continued in 316bEFR.075.503]

Footnotes

4 Impingement is defined as the trapping of fish and other aquatic life on equipment at the entrance to CWIS. Entrainment occurs when small aquatic organisms, eggs, and larvae are taken into the cooling system, passed through the heat exchanger, and then discharged back into the source water body.

5 The Delaware Case Study is Section B of U.S. EPA (2002a).

6 Other reports provide additional economic assessments related to the 316(b) Phase II Proposed Rule. See Desvouges et al. (2002), Stavins (2002), and Strand (2002). Harrison and Schatzki (2000) provides an overview of general economic issues related to 316(b) benefit-cost determinations. The biological issues in the Delaware Case Study are discussed in Heimbuch (2002).

7 EPA states that there are 539 existing power plants that would be regulated under this rule. EPA refers to these as the “in-scope” facilities (67FR 17130).

8 This report does not evaluate other aspects of the Phase II rule, including the economic criteria that should be used to determine BTA and the importance of site-specific evaluations. See Harrison and Schatzki 2000 for an evaluation of these issues in the context of EPA’s Phase I rule. Evaluations of other economic issues related to the Phase II proposal are provided in Desvouges et al. 2002, Stavins 2002 and Strand 2002.

9 Note that consistency with the EPA Guidelines is not assured. In other case studies, EPA uses a so-called Habitat Replacement Cost (“HRC”) approach that is not consistent with the EPA Guidelines or sound economic methodology. See Harrison et al. (2002) and Stavins (2002) for evaluations of the HRC approach in the context of EPA’s case studies for the Pilgrim and Brayton Point facilities, respectively.

10 In other 316(b) case studies, EPA uses what it terms the Habitat Replacement Cost (“HRC”) method to develop a comprehensive value estimate. This is not a valid economic approach, as noted in Harrison et al. (2002) and Stavins (2000).

EPA Response

This comment summarizes the overall approach EPA used in the cost-benefits analysis for the proposed Section 316(b) Phase II rule. Comments on specific methods have been included in other comments.

For EPA's response to comments on whether EPA guidelines were followed in estimating non-use values, please see the response to comment #316bEFR.005.013.

For EPA's response to comments on Commercial benefits please see the response to comment #316b.EFR.005.029.

For EPA's response to comments on recreational benefits please see the response to comments #316b.EFR.075.504 and #316b.EFR.041.452.

In the analyses for the NODA and the final rule, EPA estimates forage benefits by translating foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule. See Chapter A5: Methods Used to Evaluate I&E.

For the final 316b rule analysis, EPA has not included quantitative measures of nonuse values due to uncertainty in monetizing non-use values for this rule. The Agency, however, has explored several methods that indicate the potential for significant non-use values. See Chapters A12, Non-use Meta-analysis Methodology, and A9, Economic Benefit Categories and Valuation Methods of the final Phase II Regional Studies Document (DCN #6-0003).

Also please refer to the discussion of ecosystem services and values in Chapter A9 of the Regional Studies Document.

Commercial Fishing Benefits

[comment continued from 316bEFR.075.502]

III. EVALUATION OF THE EPA METHODOLOGY FOR ESTIMATING THE ECONOMIC VALUE OF COMMERCIAL FISHING BENEFITS

This chapter examines EPA's methodology for determining the value of commercial fishing benefits associated with a reduction in I&E. The chapter presents a brief overview of EPA's evaluation of commercial benefits, provides conceptual background on fishery economics that underlies our assessment of EPA's methodologies, and then presents our assessment of EPA's analysis of commercial benefits. The final section summarizes our conclusions regarding EPA's assessment of commercial benefits.

A. Overview of EPA's Methodology and Results for Salem

Chapter A-9 of EPA's Case Study outlines the three basic steps taken to evaluate the direct commercial fishing benefits of reduced I&E:

1. Estimate the increase in commercial landings attributable to a reduction in I&E;
2. Calculate the market value (i.e. the change in gross revenue) of the increase in commercial landings; and
3. Convert the market value calculation into an estimate of total social benefit.

The following sections discuss each of these steps in the Delaware Case Study.

1. Increase in Commercial Landings

The first step in EPA's methodology is to assess the I&E-related change in commercial landings, as measured by pounds of commercial species sold dockside by commercial harvesters. Chapter A-5 of EPA's Case study describes the specific methodology used to estimate this change. The methodology involves calculating the number of fish with commercial value that will reach harvesting age, estimating the number of these fish that will be harvested, and allocating the resulting yield between commercial and recreational anglers according to historical trends. As noted, EPA based their estimates on data collected from Salem.

Table 2 shows EPA's estimates of foregone commercial landings at Salem due to I&E for each individual "representative important species" ("RIS"), as well as the total foregone landings for all non-RIS fish. The table distinguishes between losses due to impingement and losses due to entrainment, the latter of which accounts for over 98 percent of the total.

Table 2. Foregone Commercial Landings due to I&E at Salem (pounds)
[see hard copy for table]

2. Additional Gross Revenues to Commercial Fishermen due to the Increased Commercial Landings

The second major step in EPA's methodology is to develop estimates of the additional gross revenues to commercial fishermen associated with the increases in commercial landings that could occur if I&E were reduced under a final rule for existing generation facilities under Section 316(b). EPA obtained market data on the commercial prices for each RIS from the National Marine Fisheries Service (NMFS), which lists ex vessel values and volumes for commercial landings of each species in each state (or, where isolation of individual states is not feasible, for groups of neighboring states). To adjust for differences in prices over time, EPA determined the average price over ten years and used this average to determine the price per pound of each species. EPA estimated the value for non-RIS species by taking the average of all RIS values. Table 3 shows the prices of the species affected by I&E at Salem, as estimated by EPA. Prices are given in 2000 dollars.

Table 3. Ex Vessel Prices of Species Affected by I&E at Salem as Calculated by EPA
[see hard copy for table]

EPA multiplied the change in the commercial catch for each species (Table 2) by its average ex vessel price (Table 3) to determine the change in gross revenue to commercial fisherman. Table 4 shows the change in gross revenue due to I&E at Salem for each RIS and all non-RIS fish.

Table 4. EPA Estimates of the Gross Revenues of Commercial Species Affected by I&E at Salem
[see hard copy for table]

3. Added Social Benefit

The third step in EPA's methodology is to convert the calculations of gross revenue into estimates of total economic surplus, which includes both producer and consumer surplus. Producer surplus represents the revenues that producers as a whole receive in excess of their total costs. Consumer surplus represents the benefit that consumers as a whole derive from purchasing goods or services at the relevant price, net of the amount that they pay for the goods or services.

a. Producer Surplus to Commercial Fishers

Citing studies by Rettig and McCarl (1985), and Huppert (1990), EPA first argues that

"the economic literature ... suggests that producer surplus values for commercial fishing ranges [sic] from 50 to 90 percent of the market value. That is, the wholesale landings values are a close proxy for producer surplus because the commercial fishing sector has very high fixed costs relative to its variable costs. Therefore the marginal benefit from an increase in commercial landings can be estimated to be approximately 50 to 90 percent of the anticipated change in commercial fishing revenues" (U.S. EPA 2002a, p. A9-5).

The Case Study document then cites Cleland and Bishop (1984) and a personal communication with Dr. Bishop as supporting an estimate that in Great Lakes fisheries, the surplus of commercial fishermen is approximately 40 percent of gross revenues. On this basis, EPA concludes that "producer surplus estimates in the range of 40 percent to 70 percent of landings values ... probably are a more suitable reflection of longer-term market conditions" (U.S. EPA 2002a, p. A9-5; see also p. B4-8).

b. Surplus to Consumers and Other Market Participants

EPA argues further that this surplus to fishermen is only a fraction of the total change in surplus that will also accrue to wholesalers, processors, retailers, and ultimately to consumers as a result of reductions in I&E. The Case Study document cites Norton et al. (1983), Holt and Bishop (2002), and a personal communication with Dr. Bishop for support of this claim:

"Primary empirical research deriving "multi-market" welfare measures for commercial fisheries have estimated that surplus accruing to commercial anglers amount [sic] to 22.2% of the total surplus accruing to watermen, retailers and consumers combined in the striped bass markets in New York and Baltimore (Norton et al., 1983); and 22.3% in the Great Lakes (Bishop, personal communication, and Holt and Bishop, 2002) (U.S. EPA 2002a, p. A9-5).

Thus, total economic surplus across the relevant commercial fisheries multi-tiered markets can be estimated as approximately 4.5 times greater than producer surplus alone (given that producer surplus is roughly 22% of the total surplus generated). This relationship is applied in the case studies to estimate total surplus from the projected changes in commercial landings" (U.S. EPA 2002a, pp. B4-8, B4-9).

Although the Delaware Case Study is not clear on the derivation of this estimate, a response to questions by the EPA (U.S. EPA 2002b) indicates that the multiplier is based on the total surplus derived from commercial fishing by fishermen, wholesalers, retailers and consumers, as reported in Norton et al. (1983). The authors report that in 1980, fishermen across the Atlantic coast derived $0.77 million in producer surplus from their striped bass catch. The authors calculate the total benefit to consumers, retailers, and wholesalers to be $2.71 million. The surplus to commercial fishermen therefore represents 22 percent of the $3.48 million total surplus.

4. Example of EPA's Calculation

Table 5 illustrates EPA's methodology for the calculation of annual I&E impacts on commercial fishing. This table is based upon a similar table developed by EPA in the Delaware Case Study. <FN 11>

Table 5. Example of EPA's Calculation of Total Surplus Losses from Commercial Weakfish Fishing due to I&E at Salem (baseline)
[see hard copy for table]

B. Conceptual Considerations

1. Theory of Open Access Fisheries

It has been well established for almost 50 years that under an open access fishery, competition among fishermen will drive producer surplus to zero for all fishermen. <FN 12> Ocean fisheries are typically common property resources, with no one exercising control over them. Since no individual or group has the property rights to the fishery, no single fisherman can exclude any other from exploiting the fishery. This situation has been labeled “the tragedy of the commons” in a famous article by Garrett Hardin (1968).

Under such circumstances, “externalities” associated with the use of the common resource by many independent producers result in a reduction in the productivity of that resource. In fisheries such as the Delaware Estuary, as more fishermen harvest fish from the water, the ability of the fish population to reproduce at the most profitable rate is compromised. The result is that the economic value of the resource—i.e. the producer surplus—is dissipated and even destroyed, because fish are harvested at a point where the marginal cost of harvesting them, including the effects on the future stock, is higher than the marginal benefit.

The economic inefficiencies associated with open access fisheries can be summarized as follows: <FN 13>

-Too many economic resources are committed to fishing—more fishermen employ more boats and fishing effort than would be economically optimal.

-Current fishermen therefore earn a substantially lower return on their efforts.

-Over-fishing reduces the stock below its optimal level, which in turn lowers future profits from fishing. <FN 14>

These considerations mean that an open access fishery will generate no producer surplus. For our purpose, the key implication is that changes in conditions at the fishery—such as an increase in the number of commercial fish available due to reduced I&E—will not lead to any change in producer surplus.

Freeman (1993) provides a graphical depiction of the implications of open access on producer surplus and illustrates that changes in environmental quality—such as a reduction in I&E at Salem—would not lead to increases in producer surplus to fishermen. Figure 5 shows the marginal cost curve and average cost curve for a given commercial fishery, along with the relevant demand curve. As Freeman notes, if the fishery were privately owned, the output and price would be given by the intersection of the marginal cost function and the demand curve, with price equal to and quantity equal to ; fishermen would obtain a producer surplus in this case. An improvement in environmental quality—such as a reduction in I&E at Salem—would reduce the marginal cost (not shown) and lead to an increase in quantity, a decrease in price, and an increase in producer surplus to fishermen.

Figure 5. Welfare Measurement for Open-Access Resources: The Case of a Fishery
[see hard copy for figure]

The situation is very different in the case of an open access fishery. In this case, the economic incentives lead to a situation where the price (Pc) would be equal to average cost (not marginal cost), and where each fisherman earns zero profits. Freeman notes that for the same change in environmental quality in a fishery with open access, even if quality improves and fish become more abundant, “there is no change in producer surplus.” The logic behind this result is that positive producer surplus would lead additional fishermen to enter the fishery, driving the price down to Pc and the quantity up to xc. At this point, all of the producer surplus is again dissipated and no fishermen receive any producer surplus.

The graph shows that changes in environmental quality therefore have no effect on net producer surplus. Better fishing conditions shift the average cost curve outward to ACx. This reduction in costs and temporary improvement in profit results in additional fishing effort by existing fishermen and by new entrants. The added effort increases fishing output <FN 15> and reduces the price of fish until the zero profit position is reached in the new circumstances. The net result is that the improved conditions do not yield long-term producer surplus gains to fishermen; the superior fishing conditions are dissipated by additional fishing effort (and price changes, to the extent that these occur).

2. Changes in Producer and Consumer Surplus Due to Small Changes in Additional Fish

Figure 5 suggests that consumers would gain from the environmental improvement in the form of reduced prices for fish. This result, however, depends upon the demand elasticity; the more elastic the demand for fish, the smaller the welfare gain associated with the environmental improvement. Because small segments of a given market have more elastic demand curves than the market as a whole, consumer benefit from changes to small market segments will also be small, or even negligible. As Freeman (1993) notes:

"[I]f this fishery is small relative to the market and the demand curve is perfectly elastic, there is no welfare gain [from the improvement in environmental quality]. The physical improvement in productivity brought about by the higher water quality is entirely dissipated by the uneconomic competition of fishermen for the potential increase in rents" (Freeman 1993, p. 308-9).

Figure 6 illustrates the situation in which the effect is small relative to the overall market for fish—and thus demand is perfectly elastic. As discussed below, this appears to be the case for the effect of I&E at Salem. The figure shows the shift in the average cost curve from to and the increase in the number of fish bought and sold. However, because the average cost still equals the price, there is no change in the profits to commercial fishers. Moreover, there is no change in consumer surplus, since the price remains the same. The improvement in environmental quality leads to additional fish caught and sold, but no increase in producer or consumer surplus, and thus no environmental benefits.

Figure 6. Welfare Measurement for Open-Access Resources with Perfectly Elastic Demand
[see hard copy for figure]

C. Evaluation: EPA's Commercial Benefit Estimates Are Substantially Overstated Because of Mischaracterizations of the Empirical Studies Used in the Assessment

This section evaluates EPA's approach to estimating the benefits to the commercial fishery of reduced I&E at the Salem facility, in light of the conceptual issues discussed in the previous section. Based on this evaluation, the commercial estimates reported by EPA appear to be substantially overstated.

1. Ex vessel Commercial Fish Prices

EPA's estimates of the ex vessel values appear to be reliable. The values, which range from $0.11 per pound for alewife to $3.18 per pound for striped bass, appear to be accurate estimates of the average values for ex vessel prices in New Jersey and Delaware, based on NMFS data (NMFS 2002). Although the range of certain species suggests that affected fish would be caught in other areas, these state values are representative.

Note that by using the prevailing ex vessel prices EPA appears to assume implicitly that the cropping at Delaware in-scope facilities does not affect the market price. This assumption seems sensible in light of the large overall market for fish. Note however, that EPA's use of the 4.5 multiplier (discussed below) contradicts this assumption by implying a substantial change in price.

2. Estimates of Producer Surplus Benefits to Fishermen

EPA's Delaware Case Study estimates that the producer surplus to fishermen will be between 40 and 70 percent of gross revenues.
EPA cites four published sources and a personal communication with Dr. Richard Bishop, a co-author of two of the studies, in support of the claim that producer surplus will fall between 40 and 70 percent of gross landing revenues. There are several problems with this claim, which upon further inspection does not appear to be supported by the literature cited.

a. Surplus as Proportion of Gross Revenue

A review of EPA's sources suggests that the conclusions drawn regarding producer surplus are taken somewhat out of context and that they are inappropriate for use in the present analysis. EPA's Guidelines emphasize the importance of transferring benefits from like cases. For the present case study, the differences are significant enough that they result in significant errors.

Rettig and McCarl (1985) appears to be the source of EPA's 50 to 90 percent estimate, which the authors cite in the context of the salmon and steelhead fisheries of the Pacific Northwest. They argue that in that context, "variable costs may be approximately 50% of revenues for all commercial operators" (p. 205), which would imply a (short-term) producer surplus of 50 percent of revenue. The authors suggest (again in the context of salmon and steelhead fisheries in the

Pacific Northwest) that 90 percent may be appropriate for a sensitivity analysis, based on research by two previous sources in British Columbia and Alaska. Importantly however, Rettig and McCarl note that the higher estimate was intended to include surplus to processors and retailers (p. 206). If used in conjunction with EPA's other procedures for estimating total surplus, this would double-count the surplus and result in significant overestimates.

Although not directly concerned with the rehabilitation of a fishery, Cleland and Bishop (1984) includes data from which the fishermen's surplus as a percentage of gross revenues can be calculated. After accounting for depreciation and the opportunity cost of capital, the estimated return to labor ranged from –57 percent to + 35 percent of gross revenues. Cleland and Bishop note that 1981, the survey year, was "a very good year by comparison to historical standards. Returns to labor are likely to be far lower in poor years" (p. 42).

It is important to note that the characteristics of fisheries vary substantially with respect to the methods used to harvest fish and the composition of fishing investments. Some fisheries involve significantly greater capital investment than others, for example. According to Norton et al. (1983), New England fishermen received only $0.21 per pound in surplus for striped bass, suggesting a surplus of around 11 percent of gross revenues (p. 44). Excluding fixed costs (for the short-term) the proportion would rise to around 30 to 35 percent (pp. 7-8). Norton et al. (1983) further note that for Southern Atlantic fisheries, fishermen's surplus was actually zero (p. 44). Strand (2002), one of the authors of the Norton et al. study, puts surplus at "approximately 15 percent of vessel values" for Atlantic fisheries. The Pacific Northwest and Great Lakes fisheries cited in the sources used by EPA therefore may not be representative of the Atlantic fishery analyzed for the Delaware Case Study. A complete analysis would attempt to develop estimates of fishermen's surplus that was relevant to the fisheries and markets in question.

b. Applicability of "Rule of Thumb" to Short and Long Run

In addition to these questions about the applicability of the rules of thumb used by EPA, given the different geographical location of the relevant fisheries, there are also questions related to the time-period over which the rule of thumb would be relevant if it were applicable. EPA's sources emphasize the short-term nature of the rule of thumb, particularly in the higher range. EPA does not acknowledge the difference between short-term and long-term effects in its discussion.

In his review, Huppert (1990) notes that when applying the 50 to 90 percent "rule of thumb" to estimate quasi-rents, <FN 16> the approach can only be appropriate in the very short run:

"For very short-run policy shifts, it might be reasonable to assume both labor and capital to be fixed factors, making quasi-rent equal to Total Revenue [sic] minus the component of variable costs that can be avoided in the short run (e.g. fuel expenses). A slightly different procedure, but in the same spirit, is calculation of quasi-rent or rent as a percentage of the fishery gross revenues.… Rettig and McCarl [1985] <FN 17> suggested using a range of percentages from 50 percent to 90 percent for sensitivity analysis. The logic for these percentages is that they represent the variable inputs cost as a fraction of total cost for a wide variety of fishing operation studies on the Pacific coast."

Again, this approach would be more appropriate the shorter the time period over which the benefits are purported to flow. The longer the 'run' being considered, the more elastic the labor supply is likely to be, and the less fixed is the capital. … [T]he rule of thumb exclusion of capital and labor costs in calculating fishery benefits is strictly a very short-run approximation" (Huppert 1990, pp. 28-29).

Huppert's point is that a "rule of thumb," such as used by EPA in this case, will only be applicable as long as certain fixed costs—e.g., capital investments such as a commercial fisher's boat and other equipment, and the labor of the fishing crew—are not changed in response to a change in fish stocks. Initially, when fishermen decide to expend more or less fishing effort, the only costs that change are the variable costs, which include fuel and may include the opportunity cost of labor, assuming that alternative employment is available. Since the fixed costs are already incurred and do not change, they do not figure in the producer surplus calculations. In their discussion of the salmon and steelhead fisheries in the Pacific Northwest, Rettig and McCarl (1985) make a similar point. They note that the use of a proportion greater than 50 percent would only apply in first year.

In the longer term, however, the fixed costs that were ignored when calculating the share of revenues offset by costs must also be included. In the longer run firms can make changes in their output and production mix based on external conditions because the supply of capital and labor is no longer fixed. EPA does not appear to make any attempt to adjust its estimates to account for long-term considerations, but uses the 40 to 70 percent value even as a long term value. To stay true to EPA's sources, it should stick to its lower-bound estimate for the long-term—also keeping in mind the discussion in the preceding section regarding the appropriate magnitude of producer surplus for Eastern fisheries.

c. Considerations Related to Open Access

In addition to these longer-run effects on producer surplus, which would apply in any segment of the economy, the open access characteristics of fisheries further reduce the surplus that can be expected by fishermen in both the short- and longer-term. As noted earlier in the discussion of open access, a change in the number of fish available to be harvested will have no effect on producer surplus, which will be zero regardless of the number of fish available, unless measures are taken to prevent economic over-fishing.

Indeed, the sources cited by EPA affirm this point. As noted above, Norton et al. (1983) found that for fishermen in Southern parts of the Atlantic fishery analyzed, the producer surplus was in fact zero, because net costs were equal to net revenues. Rettig and McCarl (1985) observe that under open access,

"[f]ishermen, vessels, and operating capital enter until costs have risen by as much as the increase in revenues. Profits and, hence, net benefits are dissipated." … If there were no new impediments to entry, net benefits in the long run would tend toward zero" (Rettig and McCarl 1985, p. 205-6).

As a result of these considerations, the change in surplus to fishermen that results from the change in harvest due to I&E at Salem is likely to be very small over the long-term, and may in fact approach zero.

3. Use of Multi-Market Multiplier

As discussed earlier, EPA multiplied its estimate of producer surplus to commercial fishermen by 4.5 to account for potential surplus to consumers and other producers in the supply chain. The studies cited by EPA do not support the "multi-market" multiplier (4.5) used by EPA to translate changes in producer surplus to fishermen into changes in total producer and consumer surplus. EPA applies this scaling factor to account for the purported benefits to consumers, retailers, and wholesalers, despite the fact that economic theory and its own primary sources suggest that such benefits are unlikely to exist. In a discussion of the relevance of consumer surplus in analyses of changes in fisheries, Bishop et al. (1990) write:

…most applied studies focus on single populations or a subset of all the populations of a species or group of related species. Management of such subunits may have little or no effect on prices in markets where outputs from many subpopulations are bought and sold. If market prices are unaffected, then consumer surplus does not change and the economic conclusion is that management measures would have little or no effect on consumers.

The price of fish ultimately depends upon the total catch and consumer demand for fish, as well as the availability of substitutes for any particular species that may be affected. The potential harvest affected by I&E at Salem is a very small share of the total expected fishing catch in the Atlantic market, or even for the smaller mid-Atlantic region. Because the change due to I&E in the number of fish that would be brought to market is a negligible portion of the total catch, the price of fish would not be expected to change as a result of I&E. Consumer surplus will only change if the demand curve shifts, or if the price of fish changes for some other reason. But since neither of these is expected as a result of I&E at Salem, consumer surplus will not change. As a consequence, it would be inappropriate to estimate changes in consumer surplus in any analysis of the effects of I&E at Salem. In the example from Freeman (1993) cited previously, Freeman notes that where a fishery "is small relative to the market and the demand curve is perfectly elastic, there is no welfare gain." We therefore would not expect to see a change in consumer surplus as a result of changes to I&E at Salem.

Note that this conclusion is consistent with the possibility that reducing I&E at Salem could result in a small increase in fish sales, and thus additional consumer spending on fish. Despite increased spending, however, any additional fish sales would not lead to additional consumer surplus, or benefit in excess of the price paid. One way to understand this point is to consider those consumers who might be affected by the marginal increase in fish available for sale. Recall that consumer surplus is typically depicted as the area between the demand curve and the price. At the fish purchase that "clears" the market, the marginal consumer surplus, like the marginal profit, is equal to zero. When the number of fish available increases slightly, the marginal consumers who choose to purchase these additional fish would be those at the very "tip" of the consumer surplus "triangle." They would therefore derive a benefit from these fish that was very close to zero. The effect on consumer surplus of Delaware Estuary I&E is therefore negligible.

Similar reasoning can be used to conclude that there will be no effect on retailers' surplus as a result of I&E, because the price that retailers receive from consumers will not change, and retailers' costs have not changed. Thus, although there might be marginally more fish available in the entire market, any effects on individual retailers would be negligible.

The only level of the supply chain above fishermen themselves where it is possible that there could be some producer surplus is at the wholesale level. It is possible that I&E losses could affect certain wholesalers who purchase fish from affected fishermen. Even here, however, it is unlikely that wholesalers' surplus would be affected, because neither wholesaler costs nor the prices they receive from retailers are likely to change. Although some wholesalers may purchase marginally fewer fish from commercial fishermen as a result of I&E, these fish would be at the margin, and therefore contribute very little to the overall wholesaler surplus. Nevertheless, to account for the possibility that some fishermen are themselves wholesalers, or that some wholesalers are significantly affected by reductions in catch from selected fishermen, it may be appropriate to consider potential effects on the surplus accruing to them. One way of accounting for this would be to use wholesale rather than ex vessel prices as the basis for any producer surplus calculations. This could be considered a sensitivity case that would give an upper bound to the surplus estimates. Such a case would be unlikely to increase the surplus estimates dramatically, since wholesale prices are not substantially higher than ex vessel prices.

In addition, the "mark-up" included in wholesale prices should not be interpreted as "pure profit" or surplus to wholesalers. Additional sales of fish of course will result in increased revenue to the wholesalers. But assuming that the entire "mark-up" constitutes a profit for wholesalers ignores the additional costs that are borne by a wholesaler in carrying the goods and bringing them to market. For example, Norton et al. (1983) observes that the wholesalers' mark-up of 10 to 20 percent covers many of the variable costs associated with the purchase of fish from watermen. At the very least, these variable costs must be excluded from any calculation of the surplus to wholesalers. In a competitive market, one would in fact expect that the variable costs of the additional fish sold would be the same as the price received—and therefore the net surplus would be zero.

Ignoring the additional costs associated with the wholesale mark-up when using the wholesale price to estimate gross revenues results in overestimates of the total surplus accruing to wholesalers.

D. Summary

In summary, EPA's estimates of commercial benefits are significantly overstated. EPA relies upon two "rules of thumb" that generate excessive estimates of the surplus that would accrue to market participants as a result of increases in the commercial catch if I&E were reduced at Salem.

Using more reasonable estimates of surplus associated with increases in the commercial catch would result in much lower estimates than those EPA developed for the Delaware Case Study. One plausible alternative (i.e., from Strand (2002), citing his work on Norton et al. (1983)) would suggest that the mid-range increase in surplus would be only 15 percent of gross landing revenue—or one-sixteenth what EPA has estimated.

Footnotes

11 This methodology is presented in Table A9-1 in U.S. EPA (2002a). Although the title of Table A9-1 refers to striped bass, the values appear to be based upon shad. Note that the example we present in Table 5 relates to weakfish.

12 The classic article is Gordon (1954). The basic arguments are described in environmental and natural resource textbooks. See, e.g., Tietenberg (2000).

13 These inefficiencies are sometimes described as "economic over-fishing." This is distinguished from "biological over-fishing," in which fish are harvested faster than they can reproduce their population, leading to a decline in fish stocks.

14 Note that the increase in output from the additional fishing effort may be short-lived if the increased effort further diminishes fishing stocks. See Freeman (1993). Freeman (1991) provides illustrative calculations of the magnitude of the effects of alternative demand elasticities on consumer surplus gains.

15 See Freeman (1993). Freeman (1991) provides illustrative calculations of the magnitude of the effects of alternative demand elasticities on consumer surplus gains.

16 Quasi-rents are defined as "the income of a seller of a good or service over and above its opportunity cost when the good is temporarily in fixed supply" (Pearce, 1995). Because there is limited opportunity to expand capital invested in fishing in the short-term, the fixed costs associated with it are not relevant to the calculation of producer surplus.

17 Huppert cites this as 1984, but is actually referring to Rettig and McCarl's 1985 study.

EPA Response

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment 316bEFR.005.029.

IV. EVALUATION OF THE EPA METHODOLOGY FOR ESTIMATING THE ECONOMIC VALUE OF RECREATIONAL FISHING BENEFITS

This chapter describes and evaluates EPA's methodologies for estimating recreational losses due to I&E at the Salem facility and other in-scope facilities in the Delaware Estuary. The chapter describes the two methodologies used by EPA to develop recreational benefits estimates for this category.

A. Overview of EPA Methodology and Results

The Delaware Case Study describes EPA's development of recreational fishing values. The methodology is complicated by the fact that EPA used two different types of methodologies to develop recreational benefits, the benefits transfer approach for all species and a random utility model ("RUM") study for two of the species; the final results include the use of the RUM results for those two species and the benefit transfer results for the other species.

The following is an outline of the basic steps the EPA followed in developing recreational benefit estimates for the Delaware Case Study:

1. Estimate the increase in recreational fish yield attributable to a reduction in I&E (converting pounds into number of fish).

2. Determine the additional consumer surplus for all species using the benefit transfer methodology.

3. Prepare a RUM study for two species and calculate the additional consumer surplus for these two species using the RUM study results.

4. Calculate the total social benefit from additional recreational catch based upon the results of both the benefit transfer study and the RUM study.

The following sections discuss each of these steps in the Delaware Case Study.

1. Determine Increase in Recreational Yield

The first step in EPA's methodology is to assess the I&E-related change in recreational yield, as measured by pounds of each species caught recreationally. The first elements are the same as for the calculations of additional commercial fishing, as described in the previous chapter. The total yield was partitioned by species based upon percentages obtained from the PSEG filing for Salem. Because the economic values for recreational yield are based upon numbers of fish rather than pounds, the recreational yield values were converted to numbers of fish based upon the average weight of harvestable fish for each species.

Table 6 shows EPA's estimates of recreational yield in pounds due to I&E for each individual "representative important species" ("RIS"), as well as the total for all non-RIS fish. The table distinguishes between losses due to impingement and losses due to entrainment, the latter of which accounts for over 98 percent of the total. Table 7 shows the equivalent table after the yields have been transformed to numbers of fish.

Table 6. Foregone Recreational Yield due to I&E at Salem (pounds)
[see hard copy for table]

Table 7. Foregone Recreational Yield Due to I&E at Salem (numbers)
[see hard copy for table]

2. Determine Recreational Benefits Based on Benefit Transfer

The second major step in EPA's methodology is to develop estimates of the values that recreational fishermen place on the additional yields using the benefit transfer methodology.

a. Benefit Transfer Approach

In a benefit transfer approach, results from studies of recreational anglers' willingness to pay ("WTP") for increases in recreational catch rates are applied to expected changes in catch rates that would result from reduction of I&E. For all of the species, EPA used the benefit transfer approach to value the recreational costs of I&E. EPA followed two steps in this analysis.

(1) Estimate Average Recreational Values Based on Existing Studies

EPA valued each affected species using values from previous studies of recreational fishing in the mid-Atlantic region. Table 8 shows the four studies that EPA used to develop estimates for transfer to the Delaware Estuary recreational fishery and the recreational values, which the studies derive by type of fish.

Table 8. Studies Used by EPA in Its Benefit Transfer Approach to Estimate Values for Potential Changes in Recreational
[see hard copy for table]

EPA used these studies to develop separate lower and upper bounds for recreational fish values in Delaware and New Jersey. EPA then weighted these values according to the percentage of recreational landings in each state to derive weighted average low and high values. Table 9 lists these values, as well as a midpoint value. The midpoint values for the different species range from $1.45 for white perch to $9.51 for striped bass.

Table 9. Average Recreational Values by Species Due to I&E at Salem
[see hard copy for table]

b. Calculate Recreational Losses by Species

EPA multiplied the estimated fish values by the estimated loss to the recreational catch due to I&E at Salem to produce high and low estimates of recreational losses by species, which are presented in Table 10.

Table 10. EPA Estimates Using Benefit Transfer Method of Recreational Losses due to I&E at Salem by Species
[see hard copy for table]

3. Random Utility Model

a. EPA based estimates of recreational losses associated with two species—weakfish and striped bass—on a RUM analysis of recreational fishing benefits from reduced I&E in the Delaware Estuary. EPA used these estimates--and not the benefits transfer estimates for striped bass and weakfish--in calculating the total value of losses at SalemEstimate Values by Species of Reducing I&E at Salem

EPA used data from the NMFS Marine Recreational Fishery Statistics Survey ("MRFSS") combined with the 1994 NMFS Add-on MRFSS Economic Survey ("AMES"). These data provide information about recreational anglers, where they fish, and what fish they catch.

EPA used data from the MRFSS and the AMES to develop a RUM that models site selection as a function of historic catch rates for certain species and other relevant variables. <FN 18> EPA also used a negative binomial model to predict anglers' choices as to how many fishing trips to take during a recreational season. EPA used these models to estimate the per-trip welfare gain from higher catch rates associated with reducing or eliminating I&E of relevant species.

Table 11 shows EPA's estimates of per-trip welfare gain associated with eliminating I&E of striped bass and weakfish in the Delaware Estuary. The table also shows EPA's estimate of the WTP for an additional fish based upon the RUM study. Also included are values for gains to fishermen when no target species was identified.

Table 11. EPA RUM Estimates of Per-Trip Welfare Gain by Species for Elimination of I&E at Salem and Willingness to Pay for an Additional Fish per Trip
[see hard copy for table]

b. Estimate Fishing Days for Targeted Species

EPA estimated that recreational anglers in Delaware and New Jersey engaged in a total of about 5.4 million fishing days per year. EPA determined the allocation of the fishing trips to the various target species and accounted for the (modest) effect of growth in the number of fishing days due to the improved catch rates.

Table 12 summarizes the relevant results from EPA's projections of the numbers of trips by target species in the baseline conditions, taking into account the additional trips that would result from improved fishing due to eliminating I&E at Salem. These results show that EPA's estimates of recreational fishing in Delaware and New Jersey break annual trips down by the targeted species. EPA estimates that there are almost 1 million recreational fishing trips per year that target weakfish, about 0.1 million that target striped bass, and about 1.1 million with no target.

Table 12. Total Number of Recreational Fishing Days per Year
[see hard copy for table]

c. Estimate Total Recreational Losses by Species

The estimates of fishing days by species were multiplied by the estimated welfare gains per trip by species to produce an estimate of recreational losses for each species. Table 13 shows the EPA's results for Salem. Note that although EPA provides low and high values, there is no explanation of how the two estimates differ—and in fact they appear to be virtually identical. (The total high value is only 0.4 percent higher than the total low value.)

Table 13. Total Estimated Recreational Losses from Salem by Species
[see hard copy for table]

One confusing element of EPA's recreational valuations is the calculation of the total baseline losses for "no target" species. For reasons that are not explained, the value per trip for weakfish ($1.08) is used to calculate the recreational benefits for the "other species" trips rather than the value per trip for "other species" ($0.41); the use of the weakfish value increases the value attributed to "other species" by a factor of more than 2.5 ($1.08/$0.41=2.63).

4. Combine Benefit Transfer and RUM Results to Develop Recreational Losses Due to I&E at Salem

EPA developed total recreational losses due to Salem by combining the results for the two methodologies. These values are combined and reported in Chapter B6 of the Delaware Case Study.

-RUM values are used for striped bass and weakfish.

-Benefit transfer values are used for the "other species," i.e., the species included in the benefit transfer studies other than striped bass and weakfish.

Table 14 summarizes EPA's estimates of these recreational losses for the Salem facility, based upon the two methodologies. Note that as indicated in a footnote, the recreational value for weakfish includes the value attributed to "no target" species from the RUM analysis. The table includes specific values for each species (other than weakfish and striped bass) developed in the benefit transfer analysis, although the table in Chapter B6 only shows a total for "Other Species."

Table 14. EPA Estimates of Recreational Losses Attributable to I&E at Salem
[see hard copy for table]

B. Conceptual Considerations

EPA's Guidelines (U.S. EPA 2000) describe several methodologies that are appropriate for estimating environmental benefits. OMB has also developed guidelines (1996) that are relevant to the methods used by EPA to obtain its benefits estimates. These guidelines identify best practices for conducting regulatory analysis for significant regulatory actions, such as the 316(b) Phase II Proposed Rule. In this section, we review the recommendations in EPA's

Guidelines regarding use of the benefit transfer methodology and discrete choice models, also known as RUMs.

1. Benefit Transfer Methodology

This section discusses the "benefit transfer" approach, which EPA used to obtain estimates of benefits associated with recreational fishing for all but two of the RIS evaluated for the Delaware Estuary Case Study. The benefit transfer approach adapts results from existing studies, as a substitute for conducting an original valuation study.

Broadly speaking, EPA considers benefit transfer to be an appropriate valuation methodology. As EPA's September 2000 Guidelines for Preparing Economic Analyses note,

The advantages to benefit transfer are clear. Original studies are time consuming and expensive; benefit transfer can reduce both the time and financial resources needed to develop benefit estimates (U.S. EPA 2000, p. 86).

EPA (2000) also provides guidelines for interpreting the benefit transfer methodology.

a. Describing the Policy Case and Affected Population

EPA's Guidelines recommend that the benefit transfer exercise begin with identifying and describing the policy case and the affected population:

The first step in a benefit transfer is to describe the policy case so that its characteristics and consequences are understood. It is equally important to describe the population impacted by the proposed policy. As part of this step, it is important to determine whether effects of the policy will be felt by the general population or by specific subsets of individuals (e.g., users of a particular recreation site or children) (U.S. EPA 2000, p. 86).

In order to evaluate the policy case and any alternatives, it is also important to determine the appropriate baseline against which to assess it. OMB (1996) describes considerations that are important to selection of an appropriate baseline:

The benefits and costs of each alternative must be measured against a baseline. The baseline should be the best assessment of the way the world would look absent the proposed regulation…

When more than one baseline appears reasonable or the baseline is very uncertain, and when the estimated benefits and costs of proposed rules are likely to vary significantly with the baseline selected, the agency may choose to measure benefits and costs against multiple alternative baselines as a form of sensitivity analysis… In every case, an agency must measure both benefits and costs against the identical baseline (OMB 1996).

b. Selecting Studies

The next two steps involve selecting studies to form the basis of the benefit transfer exercise:

-Identify existing, relevant studies. Existing, relevant studies are identified by conducting a literature search. This literature search should, ideally, include searches of published literature, reviews of survey articles, examination of databases, and consultation with researchers to identify government publications, unpublished research, works in progress, and other “gray” literature.

-Review available studies for quality and applicability. The analyst should review and assess the studies identified in the literature review for their quality and applicability to the policy case. The quality of the study case estimates will, in part, determine the quality of the benefit transfer. Indicators of quality will generally depend on the method used. ... (EPA 2000, p. 86)

The EPA Guidelines further note that “assessing studies for applicability involves determining whether available studies are comparable to the policy case.” They offer three criteria to be used in assessing which studies are applicable for use in the benefit transfer:

1. The basic commodities must be essentially equivalent [to the policy case];

2. The baseline and extent of the change should be similar [to the policy case]; and

3. The affected populations should be similar [to the policy case]. (U.S. EPA 2000, pp. 86-87)

c. Transferring the Benefit Estimates

After the analyst has identified appropriate studies, the values from those studies must be transferred to the policy case. The EPA Guidelines discuss four approaches that can be used in doing this (U.S. EPA 2000, p. 87):

-Point estimate. This approach involves taking the mean value (or range of values) from the study case and applying it directly to the policy case. As it is rare that a policy case and study case will be identical, this approach is not generally recommended. Rather than directly using existing values, analysts will often adjust point estimates based on judged differences between the study and policy cases.

-Benefit function. This approach is more refined but also more complex. If the study case provides a WTP function, valuation estimates can be updated by substituting applicable values of key variables, such as value estimates across studies. As with the benefit function transfer approach, key variables from the policy case are inserted into the resulting benefit function.

-Meta-analytic approach. Meta-analysis is a statistical method of combining a number of valuation estimates that allows the analyst to explore systematically variations in value estimates across studies.

-Bayesian approach. This is an alternative to the meta-analytic approach. Bayesian approach provides a systematic way of incorporating study case study information with policy case information.

d. Addressing Uncertainty

Finally, the analyst should address the sources of uncertainty involved in application of the selected studies and the chosen transfer methodology.

Benefit transfer involves judgments and assumptions. Throughout the analysis, the researcher should clearly describe all judgments and assumptions and their potential impact on final estimates, as well as any other sources of uncertainty inherent in the analysis (U.S. EPA 2000, p. 87).

2. Discrete Choice Models/RUMs

The EPA Guidelines note that RUMs (also referred to as discrete choice models) may be the best approach for analyzing the effects on social welfare of environmental quality changes, such as improvements in fishing catch rates. Discrete choice models focus on the decision to recreate at a particular site as compared to alternatives. It is important, however, that the studies use valid data on the nature of the choices, particularly on the differences in the travel costs to the alternative sites that the surveyed anglers face.

Random utility models (RUMs) were developed initially to analyze transportation-mode choices (McFadden 1973, 1974). They are also well-suited for evaluating recreation-site choices (Freeman 1993, Schuhmann 1998). The random utility approach is well-designed to estimate behavioral responses in cases where an individual is faced with one or more discrete choices among a number of different identifiable goods or activities. Using standard axioms of rational behavior, the individual is presumed to rank his or her choices according to the benefit (or "utility") that he or she expects to derive from each. The random utility approach posits that the utility an individual receives from a given activity can be observed with a degree of uncertainty, and the probability that a person will choose to recreate at a particular site will be a function of the expected utilities of all sites within his or her choice set. <FN 19>

C. Evaluation: EPA's Recreational Benefit Estimates Are Compromised by an Overly Simple Benefit Transfer Method and a Flawed RUM Study

This section provides an evaluation of EPA's economic methodology in the Delaware Case Study for evaluating the dollar value of recreational losses due to I&E at Salem.

1. Although Benefit Transfer is a Sound Methodology, EPA Uses an Overly Simple Approach

This section evaluates EPA's use of a benefit transfer method to value recreational fishing benefits. We find that EPA's decision to value these benefits using a benefit transfer method is sound, but EPA's benefit transfer technique is too simplistic and is not endorsed by EPA's Guidelines (2000).

a. EPA's Use of Benefit Transfer to Value Recreational Fishing Benefits is Sound

In general, EPA's choice to use a benefit transfer technique is sound. Benefit transfer is a reasonable approach to obtaining estimates for recreational fishing. Many studies of recreational fishing in the Mid-Atlantic region exist for use in such an assessment.

Although the Delaware Case Study is less than fully explicit in explaining how EPA selected the studies it used for the benefit transfer to the recreational fishery, the studies on which EPA relies appear to generate plausible estimates. In addition, the four studies appear to perform fairly well against at least two of the three criteria discussed in EPA's Guidelines: the basic commodities are essentially equivalent and the affected populations are similar.

b. EPA Uses an Overly Simple Application of the Benefit Transfer Method

Although EPA's decision to use benefit transfer itself is sound, the technique EPA uses to transfer the benefits is not one that is recommended by EPA Guidelines. EPA's analysis for the Delaware Estuary Case Study applies a point estimation approach to transfer a range of values developed in the studies used in the policy case. EPA uses this approach to develop a low and high estimate for each fish species.

This approach is not recommended by EPA's Guidelines. As noted above, the Guidelines state, "As it is rare that a policy case and study case will be identical, this approach is not generally recommended." Despite the fact that the point estimation approach is not recommended, EPA's Delaware Estuary Case Study fails to explain why this approach was selected, and whether other approaches were considered.

Note also that the studies used by EPA develop values for a marginal increase in fish catch. This is appropriate and answers the relevant economic question: how much is one additional fish worth? EPA applies them, however, as though they were average values. A better approach would be to treat them as marginal values. <FN 20>

2. EPA's RUM Study Has Major Flaws

As noted above, the availability of large quantities of detailed data is a prerequisite for conducting correct RUM analyses. An appropriate application of RUM would recognize that there are several levels at which people make decisions; it would model the choices available using detailed inputs to derive the expected utilities for each of them. Because of their speculative nature, RUM analyses are very sensitive and can be easily distorted by incorrect specifications and/or data inaccuracies (Desvousges et al. 2002). The analysis of recreational benefits using RUM conducted by the EPA suffers from a number of such problems, which result in a sizeable overstatement of the value of recreational losses due to I&E at Salem. These problems are described in Desvousges et al. (2002) and are summarized below:

--EPA uses unweighted intercept data, which are not representative of the general population of anglers and over-represents avid anglers who—by definition—place a much higher value on fishing than regular anglers.

--While the opportunity cost of fishing (measured most closely as the per hour wage rate) is among the most important inputs in EPA's model, the EPA relied on an incomplete dataset and made a number of inappropriate assumptions. These include:

-Using the full wage rate to value leisure time, when existing information suggests that leisure time should be valued at one-third of the wage rate.

-Making a number of questionable assumptions to fill in those survey observations that are missing due to people's unwillingness to report their income. These assumptions consistently lead to higher wage estimates. For example, those who do not report unemployment status are considered fully employed and their opportunity cost to fishing is estimated by considering their state, sex, age, and boat ownership. (Wage estimates based on such inputs are also likely to be imprecise.) Homemakers or retired employees are assigned a wage, even though they do not forgo any income by undertaking a fishing trip. Similarly, the forgone wages of part-time employees are valued at the full wage rate.

In summary, the EPA's RUM analysis uses incorrect inputs and makes a number of assumptions that result in an overestimation of the value of the recreational losses. While it is still unclear that the RUM could be successfully used in this case due to data limitations, the EPA misused even the data they obtained. These limitations would have to be corrected before the RUM results for the Delaware Case Study could be considered reliable estimates of recreations benefits.

3. In Its Final Estimates, EPA Uses Values from Both Benefit Transfer and RUM Without Addressing the Inconsistencies and Possible Double Counting

EPA's final damage estimates use the RUM values for striped bass and weakfish and the benefit transfer for all other species. They follow this procedure without addressing the potential inconsistencies and double counting.

a. EPA's Valuations for RUM Are Significantly Higher, Particularly for Weakfish

The two methods used in EPA's report yield significantly different values for weakfish. In the RUM analysis, the weakfish value per fish is more than five times higher than the benefit transfer valuation. This result is significant given that weakfish account for almost a third of the total losses estimated by EPA. EPA does not discuss this discrepancy.

b. The Inclusion of "No Target" Species Creates the Possibility of Double Counting

EPA's inclusion of all "no target" species in the weakfish valuations seems highly questionable. When these values are added to the benefit transfer estimates—which include values for many other species—EPA appears to be double counting some cases. However, it is difficult to be certain because EPA's methodology for including the "no target" estimates is not clear. In particular, EPA's per fish valuations are difficult to reproduce from the numbers and methodologies they provide.

D. Summary

EPA uses two methodologies—RUM and benefit transfer—to value recreational losses due to I&E at Salem and then uses results from both. While the benefit transfer methodology is fundamentally sound, its application in this case is not consistent with the recommendations in the EPA Guidelines (2000). The RUM analysis has several important limitations. In addition, the discrepancies between the results for these two models are never addressed. Collectively, these limitations call into question the EPA's recreational estimates. At the very least, EPA should reconsider the methodologies discussed here.

[comment text continued in 316bEFR.075.504]

Footnotes

18 The variables included in the RUM are: travel cost (including in some cases, the opportunity cost of travel time), the presence or lack of a boat ramp at the site, the natural logarithm ("log") of the number of sites within the particular reach on which the site is located, the square root of the historic catch rate for the species if targeted by the angler, and ambient concentrations of Total Kjeldahl Nitrogen as a proxy for visual water quality at the site. EPA used data on catch rates of weakfish, striped bass, flounder, bottom fish, and "big game." The model resulted in positive significant (above the 99 percent level) coefficients for the first three of these species.

19 This discussion was adapted from Desvousges et al. (2002). See this source or Freeman (1993) for further discussion of the RUM approach.

20 As an example of an alternative, and preferred, approach, PSEG's Salem filing (PSEG 1999) used a statistical meta-analysis of the marginal value of increased catch. EPA's Guidelines note that this approach "provide[s] a systematic way of incorporating case study information with policy case information" (U.S. EPA 2000, p. 87).

EPA Response

The commenter first outlines the basic steps that EPA followed in developing recreational benefit estimates for the Delaware Case Study and then evaluates EPA's methodology for estimating dollar value of recreational losses due to I&E at Salem. The commenter concludes that although EPA's choice to use benefit transfer technique and RUM studies is sound, EPA's recreational benefit estimates are compromised by an overly simple benefit transfer method and a flawed RUM study.

EPA responds here to the benefits transfer questions and issues raised by the commenter, but also notes that EPA has significantly reduced its reliance on benefit transfer to estimate recreational fishing benefits for the final rule analysis. In addition, EPA no longer uses case studies of individual facilities. Instead, EPA has estimated regional recreational fishing models. For the recreational fishing analysis, benefit transfer is used for the Inland region, and benefit function transfer is used for the North Atlantic region. EPA has estimated RUM models for all other coastal regions (Mid-Atlantic, South Atlantic, Gulf of Mexico, and California), and for the Great Lakes region.

Where the benefits transfer approach was applied, at proposal or final rule, EPA generally followed its Guidelines for Preparing Economic Analyses for benefits transfer (BT). In the § 316(b) Phase II benefits analysis at proposal, the steps were followed as recommended in the Guidelines when using BT:

1. describe the policy case;
2. identify existing, relevant studies;
3. review available studies for quality and applicability;
4. transfer the benefit estimates; and
5. address uncertainty.

All of these steps were followed in the Phase II benefits analysis at proposal.

Four alternative BT methods are described in the Guidelines: point estimate, benefit function, meta-analysis, and Bayesian. In the Phase II benefits case studies, EPA followed the point estimate approach because the data collection required to implement alternative BT approaches made them infeasible or impractical. For example, to use the alternative methods, a large quantity of socioeconomic and demographic data would need to be collected on anglers and non-anglers at each case study fishing site. Time and budget constraints did not allow for the collection of this type of data, nor did it appear that the value added in terms of potential added precision would be notable.

This is because most of the fish valuation studies assembled from the literature generated per fish dollar values of comparable levels, such that pooling the data, or dropping a few individual studies, would not alter the dollar value outcomes appreciably.

The point estimate approach involves taking the value(s) from a study case and applying it directly to the policy case. Rather than a single point estimate, the § 316(b) case studies relied on a suite of prior empirical studies to construct site-specific and species-specific ranges of values. In fact, this is a "weight of evidence" approach that is, in spirit, a practical though informal variation of more elaborate BT approaches.

The studies that EPA used for its BT analysis are published in peer-reviewed journals and estimate values for regions and fish types that are comparable to those in the case study locations. Selection of studies was consistent with the Guidelines and based on selection criteria outlined by Desvousges (1998, DCN #5-1261), which is considered standard in BT application.

Some commenters suggested that EPA rely on a single study (in lieu of drawing on the broader base of studies available in the literature) for some sites. For example, Dr. Stavins states the following concerning BT studies used in the Brayton Point case study at proposal:

"... EPA could have drawn upon a much more appropriate source for its recreational benefit transfer method, namely a recent National Oceanographic and Atmospheric Administration (NOAA) study conducted by Hicks, et al. (1999) of the National Marine Fisheries Service (NMFS)(DCN #4-1603). The Hicks, et. al. (1999) study is the most appropriate source for benefit transfers of recreational fishing values for this work since it provides estimates of the value of a marginal increase in catch for relevant species groups for the affected geographic area."

EPA notes that the Hicks study is, in fact, the main study that it applied in the BT portion of the Brayton Point recreational impacts analysis. In addition, the Agency created a range of available values by fish type and location to develop a "weight of evidence" approach. EPA believes that relying on a single recreational valuation study at a given site when additional good data are available is less preferable because it may ultimately place too much emphasis on a single source of information, even if the underlying study is site-specific and well executed. By using Hicks et al. in conjunction with several other applicable studies, EPA developed greater confidence in the results, especially because the various studies EPA used in the BT all generated dollar values of similar magnitudes.

EPA has followed standard, generally accepted methods of RUM modeling, which do estimate marginal values. See response to comment #316bEFR.041.452 for additional details regarding EPA's RUM models.

The commenter further states that the inclusion of all "no-target" species in the weakfish valuations leads to overstatement of total benefits from reduced weakfish I&E. EPA notes that weakfish catch rates were used as a proxy of the quality of recreational fishing sites for no-target anglers. Because a large percentage of no target anglers caught weakfish and because this species are common in the Delaware River estuary, it is reasonable to assume that the majority of no-target anglers would benefit from improved weakfish catch rates. As noted above, EPA no longer uses case studies of individual facilities for the final rule analysis. Instead, EPA has estimated regional recreational fishing models.

For the regional recreational fishing models, quality of recreational fishing sites for no-target anglers was defined in terms of average catch rates for all species caught by no target anglers. See response to comment # 316bEFR.306.320 for detail.

Finally, the commenter states that discrepancies between the results from the benefits transfer approach and RUM "call into question the EPA's recreational estimates." EPA disagrees. Benefit transfer involves adapting research conducted for another purpose in the available literature to address the policy questions at hand, therefore it is unreasonable to expect that recreational fishing values based on benefits transfer would be identical to values developed based on a site-specific study. Given the unavoidable uncertainties in monetizing both use and non-use values for the ecological resources that would be affected by the 316(b) rule, the Agency believes that it is appropriate to use alternative valuation techniques to develop a range of recreational fishing benefits for the proposed rule. See also response to comment # 316bEFR.338.047 regarding evaluation of uncertainty in valuation of ecological resources affected by the 316(b) rule.

V. EVALUATION OF THE EPA METHODOLOGY FOR ESTIMATING THE ECONOMIC VALUE OF NONUSE BENEFITS

This chapter describes and evaluates EPA's methodologies for estimating nonuse losses at the Salem facility and other in-scope facilities in the Delaware Estuary. The chapter begins with an overview of EPA's methodology and results, discusses conceptual considerations, and then evaluates EPA's approach.

EPA's use of a crude "rule of thumb" benefits transfer technique to value nonuse losses is fundamentally flawed, without support in the economics literature. EPA presents no information to indicate that there are nonuse losses from I&E at Salem. Accordingly, EPA should not include the nonuse losses based upon its "rule of thumb" in its benefits estimates for the final rule.

A. Overview of EPA's Methodology and Results for Salem

This section provides an overview of EPA's methodology for estimating nonuse losses and summarizes EPA's results.

1. Methodology

To estimate the nonuse losses associated with I&E at the Salem facility, EPA applied a simple "rule of thumb" that nonuse values are equivalent to 50 percent of the estimated recreational fishing benefits. EPA appears to base this "rule of thumb" primarily on two papers dating from the 1970s and 1980s, <FN 21> which claim to show that nonuse values were at least 50 percent of recreational use values in the individual instances studied. EPA did not perform an explicit benefits transfer to justify the applicability of the rule of thumb to the Delaware Estuary.

2. Results

Using this approach, EPA estimates the annual nonuse losses associated with I&E at the Salem facility. Table 15. shows this estimation.

Table 15. EPA Estimates of Nonuse Losses at Salem
[see hard copy for table]

B. Conceptual Considerations

This section discusses a number of conceptual considerations that are important in understanding whether nonuse values are likely to be important in the context of losses to I&E in the Delaware

Estuary, and if so, how they could be appropriately estimated. We begin with a brief overview of the conceptual bases for nonuse benefits.

1. Conceptual Bases for Nonuse Benefits

In his text on measuring environmental and resource values, Freeman (1993) reviews the literature on nonuse (or existence) value. He notes that nonuse value has been attributed to a number of motivations, including bequest, altruism, and an ethical concern for the status of non-human species or proper rules of human conduct. He argues that there is an important distinction between degradation of a natural resource and its permanent destruction. Freeman develops a theoretical framework for evaluating nonuse values which supports this distinction. He concludes by noting that while the literature is unresolved on this issue, nonuse values are most important when the resource in question is special or unique and the loss or injury is irreversible:

Another important question is, when are nonuse values likely to be important? The long literature on nonuse values emphasizes the uniqueness or specialness of the resource in question and the irreversibility of the loss or injury. For example, economists have suggested that there are important nonuse values in preserving the Grand Canyon in its natural state and in preventing the global or local extinction of species and the destruction of unique ecological communities. In contrast, resources such as ordinary streams and lakes or a subpopulation of a widely dispersed wildlife species are not likely to generate significant nonuse values because of the availability of close substitutes. Moreover, the literature does not suggest that nonuse values are likely to be important where recovery from an injury is quick and complete, either through natural processes or restoration (Freeman 1993, p. 162).

Thus, Freeman's (1993) review of this literature suggests two criteria to evaluate whether the nonuse value for the Delaware Estuary is likely to be important:

1. Is the resource unique?
2 Are the losses to the resource irreversible?

If both of these criteria are not met, Freeman (1993) suggests that the nonuse values are likely not to be important.

2. Estimating Nonuse Value

If nonuse value is relevant, the next question is how to estimate it. The standard method for estimating nonuse value is "contingent valuation" ("CV"). In the CV method, individuals are asked how much they would be willing to pay for a described commodity (for example, to preserve an identified resource), or whether they would be willing to pay a specified amount. <FN 22> Use of this method has been controversial among economists, because it relies on stated preferences, which can be prone to bias and misstatement, rather than on actual choices. Nevertheless, CV is an accepted method in the economic literature for measuring nonuse value.

EPA's Guidelines (2000) confirm this point. They state: "Currently, contingent valuation is the only established method capable of estimating non-use values ... " (p. 84).

3. Evaluation of "Rule of Thumb"

As noted, EPA's estimates of nonuse benefits are based on a crude benefit transfer technique, in which EPA multiplied its recreational benefits estimates by a factor of 50 percent. EPA asserts that this is a "long-standing" approach, arguing,

One long-standing benefit transfer approach for estimating nonuse values is to apply a ratio between certain use-related benefits estimates and the passive use values anticipated for the same site and resource change (EPA 2002, p. A9-10).

a. Freeman Citation

EPA's claim that this is a "long-standing" approach is based upon a 1979 review authored by A. Myrick Freeman for the Council on Environmental Quality. <FN 23> In his review, Freeman cites two papers: (1) a 1976 report by Heintz, Hershaft, and Horak, which itself describes two surveys, one by Meyer (1974) pertaining to preservation of a salmon fishery in British Columbia, and another by Horvath (1974) focused on the southeastern U.S.; and (2) a survey by Walsh, et al. (1978), focusing on improved water quality in the South Platte River Basin. Freeman notes that these studies claim to find nonusers willing to pay roughly 50 percent as much as users to preserve a recreational resource.

Although he is cited as the principal source for EPA's use of this "rule of thumb," Freeman does not appear to be very comfortable with it. First, in his 1979 review, he concludes his review of the "rule of thumb" by calling it "a tenuous empirical basis from which to estimate national nonuser benefits" (p. 171). More important, he omits any discussion of this approach from his 1993 book, The Measurement of Environmental and Resource Values: Theory and Methods, a standard text on environmental benefit estimation. Instead, Freeman points to CV and other stated preference techniques as the appropriate methods to use in estimating nonuse value. Referring to these approaches, he states: "[T]he hypothetical direct valuation methods treated [in Chapter 6 of his book] are likely to offer the only feasible approaches to estimating nonuse values for public policy purposes" (1993, p. 159).

b. Fisher and Raucher Citation

EPA also cites a 1984 review article by Fisher and Raucher, which offers a more complete review of the literature reviewed by Freeman. Fisher and Raucher note that this "rule of thumb" was apparently first used by Abel, et al. (1998). Fisher and Raucher are critical of the rule of thumb: "The proportional relationship used by Abel et al. is not in the least robust" (Fisher and Raucher 1984, p. 47). In particular, they criticize the Meyer (1974) and Horvath (1974) results as inappropriate for generalization and poorly conceived. Somewhat incongruously, however, Fisher and Raucher conclude with the claim that "the existing evidence indicates that nonuse benefits generally are at least half as great as recreational use benefits" (1984, p. 60).

c. Other Citations

In defense of the "50 percent rule," EPA further cites two studies, one by Sanders et al. (1990), and another by Sutherland and Walsh (1985). Sanders et al. use a 1983 mail survey to estimate nonusers' willingness to pay to "protect" a number of rivers in the State of Colorado. Sutherland and Walsh use a mail survey to value nonusers' willingness to pay to "protect water quality" in Montana's Flathead

Lake and River.

Both studies are problematic as a basis for application of a “50 percent rule.” These studies were conducted for resources that are altogether different from the Delaware Estuary, and therefore should not be applied to I&E at Salem.

4. Empirical Considerations Related to I&E in the Delaware Estuary: How Irreversible Are Fish Losses?

From an ecosystem perspective, it is possible to use existing information to assess how the I&E losses at Salem relate to one of the two criteria discussed at the beginning of this section, namely, whether the fish losses at Salem are irreversible.

In order to establish whether I&E at Salem is likely to yield nonuse losses of any importance, we need to evaluate the effect of Salem on the relative abundance of fish species in the Delaware Estuary. Standard theory of renewable resources such as fish stocks suggests that at some point, the stock can decline to a level below which the stock is unable to reproduce itself sufficiently fast to sustain itself and will tend inevitably toward zero (this is the so-called “critical depensation” point). <FN 24> If the stock of any species were rapidly declining, such that it could be in a state of critical depensation, and if this were linked to I&E at Salem, the irreversibility criterion for nonuse losses suggested in Freeman (1993) might be satisfied.

As we show in the section, there is no evidence of this. If anything, the stock of most key fish species in the Delaware Estuary has been increasing since the late 1970s and future projections show that Salem would have virtually no influence on the behavior of fishery stock.

A detailed study by PSEG in 1999 analyzed historical data for nine RIS and observed a consistent and significant trend for growth in the stock of seven of the species. Most species were not only increasing in abundance, but they were also increasing at a rapid rate (PSEG 1999). Several of the species, including weakfish, striped bass and American shad, were depleted in the late 1970s but experienced a recovery in abundance during the years when Salem was in operation. The declines in the stock of the two remaining species, spot and blueback herring, are not linked to the operation of Salem. According to the Atlantic States Marine Fisheries Commission (“ASMFC”), the stock of blue herring has been declining since the mid-1960s, which predates the opening of Salem by a decade (ASMFC 1998). The observed decline in the stock of spot, on the other hand, is due to the abnormally high abundance of the species observed in 1988, which created the illusion of a negative growth rate in subsequent years, when in fact the abundance of spot was at levels comparable to those before 1988. (PSEG 1999).

Future projections performed in 1999 complement the historical data showing that the operation of Salem has not led to a decrease in the abundance of species in the Delaware Estuary. Simulations with two different methodologies fully endorsed by the ASMFC, which use inputs from the NMFS, demonstrate that there is no difference in the behavior of the fishery stock with or without the operation of Salem. Figure 7 and Figure 8 illustrate representative results from the spawning stock biomass approach (SSB). <FN 25>

Figure 7. Results from SSB Modeling Comparing Potential Future Effects of I&E at Salem with a

Baseline Case: American Shad and Weakfish
[see hard copy for figure]

Figure 8. Results from SSB Modeling Comparing Potential Future Effects of I&E at Salem with a Baseline Case: Spot and Blueback Herring
[see hard copy for figure]

The two figures present the results of a Monte-Carlo type simulation of stock levels for American shad and weakfish and for spot and blueback herring under two scenarios: one with and one without the effects of I&E from Salem. The uncertainly assessment involves specifying input probability distributions for key parameters (such as stock-recruitment relationship) and using the randomly defined parameter sets to calculate probability distributions for fished populations compared to unfished populations. The shaded area depicts the stock level at which the stock could be in jeopardy of becoming unsustainable. These figures show that, as simulated, the probability distribution of the spawning stock relative to the point of potential jeopardy is not significantly affected by I&E at Salem, even for the two species (spot and blueback herring) for which decline has been observed.

Figure 9: Results from SSBPR Modeling Comparing Potential Future Effects of I&E at Salem with a Baseline Case.
[see hard copy for figure]

Figure 9 shows the results from a different approach, the spawning stock biomass per recruit method ("SSBPR"), which simulates the size of the stock (on the y-axis) for increases in the conditional mortality rate ("CMR") on the x-axis. The 30 percent biological reference point is the rate below which the stock cannot reproduce itself at the maximum sustainable yield, a rate which is often referred to as "overfishing." It is clear from the figures that even for large CMRs, the size of the stocks of alewife and American shad is not anywhere near the point of jeopardy and—more important—that there is no difference between the behavior of the stocks with or without the impact of Salem.

Overall, the historical data on fish stocks, and the future simulations based on two widely endorsed methods show that Salem poses no danger on the size of the stocks. This conclusion renders Freeman's irreversibility criterion inapplicable to the case of I&E at Salem and suggests that nonuse losses should not be valued above zero.

C. Evaluation: EPA's Nonuse Values Have No Conceptual or Empirical Support

Apart from the lack of support in the various citations for its development, EPA's use of the 50 percent rule is questionable on a number of other grounds. First, it does not appear in EPA's Guidelines. Second, as a benefit transfer approach, it fails to meet the criteria outlined in EPA's own guidance document, as described above in Chapter IV of this report. These problems with EPA's use of the "rule of thumb" are explained in greater detail in the following sections.

1. There Is No Basis for the 50 Percent Rule in EPA's Guidelines

EPA's Guidelines (2000) provide a thorough discussion of appropriate methods for valuing the effects of environmental policies. They make no mention of the 50 percent rule for estimating nonuse values.

2. The 50 Percent Rule Does Not Conform to EPA Guidelines for Benefit Transfer

As discussed earlier, in Chapter IV, EPA's Guidelines lay out three criteria for selecting studies to be used to perform benefit transfer analysis. Appropriate studies are those for which:

1. The basic commodities being valued are essentially equivalent;
2. The baseline and extent of the change are similar; and
3. The affected populations are similar.

These criteria provide an important assurance that the basis of the benefit transfer is relatively sound. Yet, the 50 percent rule used in EPA's 316(b) analysis does not meet these criteria. EPA's case study document provides only a cursory literature review, identifying a scant four studies (two of which are secondary studies) in support of its point estimate. The discussion of this issue in EPA's Delaware Case Study provides no basis for assessing whether the commodities valued are essentially equivalent, whether the baseline and extent of the change are similar, and whether the affected populations in the studies underlying the 50 percent rule are similar to those in the Delaware Estuary. A review of the four sources cited in Section A9-5 of EPA's case study document indicates that the two most recent studies cited (Sutherland and Walsh, 1985, and Sanders, et al. 1990) are focused on water quality and preservation of an ecosystem, not on changes in fish populations. For both of these studies:

1. The commodities being valued are different from those at stake in the Delaware Estuary. Sutherland and Walsh (1985) values "protection of water quality"; Sanders et al. (1990) value "protection of rivers" in Colorado. These values are much more global in scope than the more narrow commodity—fish and shellfish—being evaluated in the Delaware Estuary case.

2. The baseline and nature of the change are different. Sutherland and Walsh and Sanders et al. value preservation of an existing resource. In the Delaware Estuary Case Study, EPA is attempting to value improvement in a resource—namely, an increase in fish stocks in the Delaware Estuary.

3. The affected populations may not be similar. Both Sutherland and Walsh and Sanders et al. estimate nonuse values for populations in the Rocky Mountain West (Montana and Colorado). EPA does not even identify the affected (nonuser) population in the Delaware watershed, nor does it offer a specific reason to believe that it would be similar to nonusers in Montana and Colorado.

3. Evidence from the Delaware Suggests That Nonuse Values Are Not Likely to Be Important for I&E at Salem

As discussed earlier, Freeman (1993) develops two criteria that should both be satisfied in cases where nonuse values are likely to be important: (1) the resource in question should be unique; and (2) the damage to it should be irreversible. The evidence on the Delaware Estuary indicates that these criteria are not satisfied with respect to the key fish stocks in the Delaware Estuary and the impacts of Salem I&E. Thus, there is no evidence of any non-use values due to I&E at Salem.

D. Summary

In summary, EPA's estimates of nonuse values derive from an arbitrary approach that is poorly supported in the relevant literature and inconsistent with EPA's own guidance on how to conduct benefit-cost analyses in the context of policy decisions.

Absent a specific and sound empirical study of nonuse values in the Delaware Estuary, there is no basis for assigning a nonuse value to I&E changes at Salem.

VI. ESTIMATING THE EVALUATION OF THE EPA METHODOLOGY FOR ESTIMATING THE ECONOMIC VALUE OF FORAGE FISH BENEFITS

This chapter evaluates EPA's estimates of the economic value of forage fish losses due to I&E at Salem. We consider the methodologies used to value forage fish, the conceptual background, and evaluate the soundness of EPA's methodologies in the Delaware Case Study.

A. EPA's Methodologies for Valuing Forage Fish Losses due to I&E at Salem

In its analysis, EPA defines forage fish as all fish that have only indirect benefits for society—through their role as prey for other fish. Forage fish are not themselves fished, either commercially or recreationally. EPA uses two methodologies to value forage fish losses due to I&E at the Salem facility: (1) production foregone; and (2) replacement cost. Table 16 presents the EPA's results from both of these calculations.

Table 16. EPA Estimates of Forage Fish Losses due to I&E at Salem
[see hard copy for table]

Although the Delaware Case Study document is not fully explicit, EPA apparently developed midpoint estimates of forage fish losses at Salem by averaging the low production foregone estimate with the replacement cost estimate. The sections below describe the two methodologies.

1. Production Foregone

The production foregone methodology values forage losses "based on the dollar value of the foregone fishery yield resulting from these losses" (U.S. EPA 2002, p. B4-10). Forage species are converted into species that are commercially or recreationally relevant—those that have a direct market value. Market valuations of these species—taken from market prices or the literature—then provide dollar values for the losses.

2. Replacement Cost

EPA (2002, p. B4-9) describes the replacement cost of forage fish as having two components, the cost of raising the fish and the transportation cost. However, because of a lack of data, EPA does not consider the transportation cost. Thus, to generate the replacement cost figure, EPA estimates the cost of raising each affected forage species in a hatchery and then multiplies this number by the I&E level for each species. EPA then takes this number to be equivalent to the value of the forage fish losses at Salem.

B. Conceptual Background

Conceptually, forage fish contribute to use value (recreational and commercial) indirectly through their contribution to the stocks of those fish that are valued directly in commercial markets and for their share of the recreational catch. Thus, in principle, the appropriate way to value forage fish is to examine the effects of changes in their stocks on changes in stocks of fish that are valued directly. This approach is consistent—at least in principle—with EPA's "production foregone" approach. (See Stavins (2002) for further discussion of this point.)

C. Evaluation: EPA's Forage Fish Benefits Are Overstated by Including a Flawed Methodology—the Replacement Cost Approach—as One of Two Methods

Of the two methods EPA uses to value forage fish losses, one methodology—the production foregone method—seems consistent with sound economic principles. The second approach—the replacement cost method—however, is not a valid methodology. Indeed, the replacement cost method involves a fundamental error—it assumes that benefits are equal to costs—and should be rejected.

1. Additional Forage Fish Lead to Benefits to the Extent That They Increase Commercial and Recreational Catch

Economic benefits are the sum of producer and consumer surpluses. Thus, the economic benefits from forage fish come through their indirect impact on commercial and recreational values. That is, if forage fish increase commercial or recreational catches, then they have some economic value. Thus, an accurate model should consider how forage fish affect other species that have economic benefits that can be calculated directly.

2. The Production Foregone Method in Theory Could Lead to Valid Benefit Estimates

In concept, the production foregone method provides a valid methodology for evaluating the potential indirect benefits of forage fish changes. It attempts to measure how forage species affect populations that have direct economic benefits. Using valuations of these species, EPA can then estimate how much surplus is lost—both commercial and recreational—due to I&E forage fish losses at Salem.

This report does not assess the validity of EPA's biological estimates, which depend critically upon the accuracy of the scientific assessments of the linkages between changes in forage fish and changes in the populations of commercial and recreational species.

3. In Contrast, the Replacement Cost Method Is not an Economically Valid Benefit Methodology

The economics literature and the recent EPA Guidelines (EPA 2000) provide examples of methods that may legitimately be used to estimate benefits. Replacement cost is not among them. The replacement cost methodology purports to calculate the lost benefits from forage fish by estimating the cost of producing the lost species in a hatchery. However, replacement cost provides an estimate of the costs of undertaking an activity—hatching forage fish—that would be intended to have an equivalent result to ceasing or reducing I&E at Salem. This might be a worthwhile exercise if replacement of habitat or creation of new habitat were a potential policy alternative. If costs were used as a measure of benefits, the benefit-cost analysis would suggest all projects had a net benefit of zero.

Use of costs to measure benefits would make a mockery of benefit-cost analysis. There is no support for such a position in the economic literature. The approach cannot provide a valid measure of the willingness to pay for forage fish changes due to I&E at Salem.

D. Summary

Forage fish benefits should reflect the gains from the additional recreational and commercial fishing that are created. The production foregone method can provide a valid measure of these benefits, assuming that the underlying biological estimates are correct. In contrast, the replacement cost method is not a valid means of measuring benefits. It should be discarded from the Delaware Case Study.

VII. CONCLUSIONS AND RECOMMENDATIONS

This chapter summarizes the overall conclusions regarding the economic assessments in the Delaware Case Study. The chapter also provides recommendations for changes EPA should make in the Delaware Case Study before it issues its final Phase II rule.

A. Conclusions

We conclude that the "effects-by-effects" approach is a sound overall framework for evaluating the benefits of I&E at Salem on the Delaware Estuary. In this approach, the individual components of benefits are identified and quantified according to a three step process:

1. Identify physical effects (i.e., changes in fish populations).

2. Quantify the major physical effects (i.e., changes in populations of commercial fish, recreational fish, forage fish).

3. Estimate the dollar values of these physical effects.

EPA has followed this sensible overall approach in the Delaware Case Study.

Although the overall approach is sound, the economic values developed for the individual components have serious flaws. EPA developed individual benefit estimates for the following four categories of benefits:

1. Recreational benefits;
2. Commercial benefits;
3. Nonuse benefits;
4. Forage fish benefits.

The methodologies for all four of the assessments have weaknesses that make them unsuitable either as the basis for national estimates of the benefits of 316(b) alternative regulatory approaches or as models for those undertaking benefit-cost studies for individual 316(b) permits.

B. Recommendations

The following are recommendations following from our review of the economic issues related to the Delaware Case Study.

1. Before issuing a final 316(b) rule, EPA must revise the economic benefit methodologies in the Delaware Case Study and other case studies with similar deficiencies

It is important that the economic benefit methodologies in the Delaware Case Study be sound, both because they underlie estimates of the benefits of alternative 316(b) regulatory alternatives and because they are likely to be used by applicants and permit writers to evaluate specific 316(b) benefit-cost assessments.

2. For commercial fishing benefits, EPA should review the empirical foundations and revise its estimates

The commercial fishing benefits in the Delaware Case Study are overstated because they exaggerate the likely consumer and producer surplus due to changes in commercial catch. The values do not appropriately acknowledge the long-run tendency for producer surplus to be dissipated, which means that most additional gross ex vessel revenues do not constitute long-term benefits. Even more importantly, EPA uses a "multiplier" to translate changes in producer surplus into total "multi-market" surplus that is not justified. Such changes in multi-market surplus implies substantial changes in fish prices, and EPA has provided no information to support such a claim. Indeed, given the relatively small effect changes in I&E at Salem would have on overall supply, it does not seem likely that consumers would receive any additional consumer surplus gains.

EPA should revise its estimated range of potential commercial fishing benefits from Salem I&E to reflect long-term effects on producer surplus and the lack of any likely effects on fish prices.

3. For recreational fishing benefits, EPA should modify its application of the benefit transfer approach and revise (or ignore) its RUM study

EPA's recreational fishing benefits are based upon the benefit transfer approach and a RUM study carried out by EPA. The benefit transfer study should be reevaluated to consider using a more sophisticated approach that would allow the value per fish to vary with individual circumstances. The RUM study—which is used to value two of the relevant species—should be either ignored or revised to eliminate (or explain) apparent methodological problems.

4. For nonuse benefits, EPA should discard the estimates derived from the 50 percent rule of thumb

EPA's nonuse benefits are based upon a crude rule of thumb that has no validity and no applicability to I&E changes in the Delaware Estuary. Unless EPA has evidence of nonuser benefits, this category should be eliminated as part of the Delaware Case Study.

5. For forage fish, EPA should discard the replacement cost method and rely exclusively on the

production foregone method

Forage fish can provide benefits because of the effects they have on commercial and recreational species. EPA should base its estimate of benefits on the production foregone method and discard the alternative replacement cost method, which has no conceptual or empirical foundation as a measure of benefits.

Footnotes

21 Freeman (1979) and Fisher and Raucher (1984). Note that EPA erroneously cites this source as Freeman (1977). Despite its importance to EPA's nonuse benefits estimate, the Freeman review does not appear to be included in EPA's docket for the 316(b) proposed rule.

22 See U.S. EPA 2000, p. 83-84 for a discussion of CV, and NOAA (1993) for a discussion of methodological considerations in conducting a rigorous CV study.

23 EPA cites this source as Freeman (1977).

24 See, e.g., Clark (1990), p. 18-21.

25 This approach and the underlying justification for using it are reviewed in greater detail in PSEG (1999, p. 78-86).

EPA Response

The commenters' primary comments focus on four aspects of the valuation of benefits for the proposed rule. They are largely addressed in other comments as follows.

1) Recreational Benefits
For the analysis for the final rule, EPA modified the methods used to value recreational losses and benefits. All recreational benefits are now valued using a Random Utility Model (RUM). For EPA's response to comments on the recreational methodology, please see EPA's response to comments #316bEFR.075.504 and #316bEFR.041.452.

2) Commercial Benefits
EPA also modified the methods used to estimate commercial fishing benefits and losses. For EPA's response to comments on the commercial fishing valuation methods, please see EPA's response to comments #316bEFR.005.029.

3) Nonuse Benefits
EPA disagrees with the commenters' assertion that EPA's approach to valuing non-use benefits is not supported by EPA's Guidelines. See the response to comment #316bEFR.005.013 for a detailed response.

In the cost-benefit analyses for the NODA and for the final Section 316(b) Phase II rule, EPA did not use the 50% rule-of-thumb to estimate non-use benefits. For EPA's response to comments on the use of the 50% rule-of-thumb to estimate non-use benefits, please refer to EPA's response to comment #316bEFR.005.034.

For the final 316b rule analysis, EPA has not included quantitative measures of nonuse values due to unavoidable uncertainty in monetizing non-use values. The Agency, however, has provided several measures that indicate the potential magnitude of non-use values, including meta-analysis, the benefit transfer method, and break-even analysis. See Chapters A12, Non-use Meta-analysis Methodology, and A9, Economic Benefit Categories and Valuation Methods of the final Phase II Regional Studies Document (DCN #6-0003). Please see Chapter D1 of the final Phase II EBA document (DCN #6-0002) regarding break-even analysis. Also, see response to Comment 316bEFR.307.061 for a discussion of EPA's habitat-based approach to nonuse analysis.

4) Forage Fish Benefits
For the analysis for the final rule, EPA modified the methods used to value forage species. They are now valued using a trophic transfer method. Please see EPA's response to comment #316bEFR.005.028 and Chapter A5 of the Regional Analysis Document (DCN #6-0003) for details.

Additional discussion on the issue of nonuse values and their estimation can be found in response to comment 316bEFR.306.105.

Several other topics addressed in other comments are also relevant:

For EPA's response on comments regarding measures of uncertainty and confidence intervals, please see the response to comment #316bEFR.041.843.

Regarding the impact of I&E at Salem on Delaware Estuary fish populations, EPA disagrees with the commenter's assertion that there are no impacts. According to p. 65 of Appendix H of PSEG's own 316b study for its 1999 Permit Renewal Application for the Salem facility (DCN #1-3061-BE), the proportion of the baywide population of bay anchovy that is impinged and entrained annually at Salem ranged from 2% in 1982 to 28% in 1998. EPA maintains that a 28% impact on a fish stock is not insignificant.

Please refer to EPA's response to comments on the HRC methods (316bEFR.005.035) and the SRP methods (316bEFR.005.006); the document entitled "Habitat-based Replacement Cost Method" (Docket #6-1003); and to EPA’s Guidelines for Preparing Economic Analyses (EPA 240-R-00-003, DCN #6-1931).

Methods to Evaluate I&E

Author Name Reed W. Super

Organization Pisces Conservation, Ltd.

A critical area in which the EPA has expended considerable effort is the estimation of entrainment and impingement deaths caused by cooling water systems. These estimates can vary considerably depending upon the assumptions made, and are a key area of weakness in the assessment of the economic value of the losses caused by cooling water extraction. There can be no certainty as to the magnitude of the losses as sufficient recent data on entrainment and impingement are unavailable. However, the EPA has probably underestimated the magnitude of the problem. Particular areas identified here, which could have caused an underestimate of losses, are itemised below.

EPA Response

This comment refers to Comments 316bEFR.077.003 and 316bEFR.077.005. Please see EPA's responses to these comments.

EPA methods: age 1 equiv, yield, prod foregone

The effects of impingement losses have probably been underestimated both in terms of their impact on the populations and relative to entrainment. It is assumed that all impinged fish are age 1. “EPA used life stage-specific annual losses for assessment of entrainment losses and assumed that all fish killed by impingement were age 1 at the time of death.” (A5-2-1). This leads to a large underestimation of the number of age 1 equivalents killed by impingement at plants where adult fish are caught. Using white perch from the Salem case study as an example the number of age 1 equivalents killed by the station increased from 500,000 to over 37,000,000 when age structure was taken into account. Generally, by allowing correctly for age structure the impact of impingement on the populations was brought closer to the impact of entrainment.

EPA Response

Please see EPA's response to Comment 316bEFR.029.105 for EPA's assumptions about the age distribution of impinged fish for its final analysis for the Phase 2 rule.

Methods to Evaluate I&E

In many localities there have been appreciable recent changes in the abundance of fish. Many species have increased but some, such as the American eel, have declined. For example, striped bass numbers in the Hudson have increased possibly 15-fold since the 1970s. These improvements from historically suppressed levels may result in an under-estimation of potential entrainment and impingement losses in future years if direct cooling is continued.

EPA Response

EPA recognizes that abundances of aquatic species, and therefore the numbers of organisms vulnerable to I&E, may have increased, decreased, or stayed the same at particular sites since the time of the available I&E studies. Unfortunately, it is uncertain how old I&E data can be adjusted to reflect current abundances, particularly given the many variables that influence biological populations and therefore the abundance of organisms vulnerable to I&E.

EPA methods: age 1 equiv, yield, prod foregone

Survival rates are key variables as they are used to estimate the total mortality as age 1 equivalent numbers. In some calculations the rates are probably too low, as they are based on historical data when populations were badly suppressed by environmental damage and over-exploitation. Changing the survivorship figures used in the age-1-equivalent calculations can have a large effect on the numbers of age-1-equivalents estimated to be entrained or impinged. Generally, more reliable estimates of age-1-equivalence would be obtained by increasing survival rates by 25%.

EPA Response

EPA agrees with the commenter that survival rates are critical parameters in EPA's I&E analysis. However, EPA maintains that the survival rates used in its analysis are reasonable based on the fisheries literature and other sources that are cited in the Regional Analysis Document (DCN #6-0003). EPA does not agree that survival rates should be increased by 25%.

The commenter suggests that survival rates must be higher if the population size is larger. EPA disagrees with this reasoning because (a) survival rates and population size are not strictly linked because other factors beside survival rates can affect population size; (b) insofar as population increases are linked to increased survival rates, they may respond to increases in survival rates for only particular life stages, not all life stages; and (c) it is not self-evident that all fish populations will be larger in the future than they were during the time that survival rates were estimated. The commenter did not provide data that would allow the Agency to change any survival rates or provide EPA with a basis for selecting an across-the-board 25% increase as an appropriate correction.

Methods to Evaluate I&E

The amount of water pumped by the cooling water systems is a key variable as the rate of impingement and entrainment increases with volume. The impingement rates are particularly sensitive to flow as they increase non-linearly with the volume pumped. For many plants, particularly the nuclear stations, availability and output have increased through time. Some estimates of flow rate should be increased. For example for Salem a volume of 1722 MGD is assumed for the operational flow rate - this is much lower than the flow used when the power station is running normally. The flow for the last recorded year was 2612 MGD.

EPA Response

It was EPA's intention to evaluate I&E rates under "normal" operating conditions to avoid potential bias of the sort discussed by the commenter. For this reason, in all its analyses, EPA used average operational intake flows as reported by facilities in EPA's survey of the industry.

Ecological Evaluation Methodology

Author Name Reed W. Super

Organization Pisces Conservation, Ltd.

No future value has been assigned to fish killed by power plants. These fish do have a value as their loss reduces the growth of the population. Reproductive value is proposed as a method of assessing future worth. Reproductive value is a measure of the contribution that an individual of known age would on average make to the next generation. A worked example is given for striped bass at Salem and the top species caught at Pilgrim. Using this method the value of striped bass caught at Salem was increased by $79,000, from $56,000 to $135,000 per year. Reproductive value calculations are presented for the common species caught at the Pilgrim facility.

EPA Response

The commenter proposes that EPA's analysis should include consideration of the reproductive value of fish killed by I&E. EPA has addressed the topic of reproductive value in its response to Comment 316bEFR.206.065.

Subject Matter Code 10.04.01

Extrapolation of Case Study Ben. to National Level

The use of impingement and entrainment rates for the case study sites to estimate the losses at other power plants in the same water type are highly unreliable. The rate of capture of fish is exceedingly site-specific. The EPA has generally used data from plants that entrain and impingement appreciable numbers of animals to try to minimise the likelihood of under-estimation. However, this does not remove the uncertainty in the estimates.

EPA Response

The commenter refers to the case study analysis presented at proposal. EPA appreciates the commenter's concerns about the difficulties with data extrapolation. To improve the basis for extrapolation, EPA's final analysis evaluated many more facilities than for proposal (a total of 46), and extrapolated I&E rates within regions rather than waterbody types nationwide. Given that the goal of EPA's analysis was to develop estimates of impacts and benefits at the national scale and not site-specific estimates, EPA believes that its regional analysis for the final rule provided a reasonable basis for extrapolation.

Subject Matter Code 6.05

Impacts to T&E species

The impacts on rare species are particularly difficult to assess, as power plant sampling has rarely been sufficiently intense and over long enough periods to detect the impingement of rare or threatened species. The situation is even more difficult with respect to entrainment when many thousands of common larvae may occur for every specimen of a rare species, making them almost impossible to detect. When sea turtles and other threatened species such as insects are considered in addition to fish, most marine, estuarine and Great Lake stations will occasionally kill rare or threatened species.

EPA Response

EPA agrees with this comment. The extent to which all Phase II existing facilities are taking threatened and endangered species is unclear because monitoring has not occurred at all of these facilities at intense enough efforts over long periods of time to detect the numbers that are killed as a result of impingement and entrainment. In order to help the permit writer to take into account possible impacts to threatened and endangered species when determining the best technology available for minimizing adverse environmental impact, the Impingement Mortality and/or Entrainment Characterization Study described in § 125.95(b)(3) in this rule must include taxonomic identifications of all life stages of fish, shellfish and any species protected under Federal, State, or Tribal Law (including threatened and endangered species) that are in the vicinity of the cooling water intake structure and are susceptible to impingement and entrainment.

Available I&E technologies

The key factor in the future large-scale extraction of cooling water is likely to be the availability of technologies to reliably reduce or eliminate impingement and entrainment. The EPA gives a good summary of the present state of the available technologies, however, they significantly overestimate the effectiveness of some technologies. There is a tendency to take values reflecting exclusion performance when the technology is working as designed under optimal conditions. In practice, performance is likely to be far worse because of interference by factors such as fouling and predators.

EPA Response

EPA acknowledges that successful deployment of a technology does not necessarily predict the success or failure of the same technology at another location but disagrees that it has overestimated the effectiveness of any technology. The estimated reductions in impingement mortality and/or entrainment presented in Chapter 3 of the Technology Development Document are taken directly from the studies cited therein. EPA agrees that performance is related to a variety of factors and for this reason, among others, has opted for performance ranges instead of numeric limits.

RFC: 5% threshold and supporting documents

On first consideration flow thresholds seem to offer an approach that can give considerable protection to aquatic life. However, the use of flow thresholds does not take into account species behaviour and habitat preferences. It is not just the amount but also the locality that matters - even the 5% threshold level could have significant effects if an intake and outfall are poorly sited.

EPA Response

EPA believes the design intake flow standard for riverine facilities in today's rule affords a level of protection for the source water body acceptable under most, if not all, stream conditions. Today's rule preserves the Director's (and States') authority to implement more stringent requirements to meet the requirements of applicable State and Tribal law, or other Federal law.

Spatial scale for entrainment trading

Several drawbacks to the process of trading are noted. If the purpose of trading is to protect individual populations it should have the following restrictions:

-It should only be permitted between sites situated on the same water body:

-The plants should all be impacting the same ecological community:

-Trading should occur for the same populations of common species at similar life stages. If this does not occur there is a danger that a single adult fish will be given a value equivalent to millions of eggs and traded for large levels of entrainment.

EPA Response

Please see response to comment 316bEFR.077.051 for the discussion on the spatial scale of trading. As noted in the preamble to today's final rule, although EPA has left the decisions regarding a potential trading program to the discretion of the Permit Director, EPA is likely to approve only those potential trading programs that allow trades within individual watersheds and among numbers of the same species. However, EPA will evaluate proposals for trading programs on a case-by-case basis to ensure that the trades allowed would result in environmental performance that is comparable to the reduction of impingement mortality and entrainment that would otherwise be achieved under § 125.94.

RFC: Proposed use of restoration measures

Habitat enhancement schemes are always attractive because they can offer the prospect of real environmental improvement. However, there are no proven pathways by which Entrainment and Impingement losses can be mitigated by habitat enhancement methods. There is a tendency to trade sensible and worthwhile goals such as wetland enhancement against impingement and entrainment losses. However, there is little evidence to support the view that the improved wetland aids the populations most impacted by the power plants. The highest level of mortality on cooling water intakes tends to be for clupeid fish that are mostly pelagic, open water, species.

EPA Response

EPA believes there are uncertainties associated with the design, implementation, performance, and assessment of restoration measures. For a discussion of these uncertainties, see EPA's response to comment 316bEFR.206.055.

Nevertheless, EPA does not want to preclude use of those restoration measures that are able to meet the all of the requirements of the final rule. Allowing use of such restoration measures provides permitting authorities and permit applicants with additional flexibility while still meeting the environmental requirements of the final rule.

EPA methods: age 1 equiv, yield, prod foregone

EPA Entrainment Estimates

Description of method used for Total Number

To calculate the entrainment levels at the various stations, the EPA take the data from each station in turn. The data often have been collected for each life stage entrained (egg, larvae, post-larvae, juvenile etc.). The total numbers of all the life stages are combined to give a total number entrained by that intake for a particular year. Several years are then combined to give a mean level of entrainment. On a site-by-site basis, adjustments are made to the years used to obtain the mean. For example, 1996 data are not used at Salem as the power station was not running for much of that year. For some stations the reported number of entrained animals has been adjusted to allow for survival. The EPA re-adjust the figures to assume 100% mortality. These calculations of the raw numbers of entrained animals are well done.

The method for calculating age 1 equivalence

To obtain a total number of age-1-equivalent fish for each site, the age-1-equivalents are calculated for each year and each life stage in turn. A mean value is then obtained. For entrained animals, normally only a few days or weeks old, this could be done by simply multiplying the number in the particular life stage by the probability of survival from that stage to age 1. However, as the exact age of animals when they are entrained is not known, a modified survival rate is applied to the first age transition. For example if an egg is caught just before it would hatch the survivorship probability of that egg to a larva is obviously much higher than a newly laid egg. This has the effect of increasing the age 1 equivalent number of fish. Again site-by-site adjustments are made to years used. These calculations of the age 1 equivalents of entrained animals are well done.

Issues Identified with Entrainment Methods

Are the years left out reasonable?

For Salem the EPA omit 1996 data. The station was shut down for most of this year, and hence the numbers of impinged and entrained fish were very low. Disregarding the figures from 1996 increases the mean catch of the station. It is reasonable to leave the year out of the analysis.

At Brayton the EPA disregarded the last decade’s fish numbers, as the populations were severely depressed. However there is a steady decline in numbers impinged throughout the study. The mean numbers for this station will therefore be underestimates.

For all other stations the EPA have used the available data reasonably. They have been fair in their selection of years’ data to be used in the case studies.

When the data are given with the assumed survived animals not counted - is the calculation of total mortality reasonable?

Where the survival factors for species entrained are not given in a report, an estimate of the effect is based on a probit method. This is used to back-calculate the effect of the survivorship factors applied to the data. The method does result in higher entrainment figures and is probably the best available.

EPA Response

The commenter asserts that I&E rates at Brayton Point are underestimated. EPA agrees that to the degree that I&E rates may have been reduced as a result of the effect of plant operations on species abundances near the plant, the commenter's point is valid. However, EPA maintains that the years of data EPA used to develop estimates at Brayton Point reflect the best set of available data that (a) included loss records for most species and (b) represent years prior to known significant declines of winter flounder stock.

Author Name Reed W. Super

Organization Pisces Conservation, Ltd.

Subject Matter Code 10.01.02.01

EPA methods: age 1 equiv, yield, prod foregone

EPA Impingement Estimates

Description of method used for total number

Data are taken from each station and the total number of animals killed in each of the life stages summed for each year.

Description of method used for age 1 equivalents

For life stages below age 1, the numbers of animals impinged are multiplied by the survival probability through each of the life stages that the animal has to pass to get to age 1. Animals impinged at age 1 or higher were assumed to be age 1.

"EPA used life stage-specific annual losses for assessment of entrainment losses and assumed that all fish killed by impingement were age 1 at the time of death." (A5-2.1)

"The Equivalent Adult Model (EAM) is a method for expressing I&E losses as an equivalent number of individuals at some other life stage, referred to as the age of equivalency (Horst 1975a; C.P. Goodyear, 1978; Dixon, 1999), The age of equivalency can be any life stage of interest. The method provides a convenient means of converting losses of fish eggs and larvae into units of individual fish and provides a standard metric for comparing losses among species, years, and facilities. For the § 316(b) case studies, EPA expressed I&E losses as an equivalent number of age-1 individuals. This is the number of impinged and entrained individuals that would otherwise have survived to be age 1 plus the number of impinged individuals (which are assumed to be impinged at age 1)." (A5-3.1)

Having made this sweeping generalisation a rather curious adjustment is introduced to allow for the fact that fish may be caught over an entire year and thus are assumed to range from just age 1 to just below age 2. This adjustment has the effect of increasing the number of age-1-equivalents above the actual number impinged.

EPA Response

The majority of the comment is a restatement of portions of the EPA methods, and do not require a response. The commenter questions the method of using modified survival rates for application to the life stage in which I&E occurs. The commenter seems to have misinterpreted the motivation for the adjustment, the effect of the adjustment, and the definition of an age 1 equivalent. EPA believes the adjustment is warranted because it accounts for the fact that information about the precise age at impingement is not available. It is reasonable to expect that the estimated number of age 1 equivalents is larger than the number impinged because the definition of age 1 equivalents is the equivalent number of fish on the day they enter their second year. Impinged fish that are labeled "age 1" are actually between 1 and 2 years old, therefore one such fish represents more than one age 1 equivalent because it is older than a fish that is just entering the second year. Please see response to Comment 316bEFR.029.105 for a discussion of the assumptions about age of impingement used by EPA for its final analysis of the Phase II rule.

Subject Matter Code 6.01
Overview of I & E effects on organisms

The effect of ignoring annual variation in flow.

The importance of flow

One of the key aspects that must be considered is the relationship between the number of organisms killed by impingement and entrainment and the location and size of the intake. It is apparent that within a single water body, the larger the volume pumped the larger the number of passively transported planktonic organisms that will be entrained. However, water bodies differ in their ecology and animal abundance and species differ in their preferred position within a water body, so it can be argued that the locality and position of the intake can have a large effect on the number of fish and other creatures captured. Living animals, particularly the larger fish and crustaceans that are powerful swimmers, do not behave like passive objects and thus their catch rate can vary in a non-proportional manner with the volume of water pumped. As will be shown below there is a clear tendency for catch rates to increase as a power function of the volume of water extracted, but there are some species that behave very differently. Wyman (1984), in a study of impingement at Lake Ontario power plants operating with different numbers of cooling water pumps, found that species responded differently. Alosa pseudoharengus and Osmerus mordax were apparently attracted to the water currents entering the intake and were caught in greater numbers per unit volume as the volume pumped increased. This response has often been observed but is usually explained by increased intake velocities leading to the zone where water speed exceeds the fishes' sustainable swimming speed being larger. Morone americana, Morone chysops, Dorosoma cepedianium and Perca flavescens were caught at a constant rate per unit volume irrespective of flow and Micropterus dolomieui were caught in lower numbers per unit volume as flow increased. It was concluded that this latter species avoided faster flowing waters and was thus proportionately more vulnerable to intakes with a reduced pumping rate.

One of the most comprehensive studies of the relationship between the volume of water pumped and the number of freshwater fish impinged and entrained in power station cooling water systems was that undertaken by Kelso(1979) for direct-cooled power plants on the Great Lakes. They analysed entrainment and impingement rates separately. Using data collected from 37 power plants, the number of fish impingement per annum (I) was related to power plant generating output capacity in Megawatts (Mwe) by the regression equation:

$\log10(I) = 0.414 + 1.844 \log10(Mwe)$.

The number of fish entrained per annum (E) was similarly related by the equation:

$\log10(E) = 2.103 + 1.658 \log10(Mwe)$.

From this analysis they concluded that for entrainment: "The 'harvest' is apparently influenced more by plant size than location within the great lakes" and impingement: " in general there is a significant influence exerted by power plant size".

The output capacity and the rate of water extraction by direct cooled power stations is positively correlated, irrespective of plant design and Kelso (1979) gave the relationship between cooling water extraction rate (C) in m3s-1 and capacity in Megawatts (Mwe) as:

C = -1.288 + 0.049 Mwe.

This empirically-derived equation obviously cannot be used to extrapolate water usage for plants much smaller than those included in the dataset, as it would predict negative water use. However, it is sufficiently reliable to be used to predict fish impingement and entrainment mortality at the working power stations that were studied.

Combining the above equations and converting water flow to gallons per second (G), the following equations relate impingement and entrainment rates to flow:

log10(I) = 0.414 + 1.844 log10(G+340.25)/12.944) and

log10(E) = 2.103 + 1.658 log10(G+340.25)/12.944).

Antilogging and simplifying the above equations gives the power curves:

I = 0.023(G+340.25)1.844
and

E = 1.816(G+340.25)1.658

respectively.

A clear example of the importance of the volume of water extracted on the number of fish impinged is given by Benda (1975) in a study of impingement at the Palisades Nuclear Power Plant, Lake Michigan, while operating with once-through and evaporative cooling tower closed cooling. The volume of water extracted in each mode was 8101 and 1226 gallons s-1 respectively. Annual estimates of fish impingement were approximately 452,577 and 7,488 for once-through and closed cycle respectively. However, the number of crayfish, Orconectes propinquis, actually increased under closed-cycle cooling (see above, Benda, John et al. 1975).

Recent increases in flow

Increased utilisation of installed capacity has resulted in increases in the mean flow at many plants. This is particularly the case for nuclear-powered stations, illustrated using Figure 1 below, from the EIA website:

http://www.eia.doe.gov/cneaf/nuclear/page/nuc_reactors/reactsum.html

Note that the installed generating capacity has not increased since the mid-1980s, while the output has continued to rise. (Figure 1)

[see hard copy for figure]

Figure 1 Generating capacity and output from US nuclear power plants.

Flow calculations for Salem

At Salem, the EPA give the number of fish caught at the station each year for the conditions at the plant that year. They then average this amount to give an estimate of the number that will be caught in the future. Flow issues do not seem to be taken into account at all.

In table B3-15 the EPA give the operational flow as 1722 MGD. This is much lower than the use when it is running at normal output (see figures B2.1 and 2). The EPA state in B3-5 paragraph 5 that the catch was much larger in 1998 as the flow was higher, and that the flow was expected to be at this higher level from then on. The costs for this plant should be based on this higher figure. This would produce an increase in the value of the catch at the station (see section 1.4).

In this example we will examine the effect that not using the different annual flow of a station has on the predicted number of fish caught in the future. As an example, the data from Salem are re-analysed to calculate the number of fish caught per MGD of water. This analysis predicts that the power station would kill on average 160% more age 1 equivalent fish by both impingement and entrainment that the EPA's estimate.

The power station has pumped differing amounts of water each year. The catch in age 1 equivalents is divided by the annual flow in each year to give the number of fish caught per MGD (Table 1). This is then used to predict how many age 1 equivalents the power station would kill per year if it were to run at 2612 MGD, since the EPA state in B3-5 paragraph 5 that the catch was much larger in 1998 as the flow was higher, and that the flow was expected to be at this higher level from then on.

The flow to predict the catch of the station was 2612 MGD. The predicted number of fish entrained as age 1 equivalents at Salem increased from 336,020,975 to 553,211,986 and the number impinged from 4,801,447 to 7,894,006.

[see hard copy for table]
Table 1. Total Salem catches of all species, excluding the Non RIS species, adjusted to 2612 MGD.

EPA Response

Please see response to Comment 316bEFR.041.037 concerning EPA's assumption that I&E is proportional to intake flow. As EPA notes in this response, for the purposes of EPA's national benefits analysis, it was not necessary for EPA to determine facility-specific, location-specific, or species-specific estimates of the relationship between intake flow and I&E. As the commenter's own analysis shows, in some cases it may be possible to determine a statistically significant relationship, while in other cases species may behave very differently. EPA's analysis was not concerned with analyzing these details.

EPA methods: age 1 equiv, yield, prod foregone

Is Age 1 equivalent a fair method?

Assessing the value of fish of differing life stages and ages is difficult. How do you compare the value of an egg of a striped bass with an eight year-old fish? To overcome this problem the EPA have used the adult equivalent method. They have projected the number of eggs, larvae and juvenile eggs to the equivalent number of age 1 fish. They do not take into account that older fish impinged are worth more than age 1 fish.

Age 1 equivalent methods only work given good information to base the model on. This includes:

1. Good estimates of entrainment and impingement numbers

2. Data split into the correct life stages

3. Accurate survivorship factors from stage to stage

Impingement and entrainment data quality

For the entrainment and impingement data, the data have been extensively corrected to account for problems found in the sampling methods, day/night variation, and seasonality. The corrections have all been applied to the data to improve their quality, before the age 1 equivalent method is undertaken. There are still many issues with the quality of the data used (see later sections of this document)

Data split into correct life stages

Entrainment data are split into age classes at nearly all stations. There are problems with the identification of some species at the egg and larval stages. The impingement data are sometimes collected with all the age classes separated, but the data are combined and treated as age 1 fish. This can have significant effects on the estimates of the value of the fish impinged. (See section 1.5.1)

Accurate survivorship factors

Many of the survivorship factors used in the calculation of age 1 fish are based on back-calculations assuming a stable population. This is a dubious assumption as there have been major environmental changes in the last 30 years. If, for example, the entrainment data are from the 1970s, before the Clean Water Act significantly improved water quality, the populations of fish could have been suppressed by the poor water quality. This would lead to a significant underestimation of the survival factors. The effect of errors in the estimate of these factors is discussed in section 1.6.2.

Underestimation of impingement due to age 1 assumptions.

All the impingement and entrainment calculations are made using as a measure of the total number of fish killed the age one equivalent value. The situation with respect to entrainment is reasonably straightforward. If a plant sucks through the cooling water system say 10,000,000 larval animals, then we cannot value these animals until they reach an age (size) at which they have passed through the period of high juvenile mortality and are at a size that fishermen can catch. The number of larvae is therefore adjusted by the mortality rate up to age 1. The survival rate could be 0.000001, in which case our 10,000,000 larvae are equal to 10 age one equivalent individuals. This is a useful way of dealing with the problem, as a larval fish has no market value whereas a one year old or older fish does, so by making the equivalency calculation we are allowing for mortality and the probability of reaching an age (size) where it is possible to assign a value. Perhaps more importantly, it provides an estimate of the number of individuals that would be lost to the reproducing population, so it is a fair way to proceed.

As the EPA are using age one equivalent calculations for young fish, they should also use them for fish older than age one to take into account impingement losses. They do not, as is made clear in the documentation:

From A5-2.1

"EPA used life stage-specific annual losses for assessment of entrainment losses and assumed that all fish killed by impingement were age 1 at the time of death."

From A5-3.1 Modeling Age-1 Equivalents

"The Equivalent Adult Model (EAM) is a method for expressing I&E losses as an equivalent number of individuals at some other life stage, referred to as the age of equivalency (Horst 1975a; C.P. Goodyear, 1978; Dixon, 1999), The age of equivalency can be any life stage of interest. The method provides a convenient means of converting losses of fish eggs and larvae into units of individual fish, and provides a standard metric for comparing losses among species, years, and facilities. For the § 316(b) case studies, EPA expressed I&E losses as an equivalent number of age-1 individuals. This is the number of impinged and entrained individuals that would otherwise have survived to be age 1 plus the number of impinged individuals (which are assumed to be impinged at age 1)."

It has been demonstrated in numerous impingement studies that for many species of fish there are large numbers of individuals above age one that are impinged. Just as the larval number was adjusted downwards to make an age one equivalent the older fish need to be adjusted upwards to give an age one equivalent. The size of the error that is introduced by the assumption that all fish impinged are age 1 is illustrated below using data from Salem.

The EPA estimate the number of age 1 equivalent white perch impinged at Salem as 540,109; re-calculation indicates that the correct value is 37,880,764 fish. White perch is a particularly clear example of an underestimate that occurs for all species that live for more than 1 year. This underestimate applies to many of the species caught at power stations. In the following calculations the figures for age 1 equivalent do not match the EPA figures exactly, as the monthly data used to adjust the totals by screen mortalities were not available. However, this is a small proportional difference and does not affect the outcome of the calculations.

The values of the survivorship for each life stage are given in Table 2. The final column shows the number of age 1 equivalents that a fish at a particular life stage represents. For example, it requires 13,500 white perch to enter the age 1 life stage for 1 eight year old fish to be produced.

[see hard copy for table]
Table 2. The survival factors (SJ) used to calculate the age 1 equivalents of white perch at Salem. SJ* takes into account the uncertainty of the age at which a individual is caught

Table 3 shows the unadjusted figures for white perch impinged at Salem as raw numbers and as age 1 equivalents using the assumption that all impinged adult fish are at age 1 (EPA method). The raw number is adjusted to take into account the unknown age at impingement.

[see hard copy for table]
Table 3. The raw numbers of white perch impinged at Salem and the age 1 equivalents.

The white perch spends much of its life in inshore waters where it is vulnerable to impingement. In Table 8 the numbers caught in each year class are given. It is evident that there are large numbers of older fish killed by Salem. As a fish above age 1 is equivalent to many age 1 fish, this age distribution can have a significant effect on the total number of age 1 equivalent fish caught at a power station. Table 9 shows the number of age 1 equivalents that the impinged fish of each age represent.

Ignoring the age structure of the white perch impinged results in an underestimation of the number of age 1 equivalents killed by Salem power station by two orders of magnitude. This effect will be found for all species of fish that are impinged at ages above 1. The relative effect will differ depending on the number of year classes vulnerable to impingement and the relative proportions of the age classes caught.

Age 1 Equivalent calculation for commonly impinged fish at Salem.

Table 4 shows the number of each age group of the commonly impinged fish caught at Salem. Table 5 expresses these number as a proportion of the total adult catch. It can be seen that for many species, the assumption that most individuals caught are age 1 is false. For example, over 90% of the catch bay anchovy is age 2 or over, 30% of blue crab, 80% of non-RIS forage species, 25% of striped bass and 42% of white perch.

[see hard copy for table]
Table 4 Numbers of fish caught at each age at Salem

[see hard copy for table]
Table 5 Proportion of the fish caught at each age at Salem

[see hard copy for table]
Table 6 Age 1 equivalent values of species of fish impinged at Salem (total number over all years). These are adjusted for the age at capture.

[see hard copy for table]
Table 7 Number of Age 1 equivalents total and mean caught in at Salem. Number of age 1 equivalents

calculated totals from report and change expressed as a percentage.

The number of age one equivalents of each of the age groups is given in Table 6. The total number of animals caught at Salem is used. No adjustments are made to account for the problem of 1996 flow rates. This has the effect of slightly lowering the mean number of age 1 equivalent fish killed by the power station. The survivorships used are based on figures given in the Salem input spreadsheet.

Table 7 shows the total and mean number per year of fish killed (age 1 equivalents) when the age of the fish is taken into account. The table also shows the values given in the case study (in table B3.3) for each of the species and the new higher value expressed as a percentage. The increases can be considerable.

There are several ways that catching older fish can cause very high age 1 equivalent values.

For long-lived species which spend a lot of their life in estuaries, such as the white perch, the increase is significant as some relatively old fish can be caught.

Some species, for example the bay anchovy and the non-RIS species, are caught mainly as older fish. This can result in a much larger number of fish caught in terms of age 1 equivalents than a simple total would suggest.

Species that are impinged at age 2 or more which have a very low survivorship from year to year also give high age 1 equivalents; an example of this is the blue crab. Only about 10% of crabs survive the first year and only 20% through the second. A two-year-old crab is equivalent to many individuals at the beginning of their first year of life.

For the species that are only caught at age 1, or have very few age 2 or more individuals caught, this method of calculation makes little difference to the overall total.

Morro Bay, California: another example of age structure importance

Here we present some examples of species that are caught at greater than age 1 from Morro Bay. Assuming that these are all age 1 would significantly underestimate the number of age 1 equivalent fish caught.

-Topsmelt, Atherinops affinis: the size frequency distribution suggests that almost all the fish impinged were 2 or 3 years old.

-Northern Anchovy, Engraulis mordax: about 50% of the catch were greater than 90 mm SL and presumably older than age 1.

-Plainfin midshipman, Porichthys notatus: the majority of the fish impinged were mature and thus two or more years old. This is to be expected as this species migrates into bays and estuaries to reproduce.

-Pacific sardine, Sardinops sagax: all the impinged fish were larger than the minimum size at maturity and were likely to be 2 or more years old.

[see hard copy for table]
Table 8. The numbers of white perch impinged at different ages at Salem

[see hard copy for table]
Table 9. The age 1 equivalents of impinged white perch when analysed using the age information given.

The effect of survival rate on age 1 equivalent calculations

In this example we will examine the effect of differing values for survivorship on the age 1 equivalent calculations. Data will be presented showing that the survivorship values used by the EPA are not the same as some published data. The two examples chosen show variations of up to 50%. Varying the survivorship values used in the age 1 equivalent model produces estimates of age 1 equivalents of up to 116 % higher.

First, we examine the survivorship values used by the EPA. Here we will look at two species where we have found published data for survivorship of species entrained at case study power stations.

To match published data some life stages have to be combined.

Table 10 shows the values obtained for the striped bass at Salem and by NOAA. The values at Salem are consistently lower that those found in the NOAA estimate - on average 48% of the NOAA figures.

[see hard copy for table]
Table 10. The proportion of striped bass that survive from one life stage to the next. Data from Salem and the NOAA technical report NMfs circular 443, Synopsis of Biological data on striped bass, Morone saxatilis (Walbaum). E M Setzler et al.

In Table 11 the survivorship estimates of Cunner (Tautogolabrus adspersus) calculated by the EPA and those quoted in Horst are presented. It can be seen that the Seabrook values are on average 72 % of the values quoted by Horst.

[see hard copy for table]
Table 11. The proportion of Cunner (Tautogolabrus adspersus) surviving from one age to the next. Data used by the EPA at Seabrook and estimations of the factors from Horst et al.- Effects of Power Station Mortality on Fish Population Stability in relationship to Life History Strategy.

As can be seen from the two examples above, differences of 50% in survivorship estimates are possible. By re-running the entrainment to age 1 equivalent model and adjusting the survivorship values we could examine the effect on the number of age 1 equivalent fish estimated. We adjusted the survivorship by 25, 50,75 and 100%. This was done across all the survival factors.

[see hard copy for table]
Table 12. The effect of changing the estimates of survival on the number of entrained fish in various species found at Salem.

Table 12 shows that a 50% increase in the estimates of survival can result in a 116% increase in the estimate of the age 1 equivalent number entrained.

The survivorship figures used in the EPA case studies are largely based on the assumption that the populations are in equilibrium. Because of this assumption, the data used to calculate these figures already have the effect of the power stations built into them. As conditional mortality rates from entrainment are often in the 10 - 25% range and the survivorship values can vary by significant amounts it would seem reasonable to err on the side of caution and increase all the estimates by 25%.

EPA Response

The commenter identifies many aspects of the EPA's I&E analyses that have uncertainty associated with them, e.g., estimates of I&E loss rates and species survival rates. EPA agrees that these kinds of uncertainty exist. However, EPA does not believe that the presence of uncertainty is surprising. Indeed it is expected in any scientific endeavor, and EPA has noted the same kinds of uncertainty and commented on possible ramifications in Chapter A6 of the Regional Analysis Document (DCN# 6-0003).

The commenter misrepresents the methods used by EPA by citing this sentence out of context:

"EPA used life stage-specific annual losses for assessment of entrainment losses and assumed that all fish killed by impingement were age 1 at the time of death."

This criticism is invalid for two reasons: (1) EPA did not use impingement loss rates as if they were identical to an age 1 equivalent--EPA adjusted the impingement loss rates appropriately to express them as age 1 equivalents; and (2) EPA has revised their method of estimating the age distribution of impinged fish to include ages younger than and older than age 1, as described in response to Comment 316bEFR.029.105.

The commenter provides a series of alternative example calculations aimed at assessing the effect of the assumed age 1 distribution of impinged fish. The purpose of these calculations is obsolete because EPA has revised their method of estimating the age distribution of impinged fish to include ages younger than and older than age 1, as described in response to Comment 316bEFR.029.105.

The commenter proposes that all survival rates should be adjusted upward by 25%. EPA believes this proposal is unsupported in general. EPA notes that such rates are unavailable for most facilities and species. Therefore, it is unknown how representative rates of 10-25% may be. Please see response to Comment 316beFR.330.028 for further discussion of this issue.

Data Issues

Old data

How intensively were the stations studied?

Salem is a well-studied station, with 21 years of data available, although there have been some changes in the way the samples have been taken over that period.

Pilgrim and Brayton are also well-studied with data from 1974. For Brayton, data are only used from 1974 to 1983, as the populations of fish declined after that time. They do not provide the data to show this effect. Seabrook has 8 years of data.

The other sites are restricted to 1 or 2 years of data, often from the 1970s.

EPA Response

EPA analyzed all I&E data presented in facility reports that was suitable for developing annualized estimates, with the exception of Brayton Point Station (BPS). As the commenter notes, EPA only evaluated 1974-1983 data for this facility. This time period was selected for several reasons: (1) year-round entrainment sampling of all species began in 1972 and ended in 1984; BPS began entrainment monitoring again in 1993, but only for winter flounder, (2) 1984 and 1985 were not considered because of the use of "piggyback" cooling during some of this time, (3) Unit 4 did not go into service until 1974, so data from 1972 and 1973 were not included, and (4) this time period is prior to a dramatic decline in fish populations beginning in 1985.

Trends

Many fish communities have shown larges changes in recent years. In some habitats species are recovering after anthropomorphic impacts, others are still in serious decline. Here we present some data for the Hudson, New York, and Morro Bay, California, to demonstrate that significant changes have occurred over this period.

Hudson River, New York

Taking the Hudson River striped bass and atlantic tomcod as examples (Henderson and Seaby 2000), it can be seen that data from the 1970s would give very misleading results if applied to the area today. Figure 2 shows the number of various life stages of striped bass in the Hudson between 1975 and 2000. It can be seen that there has been a 15-fold increase in numbers over this time. This is related to the reduction in fishing pressure and the cleaning of the estuary.

[see hard copy for figure]
Figure 2: The abundance indices for the adult stock (CFM) and the larval (YSL) and post larval (PYSL) stages of striped bass. Note that all these indices show a similar trend and sequence of high and low abundance years.

The atlantic tomcod has been in steady decline over the last 25 years in the Hudson (Figure 3). Again, using data from the mid 1970s would lead to a serious misinterpretation of the impact of a station in the Hudson on the tomcod population.

[see hard copy for figure]
Figure 3: The change in estimated abundance of Atlantic tomcod at age 1. A linear regression has been fitted to the data to show the trend of declining number.

Morro Bay, California.

A comparison of impingement levels observed during the periods 1977-79 and 1999-2000 at Morro Bay, California, illustrates the large changes in fish abundance and thus rate of impingement that have occurred in American waters.

In this example there has been a loss of fish such as shiner perch, Cymatogaster aggregata, and bocaccio, Sebastes paucispinis, which were much more abundant in the earlier study. For shiner perch, the following account was given by Duke Energy (APPLICANT'S TESTIMONY ON GROUP IV ISSUES, Energy Resources Conservation and Development Commission Docket No. 00-AFC-12)

"During the 12-month sampling period of 1978, over 5,400 shiner perch were collected (Behrens and Sommerville 1982), while during this study (1999-2000) only 45 were collected. Over 75 percent of the shiner perch impinged during the previous study were newborns (Behrens and Sommerville 1982). Annual indices for young-of-the-year (YOY) shiner perch from the San Francisco Bay monitoring program show a decline from the early 1980s through the last data point in 1993 (CDFG http://www.delta.dfg.ca.gov/baydelta/monitoring/shper.html). This decline is attributed to loss of saltwater marsh areas that are recognized as important nursery areas for this species. Female shiner perch will enter coastal bays prior to giving birth to utilize saltwater marsh and eelgrass beds as nursery areas (Bane and Robinson 1970). The reduction in the area coverage of eelgrass beds in Morro Bay, especially in areas of the Bay that are closer to the intake structures (Tetra Tech 1999) may partially account for the reduced numbers of shiner perch in impingement collections."

In the case of bocaccio, the population along the Californian coast has declined significantly over the past decade, and management measures are in effect to regulate the take of this species. The reduction in impingement may therefore reflect a general decline in the abundance of the species.

Increased species richness and fish and crustacean abundance following plant closure – studies in the Bristol Channel, England

Regular long-term monitoring of fish and crustaceans impinged and entrained at Hinkley Point 'B' Power Station in the Bristol Channel, England has been undertaken for more than 21 years. Henderson & Seaby (2002) conclude "Fish abundance in the estuary is probably 3 times higher than that recorded in the early 1980s and there is also a clear trend for increased species richness" (Figure 4). They consider the reasons for this extraordinarily large increase and suggest that the reduction in power plant entrainment and impingement following the closure of a number of direct-cooled power plants from the late 1980s may be a contributory factor. The passages below are taken directly from their recent report, available from: http://www.irchouse.demon.co.uk/latestreports.html.

[see hard copy for figure]
Figure 4 The change in the number of fish species impinged per month between 1981 and 2002. The black trend line was fitted by linear regression

"Amongst a number of climatic and anthropogenic changes that may be contributing to the observed increase in species richness and abundance must be considered the recent closure of a number of direct-cooled power stations. Since sampling commenced in October 1980, Berkeley closed in 1989, Uskmouth in 1995, Pembroke in mid 1997 and Hinkley A in May 2000. All of these stations would have been killing fish and crustaceans that were members of the populations subject to capture at Hinkley B. It is highly unlikely that entrainment and impingement in power station cooling water systems would have changed species richness in the region because the estuary presents an open system that would receive a flow of recruits from other waters. However, if mortality rates are sufficiently high it is possible that direct-cooled power stations could reduce abundance by a detectable amount. Table 13 gives estimates of the number of fish > 3 cm in length that are captured per year by power stations in the Bristol Channel. The four power stations that have closed since 1989 were estimated to kill 3.44 x 106 individuals per annum. The number of small individuals that would have passed through the filter screens and been killed following entrainment has not been estimated, but would have been at least an order of magnitude greater. "

"…there are indications that the increase in abundance of some species has occurred since power station closure as would be anticipated if power stations had been having an effect on population size.

For example, Palaemon serratus (Figure 5) showed a reasonably stable mean population size until 1998 after which it has been increasing almost exponentially. There are also indications that the Common shrimp, Crangon crangon, may have recently increased in average abundance. Amongst fish, sprat, whiting, flounder and sand goby abundance have all increased since the initiation of power station closures.

[see hard copy for figure]
Figure 5 The change in abundance of Atlantic prawn impinged at Hinkley Point in the River Severn between 1981 and 2002.

Such coincidences cannot be considered proof of a causal relationship. However the Severn Estuary Data Set should allow a more rigorous statistical analysis to be undertaken within the next 18 months."

[see hard copy for table]
Table 13 Estimated number of fish killed on the filter screens of marine and estuarine power stations situated in the Bristol Channel.

EPA Response

EPA agrees with the commenter that some fish stocks affected by I&E have increased or declined substantially since the time facility I&E studies were conducted. Unfortunately, EPA's analysis was constrained by the available I&E data, which rarely provide information to determine if and how stock sizes have changed as a result of I&E. EPA agrees that new monitoring studies would help develop better estimates of current I&E.

Data Issues

Exclusion of species

How were species selected for analysis?

The EPA first pick rare and endangered species that have been affected by the station. They then move on to commercial or recreationally caught species.

Finally they consider populations thought likely to be affected by the station. It is not obvious how a species is chosen to be ignored. From the numbers given EPA do, however, analyse all of the significant species present.

The Salem study is the only study where non-RIS species account for a high proportion of the total catch. Non-RIS species were between 30 and 60% of the total impingement and 10 to 40 % entrainment.

At Big Bend unidentified fish make up about a fifth of the total fish count while at San Francisco, Contra Costa and Pittsburg, about 15% of the entrained species are unidentified and about 2% of the impinged species.

Pilgrim gives full numbers of all species caught from 1990 onwards, while before that, from 1974, the non-RIS species are reported as one number. Brayton reports only 19 species caught, though there are unidentified species mentioned.

J.R. Whiting gives all the information for all species caught. Relatively few species are caught at this station. At Monroe unidentified species account for less than 1% of total numbers caught. In the Ohio study approximately 80 species are caught, but full data are given for a reduced set of species.

Did this affect the outcome?

Species that are not rare and have no commercial or recreational value are classed as forage fish. All forage fish appear to be treated the same in terms of value. They only come into play in the calculation of production foregone. Addressing each species individually is unlikely to make much difference at most stations. The exception is where the fish are rare or have a very local population. If the forage fish caught at stations can be shown to have a higher value then it might be worth treating them individually.

EPA Response

EPA did not eliminate any I&E data for any species for which data were available in case study facility documents. Unfortunately, if only a subset of the species potentially impinged and entrained were sampled by the facility, EPA could only evaluate those species. EPA agrees that the inclusion of unidentified organisms can complicate assessments and lead to misleading results. Identification of the appropriate "best technology available" requires scientifically valid monitoring studies that identify the organisms being impinged and entrained.

The Great Lakes

Impingement in the Great Lakes.

The two case study stations are dominated by clupeids (over 90%). Table 14 shows the different types of fish impinged at two case study sites and several other power stations in the Great Lakes (as raw numbers) (data from Sharma, R. K. and Freeman, R. F. 1997, Survey of fish impingement at power plants in the United States. Argonne National Laboratory). The stations are ordered in the table by the abundance of clupeids.

At most stations on the Great Lakes, clupeids are the major species caught (Figure 6), however, at Oak Creek the smelt species make up over 17% of the total catch. Similarly over 18% of impinged fish at JP Pulliam and DE Karn are Perch species. Palisades, a closed-cycle cooling station, mainly catches sculpins whereas at Big Rock and Kewaunee, both once-through systems, smelt species are impinged in large numbers.

[see hard copy for table]
Table 14. Proportion of the major species caught at power stations on the Great Lakes. All species with more than 100,000 individuals caught at the case study stations and any species with more than 10 % of the other stations are included.

Entrainment in the Great Lakes.

From data given in Kelso and Milburn (1979 no. 453) (Figure 7) it can be seen that entrainment at power plants in each of the Great Lakes is very different. In Ontario, Detroit River and Michigan, clupeids are the dominant group entrained. In Lake Erie it is smelt and in Superior it is the percids. In Huron, smelt and the clupeids are entrained in equal measure.

The two case study stations are on Lake Erie. Kelso and Milburn's (1979) data would suggest that the species entrained would be predominantly smelts, however the case studies are dominated by clupeids, with more than 85% of the total catch. It can be seen from this that extrapolating from the case studies to other stations on Lake Erie would produce a very different result from that found in Kelso and Milburn (1979). Extrapolation to power plants situated on different lakes is even more liable to error.

Extrapolation to all the Great Lakes stations from the case studies is therefore likely to produce an extremely poor match with reality.

Estuaries

The Salem case study is intended to be representative of other estuaries. To examine this we looked at the nearby Hudson estuary and compared the major groups of fish impinged and entrained at each station.

Impingement in Estuaries

Data were obtained for Salem (the case study), Danskammer, Roseton (State Pollution Discharge elimination system permits for Bowline Point Indian Point 2 & 3 Roseton Steam Electric Generating Stations 2000) and Albany (PSEG Power New York Inc's Bethlehem Energy Centre SPDES Modification 2002). The data were classed into five groups - others, bay anchovy, drums, Morone spp and clupeids (Figure 8).

The graph shows that Salem is a poor model station for the Hudson. All the Hudson stations impinge mainly clupeids and Morone spp. whereas Salem impingement is dominated by bay anchovy, drums and the group Others. The Others at Salem include the RIS and non-RIS forage fish plus others that did not fit the above classes.

Entrainment in Estuaries

Data were obtained for Salem (the case study), Bowline, Indian Point, Roseton (State Pollution Discharge elimination system permits for Bowline Point Indian Point 2 & 3 Roseton Steam Electric Generating Stations 2000) and Albany (PSEG Power New York Inc's Bethlehem Energy Centre SPDES Modification 2002). The data from each station were classed into four groups, others, bay anchovy, Morone spp. and clupeids and plotted (Figure 9).

The picture is more complicated for entrainment than it is for impingement. Salem primarily entrains bay anchovy (90%). This is similar to Bowline and Indian Point, but both these stations also entrain significant numbers of clupeids and Morone spp. The species composition of entrained fish at Salem is completely different from Roseton and Albany, which are dominated by clupeids and Morone spp.

The presence of eggs, larvae and young fish is very dependent in estuaries on the exact salinity conditions, flow rates and habitats present.

Implications of extrapolations from case studies to other stations

As can be seen from these examples, extrapolating the catch of fish from one station is prone to many errors. As a result, the costs calculated for a case study will not be directly comparable with any other site. For example, using Salem as a model for the catch at Roseton would result in a completely inaccurate estimation of the value of the lost fish. At Salem the majority of all the fish killed are bay anchovy, which has very little commercial value. The majority of the fish entrained and impinged at Roseton are the valuable Morone spp. and clupeid species. Using Salem as the model for the Hudson Estuary would significantly underestimate the values of the fish killed.

Figure 8. A comparison of the proportion of entrained fish from the case study at Salem and stations in the Hudson River.

Figure 9. A comparison of the proportions of entrained fish from the case study at Salem and stations in the Hudson River.

EPA Response

EPA recognizes the limitations to extrapolation that are addressed by the commenter. The only real solution to such difficulties is to evaluate more facilities in an effort to capture loss rates for as many species as possible. To this end, EPA evaluated many more facilities for its final analysis, including Hudson River facilities. Nonetheless, extrapolation was still necessary given the hundreds of facilities in scope of the rule, and the large number of these facilities that have not conducted impingement and entrainment studies. To further address this issue, EPA extrapolated I&E results only to facilities within the same region. Please also see EPA's response to Comment 316bEFR.041.041 on its extrapolation approach.

Commercial Fishing Benefits

Calculating the worth of commercial species impinged and entrained

The worth of an individual lost to a population can be assessed in terms of the immediate loss to the other species, or man, which might have consumed the individual, or in terms of the future loss caused by the loss of reproductive potential.

In the EPA's calculations, the commercial species killed by entrainment and impingement are valued by calculating the age 1 equivalent number killed and multiplying it by the proportion of the population taken by commercial fishing and their market value. This only considers the immediate loss and places a value on only a proportion of the number killed. This is felt to be an extremely significant omission, liable to underestimate the value of fish killed severely.

The fish killed also represent a loss in reproductive potential to the population and thus represent a future loss to the ecosystem and fishermen. The average contribution of an individual to future generations changes with age, so that the contribution of an egg is much less than that of a one year old fish. This is because fish at or close to reproductive age are no longer subject to high mortality rates and will soon produce eggs. Fisher defined a quantity, termed the reproductive value, V, to measure the extent by which an individual of age x contributes to the next generation.

To calculate the reproductive value of fish of age a, we need a table of age-specific survival and mortality rates. If we assume that the population size is stable then the reproductive value is given by:

[see hard copy for equation]
where l(x) is the survival to age x and m(x) is the fecundity at age x.

If the population is growing or declining then the expression is a little more complex, as it includes a term to describe the change in population number. In practice, the above description should give us an approximate measure of the worth of an individual in terms of future eggs contributed to the population that is accurate enough for the estimation of the value of the loss to the population. The reproductive value of a newly produced egg is assumed to be 1, and all later ages have a reproductive value expressed as the number of eggs that would be produced on average over the rest of their lives.

Having calculated the reproductive value for age 1 fish we can use the estimated number of age 1 equivalent fish killed by impingement and entrainment to calculate the lost egg production they represent. This total lost production of eggs can then be converted into age 1 equivalent reproductive value by multiplication with the survival rate to age 1. This age 1 equivalent reproductive value gives the true loss over time to the population of the age 1 equivalent animals killed. The economic loss can then be calculated by multiplying the age 1 equivalent loss by the unit monetary value.

One important general observation is that reproductive value tends to increase until an age is reached that is close to when all the fish have reproduced once, and then tends to decline for older age groups.

Striped bass at Salem as a worked example

These calculations will be illustrated using the striped bass at Salem as an example. At Salem the average numbers of entrained and impinged fish (excluding 1996) were 419,505 and 7,200 respectively. When reduced by the 18% lost to commercial fishing, the values were 343,994 and 5,904. Thus the total number of individuals as age 1 equivalent that were not valued was 347,898. It is these fish for which we will calculate a reproductive value and thus estimate the value of their loss to the population.

Table 15 shows the age-specific fecundity and survival of striped bass and the calculated reproductive value at age(x). The change in reproductive value with age is plotted in Figure 10, which shows a typical maximum at an intermediate age in the life cycle.

The total lost production (expressed as numbers of eggs) was calculated by multiplying the reproductive value of age 1 fish (6,515 - see Table 15) by the number of age 1 equivalents caught at the station. This product was then adjusted to an age 1 equivalent number using the survival from age 0 to age 1. These calculations are shown in Table 16. This shows that the 347,898 fish not valued as age 1 equivalents have a future age 1 reproductive potential of 596,142 age 1 equivalent fish. Thus the value of the uncounted fish is the economic value of 596,142 age 1 equivalent fish.

In summary, the EPA calculations are based on the value of 18% of about 420,000 age 1 equivalent fish with a value of about $56,000. Using lost reproductive value we have a future loss of 596,142 individuals which has a value of about $79,000 plus the immediate loss of $56,000 giving a total annual loss of about $135,466 per year.

These calculations can be undertaken for all the commercial species plus many others and will allow a full valuation to be made of the loss.

Pilgrim - a worked example of a site

To illustrate the method the most frequently-encountered species at Pilgrim were chosen. The reproductive values of the top 7 species impinged and the top 5 species entrained were calculated using the same method as the Salem above example. The results are given in Table 17 & Table 18.

[see hard copy for table]
Table 15.The age-specific fecundity and survival of striped bass and the calculated reproductive value at age(x).

[see hard copy for figure]
Figure 10. The change in reproductive value with age for striped bass

[see hard copy for table]
Table 16. The age 1 equivalent values for Striped Bass (+ 58% Morone spp.) from Salem (Tables B3-3 and B3-8), multiplied by the reproductive value to find the total number of eggs lost in the future, shown as age 1 equivalents. (From egg to age 1 factor = 0.0002615).

[see hard copy for table]

Table 17. The age 1 equivalent and reproductive values for the top 7 species impinged at Pilgrim.

Technologies for reducing Impingement and Entrainment

Modified travelling screens - 'Ristroph Screens'

Efficacy of Cooling Water Intake Technologies Chapter 3 adequately summarises the effectiveness of Ristroph screens and fish return systems to reduce fish impingement mortality. The report notes that their effectiveness is highly variable but that at least a 70-80% reduction in impingement can be achieved over conventional travelling screens. In practice this figure is probably higher than will actually be achieved, for two reasons. First, it will depend on the species mix at the particular site and, as will be discussed below, some species of fish are much more easily hurt than others. Second, the need to fit modified screens into existing intake structures may result in less effective performance.

The actual reduction that can be achieved will depend on the dominant species for the locality. Generally clupeid fish are by far the most abundant species and these are particularly vulnerable to damage following contact with surfaces. Further, there are likely to be considerable differences in survival between clupeid species e.g. survival values quoted in Chapter 3 show bay anchovy 20-72%; herring 78-82%; alewife 15-44%.

Fish species	Survival %
Bay Anchovy	77
American shad	65
Blueback herring	74
Striped bass	91
White perch	86
Atlantic tomcod	83
Alewife	38

Table 19. 8 hr survival rates for Indian Point (Fletcher, 1990)

Table 19 suggests that an intake situated in waters where alewife were one of the most abundant species caught would be unlikely to achieve 70% reduction in average impingement mortality. The effect of the species mix on the average survival that can be achieved in practice can be appreciated from a consideration of the data for Salem. Bay anchovy are by far the most abundant species impinged and on average represent about 50% of all impinged individuals. The next most abundant species is weakfish, which contributes about 22% of all individuals impinged. Thus these species, with recorded survivals at Salem for bay anchovy of 20 - 72% and weakfish of 18 - 88%, represent about 72% of all impinged fish, and will effectively determine the average survival. It is clear that this value is unlikely to reach 70% and could on occasions be much lower.

An additional factor reducing the likelihood of 70 to 80% survival rates is that the data presented in Table 14 above are 8 hr survival rates, and may not be of sufficient duration to predict the long-term survival of fish. It has been found that stressed and damaged fish can take a number of days to die. There is also the problem with all fish return systems that exhausted, disorientated and damaged individuals can be picked off by predators on their return to the main water body.

Further doubt on the effectiveness of screens with modified Ristroph features comes from studies undertaken at Roseton units 1 & 2. This site has six conventional screens and two modified dual-flow screens. One of the modified screens also has a flow-straightening device. Testing of the dual flow screens found that while post-impingement survival rates were higher than at the conventional screens, they were not as high as those observed at the Indian Point or Arthur Kill intakes. It was suggested that this was linked to the pattern and magnitude of the water velocity close to the screens. Velocities were increased because the modified screens had a reduced filtering area. This was the inevitable outcome of fitting modified screens without major structural alteration to the intake system (DEIS for Bowline Point, Indian Point & Roseton GS, VIII-29).

EPA Response

EPA has not presented any of the studies cited in Chapter 3 of the Technology Development Document with the intent that the results can or should be replicated elsewhere. EPA recognizes the variability between sites and locations and thus has not pre-approved any technology for BTA (except cylindrical wedgewire for compliance alternative 4). Traveling screens modified to include fish handling and return systems are among the most widely deployed and studied intake technologies on the market today. They have a demonstrated success in reducing impingement mortality that is backed by nearly three decades of study. EPA has included this technology as one of many that are available to facilities in meeting the requirements of today's rule.

Cylindrical wedgewire screens

Wedgewire screens have a proven ability to reduce both impingement and entrainment mortality at low volume intakes (1 to 50 MGD). Their effectiveness is related to (1) the slot width, (2) through-slot velocity, (3) existence and strength of ambient cross flow to carry organisms away from the screen, (4) the amount of biofouling and (5) the amount of ambient debris. As the EPA note, they are an unproven technology for protecting once-through intakes that typically pump volumes in excess of 100 MGD. As will be discussed below, the effectiveness of wedgewire screens is linked to water velocity across the screen and this has not been quoted in the EPA discussion of effectiveness.

Wedgewire screens with slots widths of 5 to 10 mm have been used to effectively eliminate impingement at freshwater cooling water intakes. They have not been used at marine or estuarine facilities probably because of fears that biofouling and screen blockage would lead to operational problems. Small-scale trials of Johnson wedge-wire screens at Fawley, England, in the 1980s showed that standard steel wedge-wire screens developed a fouling community (Bamber and Turnpenny, 1986). Even a Johnson 715 alloy (70% Cu: 30% Ni) screen that leached copper and thus poisoned organisms that had settled, experienced some fouling.

To reduce entrainment of fish eggs and larvae appreciably the screen slot widths need to be in the range 0.5 to 3.0 mm. Weisberg et al. (1984) & (1987) found that a 3 mm slit width excluded about 50% of bay anchovy and naked goby larvae in the 5 to 6 mm long size class. A 1 mm slot width gave almost complete exclusion of bay anchovy greater than 8 mm in length and naked goby greater than 7 mm long. To give good protection to the very small larvae a slot width of 0.5 mm is required.

A 0.5 mm slot width will only be highly effective for larval exclusion when used with a suitable intake velocity. At a velocity of 7.5 cm/s this width will exclude larvae less than 6 mm in length. However, at a velocity of 15.0 cm/s (0.5 fps) about 60% of larvae less than 7.0 mm in length were entrained.

The reduction of egg entrainment is related to the size of the egg. However, eggs are not rigid and eggs greater than 0.5 mm in diameter will pass across a 0.5 mm slot. Data on the entrainment of marine fish eggs via a 0.5 mm slot width screen with a velocity of 7.5 cm/s are presented in Table 20.

Species	Egg diameter mm	% Exclusion
Tautog	0.7-1.14	80
Bay Anchovy	0.65-1.24	84-75
Windowpane flounder	1.0-1.4	96-93
Atlantic Menhaden	1.0-2.0	100
Weakfish	0.9-1.1	100

Table 20. Entrainment of marine fish eggs via a 0.5 mm slot width screen with a velocity of 7.5 cm/s (Sunset Energy Facility proposal for Brooklyn New York)

A species of particular importance in many estuaries is the striped bass. This species has a relatively large egg (2.4 to 3.9 mm diameter) and thus egg entrainment would almost certainly be eliminated by slot widths in the range 0.5 to 1.0 mm. However the striped bass yolk sac larvae range in length from 2 to 7 mm which would suggest that some young larvae would be entrained with even a 0.5 mm slot width, and only very limited protection would be offered by a width > 1.0 mm.

It is clear that the reduction in entrainment possible using wedge-wire screens will be determined primarily by the slot width, the water velocity across the screen and the mix of species present at the particular locality. The performance values quoted in Chapter 3 – 'Efficacy of cooling water intake structure technologies' indicate exclusion efficiencies of eggs and larvae at or above 90% for a 1 mm screen width (Logan 90%; Seminole 99% reduction; Chalk Point 90%). In localities where the eggs of fish such as the bay anchovy are present, or yolk-sac striped bass are abundant, a 1 mm screen width would not be able to achieve this level of efficiency with any realistic intake velocity. Further, in fully marine localities there are species with egg diameters well below 1 mm. It is therefore unlikely that 90% exclusion could be achieved by a 1 mm screen width at many estuarine sites. At marine sites this level of exclusion would be even more unlikely to be achieved because of the presence of even smaller eggs and larvae and the probability of biofouling.

A more realistic appraisal of the level of entrainment exclusion that could be achieved with a velocity of 7.5 cm/s across the screen would be in the order of 90% for a 1 mm screen width in flowing rivers, 90% for a 0.5 mm screen width in lakes and 80-85% for estuarine sites with a 0.5 mm screen width. There are no data upon which to base an assessment for an intake situated on the ocean, but it would likely be below that for an estuarine intake because of the small size of some marine fish eggs and larvae and problems of screen blockage. Biofouling at ocean and lower estuarine sites is likely to be an insuperable problem, which at best would result in regions of high cross screen velocities. It should be noted that in some localities, such as bays and inlets with small tidal ranges there may be insufficient cross-flows to sweep debris and impinged organisms off the screen surface.

EPA Response

EPA appreciates the data submitted by the commenter and notes the inclusion of cylindrical wedgewire technology as BTA for facilities meeting certain criteria and opting for compliance alternative 4.

Fine mesh travelling screens

The incidence of entrainment can be greatly reduced by the use of 0.5 to 1 mm mesh travelling screens. However, this does not mean that the mortality of young fish is proportionately reduced as the eggs and early stages are now liable to impingement damage. The EPA Chapter 3 discussion may give a misleading impression of the effectiveness of these devices by quoting the reduction in entrainment rather than the increase in survival. Survival on such screens is highly species-specific with clupeid and other pelagic fish such as bay anchovy and Alosa species having low rates of survival. Taft et al. (1981) report laboratory studies of the effects of impingement on fine mesh screens for the larval stages of striped bass, winter flounder, alewife, yellow perch, walleye, channel catfish and bluegill. Survival was highly variable and dependent on water velocity across the screen and the duration of impingement. The highly species-specific nature of survival of impinged larvae was also noted by McLaren & Tuttle (1999).

Fletcher (1990) also noted that the mortality on fine mesh screens is related to the amount of debris retained by the screen. This would suggest that fine mesh screens would not be effective in all waters. Fletcher (1992) reports a study of the effectiveness of fine mesh screens to reduce losses of early life stages of striped bass. The results showed that survival was influenced by mesh size, water velocity and exposure time. It was concluded that impingement resulted in high mortality for young larvae and many larvae that initially survived impingement subsequently died. The results suggested that striped bass up to 8.4 mm long are too delicate to survive impingement.

Given the high maintenance of fine screens together with the known high impingement mortalities of many species these devices cannot be considered a useful protective measure.

EPA Response

EPA agrees that proper operation and maintenance are essential to the optimal performance of fine mesh screens but disagrees with the commenter's assertion that they cannot be considered a protective measure. EPA has not determined any technology to be universally applicable to all facilities under all circumstances in today's rule. Instead, EPA maintains a desired flexibility for facilities to meet the performance objectives by opting for one of several design and control technologies, operational measures, and/or restoration measures. While fine mesh screens, or any technology for that matter, may not work at one facility, they may prove successful at another. For this reason, EPA has neither prescribed nor prohibited any single technology from the suite of alternatives available to facilities.

Barrier nets

Under appropriate conditions barrier nets can be effective devices to reduce fish impingement. To be effective there must be limited debris in the water, a low incidence of biofouling, relatively low water velocities and sheltered conditions with low wave action, low current velocities, etc. The last of these requirements excludes their use at open water ocean sites. In estuarine conditions the EPA assessments exaggerate their effectiveness. The following is described for the barrier net deployment at Bowline Point GS on the Hudson Estuary.

"The Bowline Point Station (New York) has an approximately 150-foot barrier net in a v-shape around the intake structure. Testing during 1976 through 1985 showed that the net effectively reduces white perch and striped bass impingement by 91 percent. Based on tests of a "fine" mesh net (3.0 mm) in 1993 and 1994, researchers found that it could be used to generally prevent entrainment. Unfortunately, species' abundances were too low to determine the specific biological effectiveness."

This account gives the impression that the 3 mm net was useful for reducing entrainment. In fact as Lawler, Matusky & Skelly Engineers (1997) report in 1993 the net clogged with fine suspended silt and sank. In 1994, even when the net was sprayed to remove clogging it fouled with the algae Ectocarpus causing two of the support piles to snap and the evaluation to end. They concluded that 3 mm barrier nets can only be considered an experimental device.

The available data would suggest that barrier nets can be effective at reducing impingement mortality at intakes situated in lakes and sheltered waters. Fine barrier nets capable of reducing entrainment have not been successful at estuarine sites and Chapter 3 gives a misleading impression of the effectiveness of the 3 mm net at Bowline Point.

EPA Response

EPA does not believe the summary of data for Bowline Point is misleading, nor does it consider barrier nets to be an experimental technology. Bowline Point in New York, JP Pulliam in Wisconsin, JR Whiting in Michigan, and Chalk Point in Maryland have all successfully deployed barrier nets as part of an effective strategy to reduce impingement losses, some for as many as 25 years. For further discussion of the effectiveness of barrier nets, see Chapter 3 of the Technology Development Document.

Barrier nets have a proven performance record but, like all technologies, must be deployed with consideration of the local conditions at each facility. Ideally, barrier nets are located in areas not subject to commercial traffic, fast currents, or high wave action. In many instances, barrier nets are deployed seasonally to reduce impingement of migrating species. Seasonal deployment, such as that at Chalk Point, can be a cost-effective means of meeting the requirements of today's rule.

Microfiltration

The only microfiltration system considered is the Gunderboom and the report makes it clear that the only data available come from the observations at Lovett GS. It is concluded that 'Entrainment reductions up to 82 percent were observed for eggs and larvae and these levels have been maintained for extended month-to-month periods during 1999 through 2001.'

This statement is a clear exaggeration of the observed effectiveness of the Gunderboom at Lovett GS. Overtopping, tunnelling and rips have been observed during testing. For example, in the Lovett evaluation report for 1999 it is stated that "the divers documented a substantial gap along the bottom of the boom. The gap extended along the bottom of the boom for approximately 3 m and ranged in depth from 0.5 to 0.6 m".

[see hard copy for figure]
Figure 11 The ratio of entrained larvae and eggs at Unit 3 and Unit 4 of Lovett during trials of the Gunderboom.

It is clear in Figure 11 of the Lovett 2000 report (above) that there was a gradual increase in entrainment through time. Further, there was also a series of events between May and August 2000 that resulted in short-term total failures. The efficiency of the Gunderboom was assessed by comparing the level of entrainment at unit 3 (protected by a Gunderboom) to that at unit 4 (unprotected). Thus a ratio above 1 for the number of fish entrained at unit 3 to unit 4 shows that the boom was offering no protection. To achieve 82% effectiveness or better the ratio would need to be smaller than 0.18. As shown in the figure below this level of efficiency was only achieved for a short period during May 2000. It is therefore incorrect to conclude that it was achieved for extended month-to-month periods during 1999 through 2001. In fact from late July 2000 the Gunderboom was completely ineffective at reducing entrainment.

EPA Response

The aquatic filter barrier technology (Gunderboom) has shown promise at Lovett Generating Station in reducing both entrainment and impingement. EPA notes that some of the difficulties in maintaining the integrity of the system have reduced the overall effectiveness of the barrier, but ongoing research and modifications by Gunderboom, Inc. have lowered the failure rate for screen panels and provided a more consistent exclusion rate over time.

EPA notes that while the Gunderboom technology has shown significant promise for reducing both impingement and entrainment, in its current state it is unlikely to be widely deployed at Phase II existing facilities due to more intensive maintenance requirements as well as specific waterbody requirements (large area, limited wave action,). EPA does not, however, believe that the Gunderboom technology should be unavailable to Phase II existing facilities if the technology can be successfully deployed.

Louver

Chapter 3 concludes that "Overall, the above data indicate that louvers can be highly effective (70+ percent) in diverting fish from potential impingement. Latent mortality is a concern, especially where fragile species are present."

Louver systems have been studied at hydroelectric facilities with migratory species in rivers; they have been little studied at steam generating plant and require further large-scale evaluation before the view that they are highly effective or capable of preventing more than 70% of potential impingement can be accepted.

EPA Response

EPA agrees that the data available for louvers are less detailed than for more widely deployed technologies and did not base the performance standards on the efficacy of this technology. EPA has not, however, excluded louvers from the suite of design and construction technologies available for facilities to meet the performance standards of today's final rule. The data EPA has evaluated for louvers (see Chapter 3 of the Technology Development Document) show promise in reducing impingement under certain circumstances but does not believe many Phase II existing facilities will opt for this technology given the level of construction required.

Angled screens

Chapter 3 concludes "Similar to louvers, angled screens show potential to minimize impingement by greater than 80 to 90 percent." This conclusion may give a misleading impression of the proven ability of such systems. There is no evidence that such high levels of impingement reduction would be achieved in practice.

EPA Response

EPA agrees that the data concerning angled screens are less detailed than for other more widely deployed technologies but disagrees with the commenter's assertion that the technology is unlikely to achieve high reductions in impingement. EPRI recently completed an angled screen study, (see Chapter 3 of the Technology Development Document for a discussion of this study) which showed significant promise for the deployment of angled screens. EPA also notes that many of the facilities that have incorporated angled screens into their cooling water intake structures have also used additional design and construction technologies (e.g. lift baskets, fish elevators) to provide comprehensive protection against impingement losses.

Velocity caps

To claim that velocity caps have been successful in minimizing impingement is an exaggeration. They have been found to reduce impingement by 50 to 80% when compared with an unprotected intake. However, it should be noted that this reduction is usually only observed for pelagic species. Other fish and crustaceans may still be caught in large numbers.

EPA Response

EPA disagrees that velocity caps have not been successful in minimizing impingement. EPA points to San Onofre Nuclear Generating Station, El Segundo, and Huntington Beach Stations in California, as well as Seabrook Station in New Hampshire that have seen significant reductions in impingement of pelagic species in part due to the use of velocity caps. EPA notes that velocity caps are often used in conjunction with other technologies to provide comprehensive protection for all species. Deployment of any technology, including velocity caps, cannot be assumed to be universally protective of all species that may be impinged or entrained and may need additional design and construction technologies, operational measures and/or restoration measures to meet the requirements in today's final rule.

Behavioural barriers

The EPA conclude that "Many studies have been conducted and reports prepared on the application of behavioral devices to control I&E, see EPRI 2000. For the most part, these studies have either been inconclusive or shown no tangible reduction in impingement or entrainment." This is certainly a fair assessment of the situation and we know of situations where sound deterrent systems have actually increased impingement. It is therefore rather surprising to read in the final sentence that "Overall, the Agency expects that behavioral systems would be used in conjunction with other technologies to reduce I&E and perhaps targeted towards an individual species (e.g., alewife)." This would suggest behavioral barriers could be usefully implemented. Except perhaps in the case of alewife there is little evidence that such systems reduce impingement and there is no evidence that they reduce entrainment at all.

EPA Response

EPA believes that there are instances where behavioral barriers can be successfully deployed in concert with other design and construction technologies to realize an overall facility reduction in impingement mortality. Data collected and reviewed by EPA have shown limited effectiveness for these technologies (strobe lights, electric barriers, sound systems), which is usually limited to the adults of one or two targeted species. Such effectiveness, however, may be all that is necessary for a facility that experiences the majority of its impingement events with one or two species of fish. In these cases, the behavioral technology may be all that is necessary to meet the requirements of today's rule.

Organization Pisces Conservation, Ltd.

Subject Matter Code 7.03

Available I&E technologies

Other technological alternatives

The heading holds a number of techniques that might be considered simple good practise rather than fish protection technologies.

The fitting of variable speed pumps can reduce the amount of water consumed compared with one-speed pumps and can therefore result in a reduction in the quantity of life entrained and impinged. However, the effectiveness will depend on the coincidence in time of the periods when the young fish are most abundant, the plant has the highest demand for electricity and the source water is warmest. In practice, for some localities the proportional reduction in fish killed will be less than the reduction in the volume pumped because demand, water temperature and young fish abundance all peak during the summer. Therefore the 10-30 % reduction claimed may not be achieved in practice and is more likely to be at the lower end of the estimate.

Continuous screen operation is probably useful as it reduces fish exhaustion prior to their return.

EPA Response

EPA agrees that variable speed pumps are an effective technology in reducing entrainment and impingement events at those facilities that experience seasonal impacts. Pump operations can be reduced during migratory or spawning seasons to avoid the increased impacts that might have occurred with traditional circulating water pumps. Such operations can be incorporated into an NPDES permit requirements to restrict intake flow and achieve the desired reductions in impingement and entrainment. Data evaluated by EPA has demonstrated the connection between reduced flow and reduced levels of impingement and entrainment.

Higher survival of impinged organisms has been demonstrated on systems whose screens are rotated continuously, but continuous operation is not necessary to achieve survival rates in line with the performance standards of today's rule. If a facility opts to install such a system, or already has one in place, the optimal rotation interval, which may include continuous rotation, should be investigated prior to determination of final operational criteria.

Subject Matter Code 14.01

RFC: 5% threshold and supporting documents

5% flow threshold for rivers

This proposal is based on the concept that the proportion of eggs and larvae and juvenile fish entrained from a population is directly proportional to the volumetric proportion of the habitat that is pumped through the cooling system. This will rarely be the case because larvae and juvenile fish are not randomly distributed throughout the water. For example, the common eel Anguilla, which migrates up East coast rivers as elvers, often travels close to the bank, sometimes in ribbons of thousands of individuals. For such species the position of the intake is an important factor in determining the level of entrainment. It is therefore essential that the 5% threshold is never taken as a sufficiently protective measure to protect fish, hence allowing poor design and placement of intakes. Given good intake design, the proposed threshold has merit and, as will be discussed below, is probably superior to some of the alternative withdrawal thresholds.

There are concerns relating to the use of mean annual flow, as the level of protection given to the fauna would be far from certain. The use of mean flow could result in a far higher proportion than 5% of the flow being taken during seasonal or unusual periods of low flow. If an animal is to be afforded good protection, then all of its life stages must be protected. Using average flows as the basis for 5% threshold calculations may result in variable levels of protection through time and could produce high mortalities during low flow periods sufficient to negate any protection afforded at other periods. It is common for regions to suffer extended periods of drought lasting one or more years when river flows may be well below the long-term average. During such periods the plants would presumably still be able to extract at a rate determined by the mean annual flow prior to the drought; this could be particularly damaging.

EPA Response

EPA believes the design intake flow standard for riverine facilities in today's rule affords a level of protection for the source water body acceptable under most, if not all, stream conditions. Today's rule preserves the Director's (and States') authority to implement more stringent requirements to meet the requirements of applicable State and Tribal law, or other Federal law.

EPA has retained in the final rule the 5% threshold based on design intake flow, rather than actual flow, for several reasons. Design intake flow is a fixed value set based on the design of the facility’s operating system and the capacity of the circulating and other water intake pumps employed at the facility. This allows a clear and timely classification of facilities. The design intake flow does not change, except in those limited circumstances when a facility undergoes major modifications or expansion, whereas actual flows can vary significantly over sometimes short periods of time. EPA believes that an uncertain regulatory status is undesirable because it impedes both compliance by the permittee and regulatory oversight, as well as achievement of the overall environmental objectives. Further, using actual flow may result in the NPDES permit being more intrusive to facility operation than necessary since facility flow would be a permit condition and adjustments to flow would have to permissible under such conditions and applicable NPDES procedures. It also would require additional monitoring to confirm a facility's status, which imposes additional costs and information collection burdens, and it would require additional compliance monitoring and inspection methods and evaluation criteria, focusing on operational aspects of a facility.

5% of mean flow during the spawning season. This proposal would likely be less protective of juvenile fish and would offer no protection to small migratory fish such as eels and lamprey that can be subject to entrainment and might not be moving past the intakes during the spawning season. It would presumably allow a far larger proportion of the mean flow to be taken outside of the spawning season, resulting in far greater damage to populations than would be the case with the 5% flow threshold.

RFC: Alt. thresholds for entrainment (E) controls

25% of the 7Q10. The flow of most US surface waters is highly seasonal and varies considerably between years so it is possible that the 7Q10 minimum constraint would give a lower constraint than the 5% of average flow threshold. In drought years this constraint would effectively allow a reduction in the level of environmental protection over that offered in more typical periods. Over the usual life of a power plant of 40 years or more it is likely that there will be periods when flow is lower than the 7Q10 and thus, for short periods, even more than 25% of the flow could be removed. The problem from the ecological viewpoint with this proposal is that during extreme droughts, when the aquatic life is already stressed, the impact from water extraction (and discharge) would be particularly high. This could result in considerable ecological damage from which it might take the river fauna a number of years to recover. It is unclear if this option is better or worse than the 5% annual average. It is certainly much more difficult to quantify.

EPA Response

EPA has opted not to include the 25% 7Q10 threshold in today's rule and instead adopts the 5% mean annual flow threshold. Based on comments received at proposal, EPA believes the 5% threshold to be sufficiently protective for freshwater streams and rivers. The 7Q10 threshold would achieve only marginal increases in the protection of aquatic species compared to the 5% threshold while imposing unnecessary costs on Phase II existing facilities.

RFC: Regulating limited capacity facilities

15% Capacity utilisation cutoff

This proposal would remove plants that operate for less than 55 days per year from the need to reduce entrainment. Providing such plants are usually operated during mid summer and mid winter this is probably a reasonable concession. However, there are ways in which it could result in far higher entrainment levels than is implied in the proposed rule.

First, the 15% is “over the course of several years”. This would allow a plant that meets an average of 15% to be used for far more 55 days in some years. This in turn could result in large entrainment losses for some years.

Second, it is implied that the 15% of available operating time would be taken as one or two blocks: “the plants typically operate during two specific periods: extreme winter and extreme summer demand periods”. The implication is that this pattern reduces the need for entrainment protection as these periods correspond to periods of naturally low entrainment, which they often do. However, it is possible to envisage other patterns of operation that would result in 15% availability and which would result in far higher entrainment losses. For example, a plant could be used to meet peak morning and evening demand only.

Third, there is no assurance that the 55-day period of operation would not correspond to periods of high larval fish abundance. Indeed, in a worst possible scenario a plant with 15% utilisation could kill almost as many organisms by entrainment as a plant with a 60-80% utilisation. To illustrate the point the Table 21 shows the conditional mortality rates for abundant larval fish at the Indian Point Power station in the Hudson estuary, NY (reproduced from the Indian Point Draft DEIS).

[see hard copy for table]
Table 21. The conditional mortality rates for abundant larval fish at the Indian Point Power station in the Hudson estuary, NY. (Entrainment CMR x 1000). (Reproduced from the Indian Point Draft DEIS).

Note that almost all the larval entrainment occurs over two periods, 23-Feb to 28-Mar and 17-May to 25-July. If the plant were used in both these periods, even a 55-day utilisation could produce high levels of entrainment. It should also be noted that February and July are often months when electricity demand is at a peak so such an outcome is quite possible.

The above considerations indicate that a simple 15% threshold would not necessarily give the level of entrainment protection that the modest level of utilisation might suggest. If a low-utilisation plant kills a large number of organisms by entrainment then the fact that it is not used for the majority of the time should not exclude it from taking protective measures.

RFC: Proposed use of restoration measures

A summary of methods of aquatic habitat creation, restoration and modification

There is a very wide range of methods available to man for modifying, restoring or creating habitat; covering the full spectra of scale, target species, habitat type, antiquity and, ultimately, effectiveness. Below are listed some means of altering the physical and biological characteristics of an ecosystem; divided into habitat- (H) and species-related (S) measures. It is of course likely that a combination of measures would be used to address different aspects of an ecological problem.

a. Creation

-Saltmarsh and wetland creation: managed retreat from protected areas by breaching of existing sea defences, or creation of new creek systems. Creation of entirely new reclaimed land by dumping of spoil, or encouragement of silt deposition and stabilisation. (H)

-Artificial reefs: disposal of fly ash, tyres, etc, sinking of old ships, oil rigs. (H)

-Creation of new river channels; permanent or temporary diversion of flow. (H)

-Translocation of animal or plant species – to new non-threatened habitat or to replace organisms lost/damaged. (S)

-Dune planting and stabilisation. (H) & (S)

-Quarry pit restoration for e.g. bird species or angling. (H)

-Flooding of low-lying farmland to create water meadows (H)

b. Restoration/modification

-Physical cleaning, removal of oil, debris, contaminated silt etc; biological or chemical cleaning methods. (H)

-Dredging to restore estuarine habitat lost to siltation (H)

-Removal or modification of large-scale river obstructions: weirs, dams etc. (H)

-Removal, addition or modification of small-scale features, such as litter banks or debris dams, bank profiling, meanders, riffles/pools, adding obstructions, pinch points, bed widening, reedbed and bankside planting, weed-cutting, removal of shading vegetation. Provision of shallows for breeding and juvenile fish. (H)

-Culling or discouragement of damaging species, such as geese: herbicides to remove alien plant species – water hyacinth, Crassula, etc; biological control species. (S)

-Stocking with increased numbers of existing species, or with new, higher-value species. (S)

-Grazing by farm stock, fencing off (alternatively, removal of fencing to allow natural trampling of banksides by animals). (H)

-Regulation of salinity, water depth, sedimentation, by sluice gates; augmentation of flow. (H)

-Closing (or opening) of channels; building of protective barriers, wave screens to protect fragile inshore habitats. Groynes & breakwaters to prevent erosion of beach substrate. (H)

-Changes in input to food chain; removal of organic input from sewage works, agricultural run-off etc. (H)

-Building of fish-passes and ladders. (S)

-Cleaning, de-silting or addition of fish spawning areas such as gravel beds. (S)

EPA Response

EPA agrees with the commenter that there are many methods of restoration. All restoration measures used for the purposes of the final rule must meet all of the requirements described in the final rule.

RFC: Proposed use of restoration measures

Defining and assessing ecological equivalence

Having identified habitat enhancements that can be employed, the key is to assess how much enhancement, and of what type, is necessary to offset a given scale of ecological harm caused by impingement and entrainment losses. It is clear that like-for-like replacement can occasionally be achieved. For instance, if a power station is built on reclaimed saltmarsh, then a similar area of adjacent saltmarsh can be created or restored. Similarly, an area damaged by thermal discharges could be compensated for by restoration nearby. However, like-for-like restorations for impingement / entrainment are impossible on the community level, implying that a means of assigning equivalence to such losses is necessary.

The principle of Habitat Equivalency Assessment (HEA) demands that

-both a scale or multiplier, and a measure common to both damaged and replacement habitats, exist, and that

-the damage to the original habitat be measurable.

“For compensatory restoration actions, the scaling question is: what scale of compensatory restoration action will compensate for the interim loss of natural resources and services from the time of the incident until full recovery of the resources? The scale of compensatory restoration actions is conditional upon the choice of primary restoration actions. … Necessary conditions for the applicability of HEA include that (1) a common metric (or indicator) can be defined for natural resource services that captures the level of services provided by the habitats and captures any significant differences in the quantities and qualities of services provided by injury and replacement habitats, and (2) the changes in resources and services (due to the injury and the replacement project) are sufficiently small that the value per unit of service is independent of the changes in service levels”. - (NOAA, 1995).

According to this principle, therefore, it is possible to place a value on the resource that is damaged or lost, and create or improve habitat with an equivalent value. For example, if X thousand of a particular species die each year, then their loss can be offset by creating enough habitat to support X thousand more. In most cases, this implies the creation or restoration of estuarine and wetland habitat. It should be noted that almost all examples of habitat equivalency analysis are concerned with the replacement of past damage, such as compensation after oil spillage. It is also evident that a considerable time-lag is likely, between the original damage and the establishment of the new resource at its full potential.

NOAA’s Habitat Equivalency Analysis (HEA) states: “The principal concept underlying the method is that the public can be compensated for past losses of habitat resources through habitat replacement projects providing additional resources of the same type”. (NOAA, 1995). Thus the origin of the concept appears to be as compensation for finite, existing, discrete and quantifiable losses, rather than justification for continuing and future loss.

EPA Response

For a discussion of the use of out-of-kind restoration, see EPA's response to comment 316bEFR.206.055. All restoration measures must meet all of the requirements of the final rule.

RFC: Performance/effectiveness of restoration

Measuring the success of a restoration project.

Probably the most appropriate and complete list of principles for successful restoration is set out by the partnership of Restore America's Estuaries and the Estuarine Research Federation, (RAE-ERF 1999).

RAE-ERF guidelines for successful restoration of estuarine habitat include:

-Preservation of existing habitat is critical to the success of estuarine restoration

-Estuaries can be restored only by using a long-term stewardship approach and developing the constituencies, policies and funding needed to support this

-Restoration plans should be developed at the estuary and watershed levels to set a broad vision, articulate clear goals and integrate an ecosystem perspective

-Project goals should be clearly stated, site specific, measurable and long-term – in many cases greater than 20 years

-Success criteria for projects need to include both functional and structural elements and be linked to suitable local reference habitats

-Site plans need to address off-site considerations, such as potential flooding and salt water intrusion into wells, to be sure projects do not have negative impacts on nearby people and property

-Scientifically-based monitoring is essential to the improvement of restoration techniques and all-over estuarine restoration

-Ecological engineering practices should be applied in implementing restoration projects, using all available ecological knowledge and maximising the use of
natural processes to achieve goals

-Long-term site protection is essential to effective estuarine habitat restoration

-Public access to restoration sites should be encouraged wherever appropriate, but designed to minimize impacts on the ecological functioning of the site.

EPA Response

EPA believes that some of the principles from habitat restoration are useful for the purposes of the final rule, which focuses on the restoration of aquatic organisms. This is true for two reasons. One, habitat restoration is one means of restoring aquatic organisms. Two, some of the principles from habitat restoration can be generalized to restoration of various types of biological entities, whether habitat or organism. EPA has incorporated requirements for monitoring, adaptive management, and peer review into the final rule which reflect some of the principles the commenter mentions above.

Examples of existing projects.

a. Delaware Bay Estuary Enhancement Program.

The best-known example of large-scale ecosystem replacement is the Estuary Enhancement Program (EEP), carried out by PSEG to mitigate impingement / entrainment losses at the Salem CWIS.

"As an alternative to the construction of two natural draft cooling towers, PSEG proposed the EEP, an ecosystem-scale restoration project, to replace the species of concern [weakfish (Cynoscion regalis); spot (Leostomus xanthurus); white perch (Morone americana); and bay anchovy (Anchoa mitchilli)] lost in the cooling system. Based on the positive correlation between the primary production of salt marshes and the secondary production of nekton, an aggregated food chain model was employed to estimate the required area of tidal salt marsh needed to offset the loss of the major species of concern in the Bay. From the model, over 5,040 ha of diked salt hay (Spartina patens) marsh and common reed (Phragmites australis) degraded brackish marsh was proposed for restoration, enhancement and protection". - (RAE-ERF, 1999)

PSEG's project eventually totalled 20,500 acres (8,300 ha). As well as wetland restoration, fish ladders have been built to allow upstream migration of river herring, and stocking of the waters upstream with herring has taken place. The new fish ladders "open more than 100 miles of river, and 700 acres of ponds to additional spawning habitat for the river herring".

Whether, on the other hand, these measures truly replace, year-on-year, that which is lost to the CWIS at Salem, or simply replace it with something of roughly equivalent value – which may, arguably, have been provided by another benefactor had circumstances differed – is an interesting point. It is worth noting in passing that opening 100 miles of river habitat to spawning herring is very far from a guarantee that spawning will take place. Similarly, there are well-documented disadvantages associated with replenishing wild stocks with reared fish.

In summary, the project sought to replace lost productivity, rather than address losses at source of particular species, such as the bay anchovy. It is unclear whether the theoretical enhanced productivity in the restored saltmarsh will in fact move through the food web to increase the number of bay anchovy, and other pelagic spawning species. What is more, the increased productivity could favour other species less sensitive to impingement and entrainment than the anchovy, resulting in a change in the species balance and increased predation on the target species.

While the Delaware Bay EEP is "the largest privately-funded restoration in the world" (NJDEP 2001), there is strong evidence that it does not, and was not intended to, fulfil its stated aim of equivalency with the losses at the Salem plant.

The New Jersey Dept. of Environmental Protection document 'Frequently Asked Questions Regarding the Salem NJPDES Permit' makes the following points:

-“While many commentators praised the environmental benefits of the wetland restoration program, some commentators expressed specific concern regarding the continued need to use herbicides to meet restoration goals for portions of the Alloways Creek site”. (When called on the matter, PSEG stated that they would cease utilizing herbicides to ‘manage’ Phragmites-dominated marshland, and “purchase approximately 1,000 additional acres to ensure compliance with the permit conditions”).

-The final success criteria of the various parts of the site are still a very long time in the future, falling due between October 2008 and October 2011. Compliance is determined by the Department’s review of aerial photography, and “Currently the permittee is in compliance with the approximate 9% coverage of Spartina and other desirable marsh vegetation per year”.

-“The ultimate goal of the wetlands restoration program is to restore these diked or Phragmites-dominated wetlands to Spartina wetlands.

-In reply to the question: ‘Does the proposed draft permit authorize the use of glyphosate at the wetlands restoration sites?’: “No. To receive permission to apply glyphosate, the permittee must apply to the Department’s Land Use Regulation Program for a land application permit or permit modification … The Department continues to encourage minimization of the use of glyphosate on the wetland restoration sites. Once the proper hydrological regime is established in an affected area, the Department’s goal is for native wetland vegetation such as Spartina alterniflora to out-compete Phragmites. In the event that the Department determines that a repetitive application of glyphosate is the only available method for Phragmites control, PSEG will be required to eliminate the “failed” acreage from the program and to provide other wetland or upland acreage to meet the NJPDES permit requirements.”

-In reply to: ‘Is PSEG required to produce the same number of fish on the preserved or restored wetlands that are being lost at the intake structure?’: “In its 1994 permit, the Department determined that PSEG’s voluntary proposal to restore or enhance a minimum of 10,000 acres of wetlands in the Delaware River Basin would further minimize the effects of Station-related operations. This acreage value was intended to increase detrital production (finely divided particulate matter available for consumption by aquatic life) to the Delaware Estuary as well as provide additional fish habitat. This acreage value was not intended to replace the losses at the intake structure at a one to one ratio. The Department reaffirmed this acreage value in its July 29, 2001 final permit. However, the permittee did provide analyses in its application to estimate the range of numbers of fish produced on the formerly diked wetland restoration sites. Due in part to the fact that the permittee continues to make general statements about the level of fish productivity from wetlands restoration as a factor in fish population trends, the Department has determined that the quantification of fish production is important in a general sense. Therefore, the Department included a requirement in the June 29, 2001 permit to require the permittee to provide estimated production levels at the wetland restoration sites. Again, it is important to note that these sites are still evolving and not yet complete which has a bearing on the production amounts.”

While the replacement of Phragmites with Spartina continues, studies of isotope transfer through the Delaware Bay food chain suggest that Phragmites contributes to the nutrition of white perch and bay anchovy, two of the key species of concern.

"At upper estuary locations, Phragmites australis appeared to contribute to the nutrition of white perch and bay anchovy …, whether they were captured in salt marshes or in the open bay. This was especially true for white perch collected from the two upper estuary marshes where the signatures for all three isotopes were not significantly different, and the fish could not readily be distinguished … However, another C3 plant was also present in Mad Horse Creek, Amaranthus cannibus, which has a carbon signature similar to that of P. australis, about -23.7‰ (34S =13.0‰) (Stribling and Cornwell 1997). Together, these macrophytes comprised about 10 to 15 % of the coverage of the marsh plain, virtually all of it adjacent to tidal creeks. It is possible that plants growing along creek banks may contribute disproportionately to nutrient flow into finfish …". Weinstein, Litvin et al. p.18 Whether the other plant species mentioned, A. cannibus, occurs on the 'new' Spartina marsh, and how it is affected by the considerable use of glyphosate to control Phragmites, is not clear.

Furthermore, the following flaws in PSEG's model are pointed to on the 'Clean Ocean Action' website, produced by the New Jersey Environmental Federation:

-"any 'new fish' that are produced by the converted saltwater wetlands may increase the number of some fish species found in the bay. In turn, this will also increase the number of fish that will become impinged, entrained and killed by the power plant. Thus, there are more fish in the water, there are more fish going to be destroyed by the nuclear power plant. PSE&G can not protect "new fish" produced by this proposal without greatly reducing the water intake of the power plant;

-The wetland mitigation of the "Estuary Enhancement Program" does not create any new marshlands; it just changes the marsh from freshwater wetland to a saltwater wetland. In this process the net gain of wetlands is zero. The salt-hay farms that are to be converted in this mitigation process do provide nutrients and vegetative material to the Delaware estuary during peak flood tides throughout the year. … The change in productivity in this mitigation process is not large enough to compensate for the adverse impact that the cooling system of the SNGS is having on the environment. While productivity is not as high as a saltwater wetland, a freshwater wetland will provide an important habitat to many species like painted turtles, tadpoles, black rails, cattails, black ducks and mosquitofish. PSE&G attempts to balance an environmental equation. They stated that the productivity (based on their theoretical model) of the new salt marsh is greater than the negative impact of the cooling system. Based on this PSE&G gained approval for its permit. But, PSE&G leaves out the lost productivity of the destroyed freshwater marsh [from its productivity calculations]. In either case, the destruction of a freshwater wetland to create a saltwater wetland does not seem like a viable solution to killing fish via the water intake system of the power plant;

-the "Estuary Enhancement Program" has had a negative impact [on] other species, most noticeably the horseshoe crab. Since 1993 there has been a dramatic decline in the population of horseshoe crabs. While commercial fishing is the primary factor that has impacting (sic) the population, the "Estuary Enhancement Program" located at Thompson's Beach has caused the death of hundreds of thousands of horseshoe crabs over the past couple of years".

PSEG's Gerald Lauer states

"I have found that the loss of even large number of small organisms and early life stages of fish species are not determinative of a potential for adverse impact." - (COA 2002).

This statement is at odds with the NJDEP's own:

"It is important to note that the Department views the term "adverse environmental impact" in the context of the Clean Water Act as meaning the loss of one fish through a cooling water intake structure. In other words, in the Department's view it is irrelevant whether the losses at an intake structure include one fish or a million fish. Either way the Department requires the permittee to implement any technological measures for which the costs are not wholly disproportionate to the environmental benefits".

The points above make it reasonably clear that the EEP was not considered as a direct equivalent to the losses through impingement and entrainment. Meanwhile, the policy of eradicating Phragmites marsh, seemingly central to the program, is not wholly beneficial, relying on heavy use of herbicides. PSEG appear not to quantify levels of increased production in the wetland restoration areas, and the judgment of their eventual success is still a long way in the future. Finally, various aspects of the calculations employed by PSEG are called in to question.

EPA Response

EPA agrees with the commenter that there are uncertainties associated with the performance, design, assessment, and implementation of restoration measures. For a discussion of these uncertainties, see EPA's response to comment 316bEFR.206.055.

For a discussion of the role of restoration in the final rule, see EPA's response to comment 316bEFR.056.003 and the preamble to the final rule.

Morro Bay.

Interestingly, it was exactly this lack of equivalency that resulted in the rejection by the California Energy Commission staff of habitat enhancement measures for Morro Bay, California. As in the case of Salem, the habitat enhancement measures were clearly beneficial. It was proposed to attempt to reverse the loss of estuarine habitat through sedimentation. However, it was unclear as to whether these enhancements would directly aid the species most affected by impingement and entrainment. The conclusions were as follows:

"… staff believes it is less appropriate and is not our preferred approach to mitigate the marine impacts for MBPP for the following reasons:

1. It does not directly eliminate or reduce the adverse impacts caused by once-through cooling, which are causing ecological damage/losses to the ecosystem in a protected State and Nationally designated Estuary, that is in decline. Staff believes that it is preferable to avoid impacts than to attempt to mitigate them after the fact;

2. New USEPA regulations on cooling water intakes, and the special status of the Morro Bay Estuary, reinforce the need to eliminate the adverse impacts of once-through cooling;

3. The acquisition of suitable habitat adjoining Morro Bay and in the supporting watershed may be challenging;

4. The restoration of in-situ (in-kind habitat) in Morro Bay may be challenging;

5. The long-term nature of the impacts associated with the Applicant's proposed once-through cooling will result in continuing and increasing (because the estuary is in decline) impacts for decades;

6. The uncertainty and difficulty of determining if mitigation is ultimately effective and complete many years after licensing; and

7. The extensive annual monitoring of the health/improved productivity of the bay/estuary that would be needed for the life of the project with the possibility of modifying/increasing the mitigation to be more effective as needed".

(California Energy Commission, 2002).

EPA Response

EPA does not believe restoration measures will be a feasible alternative for every permit applicant.

For a discussion of why EPA wishes to allow restoration measures despite associated uncertainties, see EPA's response to comment 316bEFR.077.013.

Comment ID 316bEFR.077.045

Subject Matter Code 11.01

RFC: Proposed use of restoration measures

Author Name Reed W. Super

Organization Pisces Conservation, Ltd.

Conclusion

From these case studies we can see quite clearly the limitations of habitat enhancement as a means of mitigation for entrainment/impingement.

-Habitat equivalency analysis is primarily aimed at offsetting past losses or damage, rather than continuing loss;

-Considerable uncertainty exists as to whether equivalence can be focused on actual species harmed;

-Potential lack of availability of sufficient habitat to adequately offset losses or damage.

There is, then, a strong argument that the Delaware estuary improvements are not a direct compensation for CWIS losses, since

-Only losses due to impingement have been reduced at source, and damage to the original ecosystem will continue;

-Many of the losses in the original habitat have no direct equivalent in the restored ecosystem, which is aimed at mitigating damage to the Species of Concern (in the 1998 raw figures, the 4 species of concern amount to only 53% of the estimated total production foregone), and so only a part of the damage is addressed. Crucially, increased productivity in the restored area does not inevitably lead to improvements in numbers or condition of the target species – and may even exacerbate their problems.

-Concerns have been raised over the considerable use of glyphosate herbicide to control Phragmites.

-The eradication of Phragmites has been shown not to be wholly beneficial, and the program may have had a negative impact on other estuarine species.

-Aspects of PSEG's calculations of future productivity required are called in to question; in particular that the gains from 'new' saltmarsh were not balanced by the lost productivity from the old habitat it replaced.

-The criteria of final success of the project remain some years in the future, and firm evidence of increased productivity is not forthcoming from PSEG.

-Most crucially, the goal of the EEP was not specifically to provide equivalence to the losses at the Salem plant.

EPA Response

EPA believes permit applicants and permitting authorities should consider the net environmental impacts of a restoration measure when assessing its feasibility.

For a discussion of why EPA wishes to allow restoration measures despite associated uncertainties, see EPA's response to comment 316bEFR.077.013.

Comment ID 316bEFR.077.046

Subject Matter Code 11.01

RFC: Proposed use of restoration measures

Organization Pisces Conservation, Ltd.

Other projects.

Other habitat replacement projects aimed directly at the mitigation of impingement / entrainment losses are few – perhaps for the reasons outlined above, and due to the large scale of habitat provision necessary to sustain a breeding population capable of supporting such high losses. While PSEG have been able to alter over 20,000 acres of habitat; many other utilities would not have sufficient funds to provide this level of reparation, and large enough areas of habitat to be restored or created may well not exist close enough to the facility to be deemed truly a replacement for losses. It has been calculated, for instance, that the intertidal zone production of an extra 8 miles of coastline would be required to replace the losses of goby (Gobiidae) species at Morro Bay power station, California.

EPA Response

EPA agrees with the commenter that space limitations may make restoration measures infeasible for some facilities.

For a discussion of the use of out-of-kind restoration measures, see EPA's response to comment 316bEFR.206.055.

RFC: Proposed use of restoration measures

How successful is habitat replacement?

a. Success of current schemes

Ongoing wetland and estuarine restoration schemes are documented by RAE-ERF (1999) in the Gulf of Maine, North Carolina, San Francisco Bay, Tampa Bay and Virginia's Lafayette River. These are on a considerably smaller scale than the Delaware Estuary EEP.

Of the Gulf of Maine project RAE-ERF say:

"Restoration efforts include mitigation projects to compensate for permitted impacts and proactive projects to increase the amount and quality of coastal habitats. Despite this emphasis, the overall effectiveness of tidal wetland restoration in the region is uncertain. Contributing to this uncertainty are a lack of comprehensive baseline information on sites available for restoration, widely varying degrees of restoration project monitoring, inconsistencies in monitoring data collection and a paucity of scientifically-defensible standards and criteria for determining restoration success". - (RAE-ERF, 1999).

In Virginia, the target was the once-prolific oyster reefs of Chesapeake Bay:

"In 1998, the Chesapeake Bay Foundation (CBF) joined forces with the Norfolk Rotary Club, the Virginia Marine Resources Commission (VMRC) and Old Dominion University (ODU) to begin restoring the depleted oyster population of Virginia's Lafayette River. Recognizing that a healthy bay and a healthy economy are inextricable linked, the Norfolk Rotary Club raised $28,000 to put toward the construction of two oyster sanctuary reefs. Using the funds as leverage, CBF and VMRC attracted additional funds to complete the reefs.

ODU scientists helped determine the best locations for the reefs based on circulation patterns, sediment and water quality considerations to maximize larvae survival and spat settlement. Once the sites were chosen, VMRC constructed the reefs by piling shell material to simulate historic inter-tidal oyster reefs. The three-dimensional reef design was based on research conducted by the Virginia Institute of Marine Science which shows that placing oysters higher in the water column improves their health. CBF helped stock the reefs through its oyster gardening program, in which citizens and schools raise oysters in floating cages to protect them from sedimentation and predation.

With the help of hundreds of volunteer oyster gardeners, CBF has transplanted nearly 250,000 oysters the Lafayette River and other oyster reefs in Virginia. So far, the project has resulted in a tremendous increase in the oyster population in the Lafayette River—the number of new oysters around the reef and up to one mile away has grown 23-fold. The Lafayette River oyster restoration project represents just one example of massive restoration efforts now taking shape in Virginia and Maryland. The goal now is to achieve a ten-fold increase in the number of oysters in the Chesapeake Bay over the next five years". - (RAE-ERF, 1999).

Elsewhere, researchers at the University of Rhode Island are attempting the restoration of offshore eelgrass (Zostera sp.) beds, albeit with limited success:

“Anything close to 50% survival in the field would be an unqualified success. Dr. Robert Orth of the Virginia Institute of Marine Science has worked with seed-based eelgrass restoration in the Chesapeake Bay for over 10 years. In his experience, survival rates only approached 50% when the seeds were contained in burlap bags. Moreover, attempts by his lab to use an underwater planting sled did not exceed the 5 - 15% survival rate achieved when the seeds were simply thrown over the side of the boat”. - (EPA, 2001b)

The success of a typical habitat restoration scheme on a small river system was analysed by Langford et al. (2000). In the late 1990s, habitat modification was undertaken on several rivers in Southern England.

“The techniques were mainly classified as “substrate redistribution” (bed re-profiling, weirs, flow diversion, narrowing) or “substrate augmentation” (introduction of gravel beds). Many reaches were fenced to exclude stock and reduce grazing pressure.

Between 1996 and 1998 surveys showed increased fish populations in restored reaches. Analysis of these data showed increases to be statistically significant for salmonids and some coarse fish in all three rivers.

In 2000, surveys were commissioned … to assess the effects of the restoration work on other biota, namely plants and invertebrates. Total species richness of plants was lower overall in restored than in unrestored reaches. This was a result of significantly lower numbers of bankside and terrestrial species in fenced reaches. Aquatic species showed similar diversity in restored and unrestored reaches … There was a non-significant difference in Ranunculus cover between unrestored and restored reaches though this was probably a result of better flows than in [previous] dry years. In all streams the greatest influence on instream weed was shade … There were no significant differences in invertebrate diversity between restored and unrestored reaches. Diversity of invertebrates in marginal river habitats was significantly greater than in midstream habitats and the species compositions differed … There were no separable effects of restoration on the marginal and midstream invertebrates”. - (Langford et al., 2000)

EPA Response

EPA believes there are uncertainties associated with restoration measures and that restoration science continues to develop. For additional discussion of uncertainties, see EPA's response to comment 316bEFR.206.055.

RFC: Proposed use of restoration measures

Unexpected effects.

Some restoration measures can prove to have worse environmental impacts than the problem they were intended to solve. For instance, following the removal of dams or weirs, or changes in their regime of water flows, increased current velocity downstream can scour sand and silt, disrupt spawning areas, remove nutrients, and damage fragile banks and shallows. It can also release contaminants locked in the accumulated silt layer behind the obstruction, or lead to physical choking by silts.

Following severe erosion problems caused by flow fluctuations at the Glen Canyon dam on the Colorado River, efforts were made to restore beaches and other features of the river; firstly by limiting variations in flow, and secondly by more extreme measures:

“[After limiting flow variations] the center found that conditions on the river were deteriorating alarmingly. Whole beaches had disappeared. Four species of native fish had become extinct. An Asian tapeworm appeared; it now infects most native fish that survive. Rainbow trout, now spawning naturally in the wild, increased their numbers sixfold, so that some parts of the river contained 17,000 trout per mile. Steadier flows apparently increased their survival rates but reduced their food resources, so they became smaller and thinner.

In the spring of 1996 … researchers tried out their first big experiment using the Glen Canyon Dam. For one week, they released 45,000 cubic feet of water per second, using special spillways. They figured the high water would lift sand stored on the bottom of the river and deposit it onto beaches.

While the experiment looked like a huge success at first, it quickly went awry. A year later, most of the sand was gone. "We made a huge mistake," said Dr. Theodore Melis, a sediment expert at the research center. The sand that built the beaches, it turned out, had come not from the river bottom but from existing beaches and eddies. Then fluctuating flows continued to erode sand as before. Two different experiments in 1997 and 2000 also failed to make beaches or retain sand.

Meanwhile, the rainbow trout continue to proliferate, said Dr. Lew Coggins, a fisheries biologist at the center. As many as a million rainbow trout are now in the river, eating midges, plants and possibly a native fish called the humpback chub. Ten years ago, some 8,300 adult chub lived in the river; today there are only 2,100 large enough to spawn. Biologists worry that this may not be enough to sustain the population”. - (Blakeslee, 2002)

EPA Response

EPA believes permit applicants and permitting authorities should consider the overall environmental impact of a restoration measure.

For a discussion of the uncertainties associated with restoration, see EPA's response to comment 316bEFR.206.055.

RFC: Performance/effectiveness of restoration

Measurement and prediction of success of restoration projects

The degree of success of a habitat replacement scheme can be measured in a number of different ways, and is plainly far from guaranteed. Reasons for failure to meet expectations include:

-Inadequate baseline knowledge, planning, monitoring and long-term commitment to after-care;
-Incomplete understanding of all issues involved.
-Deviation from initial goals.
-Heavy dependence on the selected target species, its biology, and the solubility of the factors causing the problem in the first place;

Furthermore, success cannot be gauged by a short-term increase in species numbers or diversity, but must be measured over periods as long as decades. What is more, it seems plain that habitat replacement is still a relatively young and experimental science, with many details yet to be firmly settled.

“Practicioners (sic) need to build on the existing foundation for restoring physical structure in estuaries, like water flow patterns and vegetation, to learn how to restore function. They must identify ways to transfer knowledge from smaller intensively managed restoration sites to much larger restoration efforts, moving from demonstration projects to larger geographic areas. They need to learn more about the effects of sea level rise, sedimentation and a host of other variables to help set appropriate goals and success indicators for restoration projects in their dynamic natural environments. They need improved models at the habitat level to help with site selection, understanding tidal flows and selection of reference sites for individual projects. Better models at the ecosystem level will help in understanding things such as life cycles of particular species and links between habitats”. - (RAE-ERF, 1999).

“But restoration and mitigation are not cure-alls. There has been great debate within the HWG [Habitat Workgroup] as to whether the current wetland regulatory guidelines requiring one-to-one or three-to-one mitigation replacement acreage in public works projects and damages claims are too conservative. It is uncertain whether wetland mitigation, as it is practiced, maintains the goal of no loss or no net loss. While state-of-the-art restorations and creations can "build" wetlands that look natural, there is considerable controversy as to how long it will take, if ever, for these created or restored systems to function as high-quality natural wetlands. Successful replacement of wetlands is usually measured only at the grossest structural level -- replacement of dominant vegetation cover type -- and does not account for the full complement of the wetland ecosystem functions, including development of the peat substrate, abundance of invertebrate populations, storage of essential nutrients, and development of nutrient cycles. Forest restorations take decades longer to recover full structural and functional values”. - (EPA, 2001a)

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

EPA believes restoration measures will be well suited for some sites, and not well suited for others. Evaluation and monitoring difficulties are two reasons why restoration measures may not be suitable for a particular site.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

RFC: Proposed use of restoration measures

Conclusion: the utility of habitat replacement.

a. No-loss solutions vs. no net loss

Fundamentally, it is arguable whether designing and building a habitat to promote the few key species identified as being under threat is a suitable replacement for an entire mature ecosystem. It is also questionable whether replacement wetland and estuarine habitats can effectively mitigate for the extremely high numbers of fish and larvae impinged and entrained by CWIS. PSEG's initial estimate that over 5000 hectares would be required to offset I&E losses at the Salem plant gives a reasonable indication of the scale of mitigation required. The assumption that the productivity of a relatively small area of habitat can truly replace potential losses of several billion eggs, larvae and adult fish every year must be questioned. And if losses cannot thus be replaced, then we must ask whether the cost of such a scheme might not be better employed in effective anti-entrainment / impingement measures.

In addition, estuarine improvement may provide extra habitat for estuarine and brackish water spawning species, but it cannot mitigate for losses of deepwater spawners whose juveniles subsequently move into estuaries and are entrained (e.g. atlantic croaker, spot and menhaden), or those species which spawn upstream in freshwater (for instance salmonids and shad) and are entrained or impinged on their journey downstream. Further, it provides no recompense for losses of threatened and endangered species such as (at Delaware) the shortnose sturgeon and various turtles.

b. Broader considerations.

Balanced against the points above is the developers' desire for a higher environmental profile, and, as PSEG put it, to provide "long-term, broad-based benefits for the natural resources and people of the region". Existing and planned environmental protection regulations may well also discriminate in favour of a broad-based benefit, and provide the opportunity for enhancements to the wider community.

These are valid and valuable ideals, but it is far from certain that they are a true replacement for losses, and so it can be argued that they should not be used as a bargaining chip to enable utilities to reduce their commitment to solving the primary environmental problems, impingement and entrainment. Furthermore, we must question whether habitat restoration should be offered as a viable alternative to effective measures against I&E, on the grounds of the apparent success of one project, on a scale greatly exceeding other projects likely to be put forward.

EPA Response

For a discussion of the role of restoration in the final rule, and EPA's authority to include restoration measures, see EPA's response to comment 316bEFR.056.003 as well as the preamble to the final rule.

For a discussion of the requirement to consider design and construction technologies and operational measures before choosing restoration measures, see EPA’s response to comment 316bEFR.033.005.

For a discussion of ancillary benefits from restoration measures, see EPA’s response to comment 316bEFR.032.011.

Spatial scale

The EPA would prefer that trades be conducted between water bodies that share similar ecological characteristics regardless of geographic proximity of the facilities to each other.

There are two problems with this preferred option. First, it is unclear what is meant by share similar ecological characteristics. All estuaries share the characteristic that they are nursery areas for marine fish, however the species occupying estuaries differ with geographical locality. This phrase would need to be carefully defined. In particular, the use of ecological characteristics is too vague to be useful.

The second problem relates to the sharing of populations within the region where trading would be allowed. The one key ecological characteristic that must be shared for trading to be ecologically protective would be the populations of the impinged or entrained species. Two rivers or lakes may have many species in common and a generally similar ecology, but their populations may be completely isolated. Therefore improvements in one system would be of no benefit to the populations in an unconnected system. Also, the characteristics and genetics of species change with geographical locality. Therefore geographic proximity and in particular some degree of connectivity are important so that waters can share populations or occasionally swap migrants. This is essential if they are to have ecological characteristics that can be considered shared.

If the primary aim is to protect the populations of fish and crustaceans, then the geographical scale and the nature of the ecological characteristics for consideration must be determined by the extent and isolation of the populations of target species. A necessary, but not sufficient, criterion must be that all waters over which trading is conducted must be connected so that they interchange their most abundant fish species. In situations, such as estuaries, where they are connected by the ocean it must also be proven that trading is occurring between localities between which the main species do actually move. While for some species, such as striped bass, the ocean may be no obstacle, for others it may be effectively insurmountable. A similar situation can occur in large rivers where different tributary catchments can be isolated islands for species unwilling to enter the main stem of the river. This brings into sharp focus the fact that the appropriate geographical scale changes with the species.

The above considerations suggest that trading should only be allowed over limited geographical zones and normally confined within a single estuary, river or lake. Further, in large water bodies, where clear environmental gradients are present, it would be inappropriate to allow trading between sites with very different lists of commonly entrained and impinged species. For example, in the River Hudson Estuary there are great differences in the larval fish entrained between low salinity waters towards the head of the estuary and higher salinity waters towards the mouth. In the case of ocean sites they would need to be within a zoogeographic zone that shared fish populations. For large rivers there would also need to be habitat subdivisions reflecting habitat features. This leads to the conclusion that the appropriate spatial scale is trading within specific water bodies with further subdivisions for large and very large water bodies.

The above arguments lead to the view that trading should only be permitted between sites situated on the same water body and ecological community and that impact the same populations of common species at similar life stages.

EPA Response

Trading in the context of section 316(b) raises many complex issues. One fundamental complex issue is the scale within which trades can be made. Identifying the proper scale for trading entails a balance between allowing enough flexibility so that there is a potential for trades to occur and ensuring the protection of the ecosystem structure and function in the vicinities of the facilities involved in the trade. The decision made regarding the scale will determine whether the program is implementable. Due to the complex issues relating to trading, including those raised by the author of this comment, EPA has elected not to specify how a trading program in the context of section 316(b) should be implemented but rather has left it to the discretion of a permit director to decide whether a trading program is a beneficial use of State resources.

A determination on the appropriate spatial scale within which to allow trades will ultimately determine the possible number of trades. Larger geographic units will allow for more possible trades between more facilities; however, it may compromise the ecosystem structure and function in the vicinities of the facilities if too large due to site-specific differences in species diversity and abundance. Too large of a scale could cause greater impacts in one waterbody than in another and will do little to improve stocks in either waterbody. Trading programs that allow trades to occur at too large of a scale run the risk of disrupting ecosystem function, community structure, biodiversity and genetic diversity if trades are made that involve different species or even different populations of a single species. Smaller geographic units may make trading less likely because fewer partners will be available to trade. However, trades in the same waterbody will ensure that a net positive effect on the local stocks will occur due to implementation of the requirements of this rule. A smaller trading scale would also ensure that the same ecological community is affected. EPA believes that the geographic scale would need to ultimately be set at a size that is protective of fishery resources and does not cause localized impacts. Should a State choose to propose a trading program under § 125.90(c), EPA will evaluate the State's proposal on a case-by-case basis to ensure the program complies with the regulatory requirement – that it will result in environmental performance within a watershed that is comparable to the reductions of impingement mortality and entrainment that would otherwise be achieved under the requirements established at § 125.94. To this end, EPA foresees potentially approving only those trading programs which allow trades within individual watersheds.

RFC: Potential trading units/ credits

The unit for trading

The EPA propose three possible units of exchange, species density, species counts and biomass. As will be discussed below there are considerable problems with all 3 possible units for trading and further clarification and definition is required.

Using species density; numbers of eggs, larvae, juvenile fish and shellfish species entrained per unit volume would be used. This could only be an appropriate measure for trading if trading were strictly limited between sites in the manner proposed above under spatial scale. The distribution of all species is far from uniform and is variable through time. Therefore this proposal will not offer equal protection to all species. In particular, the density of shellfish species needs to be considered in more detail as it may seriously distort the outcome. Crustaceans are normally much more abundant than fish in both entrainment and impingement samples. For example, in estuarine and marine sites very large numbers of shrimp (Crangon spp.), mysids and young crab are entrained. Is it proposed to give these organisms equal weighting to that of larval fish? The situation is even more difficult if molluscs are to be considered. In some estuarine and marine localities large numbers of small molluscs such as just ready to settle mussels (Mytilus spp.) may be entrained. Such ‘fouling’ organisms are frequently viewed as a pest and sometimes are actively killed using biocides or heat treatment. The implication would seem to be that these would be given equal weight to larval fish for trading purposes. The example of trading under the EPA’s preferred alternative (p17172) is based on only a few abundant fish species and gives no mention to shellfish. A final area that needs to be clarified is the base data that will give a measure of the entrainment at each plant between which trading is proposed. The recruitment of fish and the abundance of other entrainable organisms can vary dramatically from year to year and change greatly through time. A clear example of long-term change is the 15-fold increase of abundance in striped bass in the River Hudson estuary since the 1970s. If trading is to be fair and appropriate it is essential that each of the sites within the trading group must have contemporaneously collected entrainment data and that the time period for comparison between the sites must be of equal length.

Species counts would use data on the numbers of each species. Further, these numbers would be subdivided into age classes. A value would need to be given to each species at each life stage. It is far from clear how each species and stage will be given a monetary value, and the amount of work required to collect and organise the data would be considerable. In reality this method could only be used for selected species. How would these species be selected? There would be a great temptation to focus on important commercial species, as they would be easier to value in monetary terms. As for species density, if trading is to be fair and appropriate it is essential that each of the sites within the trading group must have contemporaneously collected entrainment data and that the time period for comparison between the sites must be of equal length.

Biomass; trading would be based simply on the weight of entrained organisms per unit volume. This would give equal weight to all living (or possibly recently killed) life. The effect would be to effectively have a trading system based on phytoplankton. For marine and estuarine systems these would be mostly diatoms, Phyocystis and other colonial forms and dinoflagellates. In some freshwaters diatoms and even blue-green algae could dominate. The most abundant animal groups are frequently ciliates and other protozoans and microcrustaceans such as copepods and cladocerans. At ocean sites it is often observed that the biomass of ctenophores entrained is considerable. The biomass of eggs and larvae of fish and macrocrustaceans such as crab and lobster would be negligible. A biomass trading system would be completely inappropriate, as it would focus protection towards the rapidly reproducing, short-lived lower-life forms that are best able to cope with the losses caused by entrainment.

EPA Response

Trading in the context of section 316(b) raises many complex issues. One fundamental complex issue is the appropriate unit of trade. Identifying a unit for trading entails a balance between allowing enough flexibility so that there is a potential for trades to occur and ensuring the protection of the ecosystem structure and function in the vicinities of the facilities involved in the trade. The decision made regarding the unit of trading will determine whether the program is implementable. Due to the complex issues relating to trading, EPA has elected not to specify how a trading program in the context of section 316(b) should be implemented but rather has left it to the discretion of a permit director to decide whether a trading program is a beneficial use of State resources.

A determination of the appropriate units to trade would introduce so many issues that EPA believes it should be left to the discretion of the permit director whether they want to take on the burden of a trading program. EPA does not support trading biomass because it may not be protective of populations of fish and shellfish, since phytoplankton and zooplankton would be included in the weight and since one large individual of an abundant species could potentially be traded for many eggs or larvae of a rare species. In addition, EPA does not advocate trading similar species because it introduces a host of problems in assessing similarity given that each species occupies a separate niche within an ecosystem. EPA does not believe that it is possible at this time to quantify with adequate certainty the potential effects on ecosystem function, community structure, biodiversity, and genetic diversity of such trades, especially when threatened and/or endangered species are present. Trading the same species would eliminate many issues regarding measuring equality of species; however, it would still be burdensome to implement. EPA would like to caution permit directors that measuring any units of trade effectively would be extremely difficult given the inherent variability and dynamic nature of the populations of aquatic organisms subject to impingement mortality and entrainment. Should a State choose to propose a trading program under § 125.90(c), EPA will evaluate the State's proposal on a case-by-case basis to ensure the program complies with the regulatory requirement – that it will result in environmental performance within a watershed that is comparable to the reductions of impingement mortality and entrainment that would otherwise be achieved under the requirements established at § 125.94. To this end, EPA foresees potentially approving only those trading programs which allow trades within individual watersheds and trade for numbers of the same species. In addition, EPA would like to explicitly state at this time that a trading program that would allow trading between aquatic organisms and pollutant discharges, as has been suggested by some stakeholders, would introduce comparability and implementation challenges that would be difficult to overcome; therefore, EPA does not expect that such a program would meet the requirements for approval. EPA also questions whether such a program would be consistent with the recent Water Quality Trading Policy.

Impacts to T&E species

The extent of threatened and endangered species problems

Cooling water systems impact threatened and engendered species directly by entrainment and impingement and indirectly by habitat degradation. Fish, crustaceans and molluscs are often directly impacted because they have swimming stages that can enter the intakes. However, other animal groups such as turtles and even seals have been entrained and caught on screens or in screen wells. Aquatic birds and mammals tend to be indirectly affected via lost food supplies and habitat degradation.

It should be assumed that all power plants situated on estuarine and coastal sites will impact to some degree threatened or endangered (T & E) species. Major American river estuaries are all heavily utilised by man and because of overfishing and habitat damage they all hold fish populations that are considered endangered or threatened. In many cases these species are fish that were once quite abundant but have been much reduced by man, such as sturgeon and migratory salmonids. Where entrainment or impingement data for a power plant have been thoroughly collected for a number of years it is usually the case that T & E species have been recorded. Where insufficient data are available to make it likely that a rare fish would have been detected there is often information to suggest that T & E species occur in the area and would be vulnerable to harm by the cooling water system. For example, the San Francisco Bay / Delta estuary study includes the following in the list of species vulnerable to I&E:

1. Central Valley ESU steelhead - Oncorhynchus mykiss

2. Central Valley fall/late fall-run ESU Chinook salmon – Oncorhynchus tshwytscha

3. Central Valley spring-run ESU Chinook salmon – Oncorhynchus tshwytscha

4. Delta smelt – Hypomesus transpacificus

5. Green sturgeon – Acipenser medirostris

6. Longfin smelt – Spirinchus thaleichthys

7. Sacramento River winter-run ESU Chinook salmon – Oncorhynchus tshwytscha

8. Sacramento splittail – Pogonichthys macrolepidotus

Along the same coast at Morro Bay, the April 2002 staff report for the California Energy Commission notes that the estuary used for cooling water by Morro Bay GS is inhabited or potentially inhabited by the federally endangered tidewater goby (Eucycloglobius newberryi) and the steelhead trout (Oncorhyrnchus mykiss). Note that the tidewater goby is not listed as present in the San Francisco Bay area.

Similarly sized lists of T & E species could be complied for almost all ocean and estuarine sites. For example, in the Hudson Estuary both shortnosed (Acipenser brevirostrum) and Atlantic sturgeon (Acipenser oxyrinchus) have been impinged on cooling water intakes.

At many ocean and lower estuarine sites young turtles are potentially vulnerable to entrainment. For example, in the recent assessment of the impact of the Sunset Energy proposal for a power plant in New York harbour the following turtle species were listed as potentially present:

1. Green sea turtle – Chelonia mydas

2. Loggerhead sea turtle – Caretta caretta

3. Leatherback - Dermochelys coriacea

4. Kemp’s ridley turtle – Lepidochelys kempii

5. Hawksbill – Eretmochelys imbricata

With the exception of a few leatherbacks, most of the turtles in nearshore waters in the New York coastal region are small juveniles. The loggerhead is the most abundant, followed by the Kemp's Ridley. These two species, along with a few green turtles, move into harbours and estuarine waters, while the leatherback turtles remain along the coast and are rarely seen in embayments. Kemp's Ridley inhabits the shallower areas of Chesapeake Bay in search of blue crab, their preferred prey. Their preference for shallow waters and blue crabs makes the Kemp's Ridley the most likely sea turtle species to venture into the New York & New Jersey Harbor area. Similar lists would be produced for many east coast marine or lower estuarine power plants situated to the south of New York.

A point to note is that if conservation measures for species such as sturgeons and turtles were successful then populations could greatly increase, resulting in extended ranges and the risk of higher impingement in future years.

It is not so easy to make generalisation about freshwater habitats. Plant situated on rivers, particularly smaller rivers, are almost certain to impact T & E species, as are those situated on the great lakes. Kelso and Kilburn (1979), in an examination of impingement and entrainment at Great Lakes power stations, report:

“There were seven species found among impinged fish that were rare or never before detected (Scott and Crossman 1973) in the Great Lakes including pirate perch (Aphredoderus sayanus), redfin pickerel (Esox americanus americanus), golden redhorse (Moxostoma erythrurum), orange spotted sunfish (Lepomis humilis), brindled madtom (Noturus miurus), warmouth bass (Chaenobryttus gulosus) and chestnut lamprey (Ichthyomyzon castaneus)”.

Plant using water from reservoirs or smaller lakes may not directly impact T & E fish, birds or reptiles. This is because these may be in areas of low aquatic biodiversity or even utilise water from man-made water bodies. However, the isolation inherent in freshwater water lakes and some river catchments results in the formation of distinctive biological races of many species of fish. The maintenance of this genetic biodiversity is recognised as important and loss of genetic diversity may be a more important impact on freshwater fish than is generally appreciated.

In addition to direct impacts indirect effects in terms of habitat degradation are likely to be affecting other T & E species. This is particularly the case when power plants are situated on smaller estuaries, inlets or close to less common types of habitat. For example, Morro Bay Power Plant is situated on a small estuary on the Californian coast and the region holds threatened sea otter (Enhydra lutris) and federally endangered California brown pelican (Pelicanus occidentalis). These species rely on the Bay for food that can be reduced by impingement and entrainment. In many localities the abundance of fish feeding birds is probably directly proportional to the level of food resources available for the birds. Thus any damage to the populations of often rather small, non-commercial fish species can have a direct impact on aquatic birds.

EPA Response

In order to help the permit writer to take into account possible impacts of cooling water intake structures on threatened and endangered species when determining the best technology available for minimizing adverse environmental impact, the Impingement Mortality and/or Entrainment Characterization Study described in § 125.95(b)(3) in this rule must include taxonomic identifications of all life stages of fish, shellfish and any species protected under Federal, State, or Tribal Law (including threatened and endangered species) that are in the vicinity of the cooling water intake structure and are susceptible to impingement and entrainment.

Definition: Existing Facility

EPA should specify directly in the Phase II regulations, not the preamble alone, that they do not apply to facilities whose primary business activity is not power generation.

The proposed Phase II regulation includes criteria for applicability if the facility "both generates and transmits electric power, or generates electric power but sells it to another entity for transmission." Section IV of the preamble further clarifies the above applicability by stating: "Today's rule does not apply to facilities whose primary business activity is not power generation, such as manufacturing facilities that produce electricity by co-generation." The Council supports this statement and recommends that EPA include this directly in the regulations to provide more clarity on the applicability of the Phase II Rule.

EPA Response

Withdrawal threshold of 50 MGD

Permittees should have the option of meeting an actual flow threshold in lieu of the 50 MGD design flow threshold.

The proposed rule lists a design intake flow of 50 MGD as one of the criteria for applicability of the proposed Phase II regulations. In many cases, however, actual intake flow is below the design capacity. This is typically due in part to water conservation initiatives, process improvements, and more efficient use of water resources since the original design and construction of the intake structure and/or the facility. If a permittee is willing to accept permit limitations that restrict actual water usage below 50 MGD, EPA should encourage such actions as a means of reducing the potential for entrainment and impingement, which is the goal of Sec. 316(b) of the Clean Water Act.

RFC: Use of previous demonstration studies

Author Name Brad Shanks

Organization American Chemistry Council

Once “Best Technology Available (BTA)” has been determined and no significant cooling water increases occur afterwards, there should be no further need for a Sec. 316(b) analysis.

The Council believes that a Sec. 316(b) analysis should be a one-time only requirement. That is, once “best technology available” has been determined for a facility, installing and operating that technology should relieve the facility of further Sec. 316(b) reviews. The “location, design, construction, and capacity” of the cooling water intake structures are matters of design and construction, not operation. Congress could not have intended that facilities be in the business of redesigning, demolishing, and reconstructing their intake structures every five or ten years.

For each NPDES permit renewal cycle, a permittee could certify that there have been no changes in the plant operations or the design of the intake structure. From this, the Director should then accept the original Sec. 316(b) analysis and BTA determination. However, the Council does support the need for a new Sec. 316(b) analysis if there have been significant changes in plant operations or the design of the intake structure that may lead to adverse changes to the aquatic populations.

EPA Response

EPA agrees that a comprehensive demonstration study may not need to be conducted each time a permit is renewed. Please see response to 316bEFR 041.126 for a discussion.

Option: UWAG's recommended approach

THE COUNCIL SUPPORTS UWAG'S SITE-SPECIFIC APPROACH AND DEFINITION OF ADVERSE ENVIRONMENTAL IMPACT

The Council believes that the regulations governing cooling water intake structures should maintain the greatest possible flexibility for meeting best technology available performance standards, which are meant to minimize adverse environmental impact. Including a flexible site-specific option as well as voluntary restoration will allow permittees' to cost effectively protect the environment.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Option: UWAG's recommended approach

The UWAG site-specific approach when applied in the Phase II rule will providE greater flexibility for permittees and provide protection for the environment.

The Council recommends that EPA adopt the UWAG site-specific approach as presented in Section VI.C. of the preamble since it provides the most flexibility of the proposed site-specific options and provides protection for the environment.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Burden on permitting agencies (general)

Author Name Brad Shanks

Organization American Chemistry Council

The additional burden imposed on regulatory agencies under the site-specific approach is outweighed by the enormous value to the permittee and its customers.

EPA expresses a concern related to the "Implementation Burden under Any Site-specific Approach." Specifically, EPA is concerned about the resources needed by the State permitting agencies to implement a site-specific option. The Council urges EPA to consider any burden that may be imposed by this rule on the States and other governmental agencies against the huge burden that would be otherwise imposed on the regulated community. EPA should not oversimplify regulations and eliminate regulatory flexibility such that substantial additional costs are imposed on the regulated community for environmental controls that provide minimal benefit to the environment. The Council supports appropriate regulation of cooling water intake structures, if an adverse environmental impact exists, but urges that they be flexible and cost effective in protecting the environment.

EPA Response

See response to comment 316bEFR.034.005 for a discussion of the efficiencies added to today's final rule to speed permitting and reduce potential burden on the regulated community.

Comment ID 316bEFR.078.008

Subject Matter Code 11.01

RFC: Proposed use of restoration measures

Author Name Brad Shanks

Organization American Chemistry Council

The Council supports restoration and recommends that it be voluntary as part of the permittee's overall assessment.

EPA maintains in the preamble that the role of restoration measures in addition to or in lieu of technology measures for mitigating impingement and entrainment impacts or in establishing best technology should be available on a site-specific basis.

The Council strongly urges EPA to include restoration as a voluntary tool that the permittee may use to minimize adverse environmental impact.

EPA Response

For a discussion of the extent to which restoration measures are voluntary, see EPA's response to comment 316bEFR.060.022.

For a discussion of the role of restoration in the final rule, see the preamble to the final rule.

Option 3--Site-specific determination

Author Name Jim Stevens

Organization Vero Beach Power Plant

EPA should be complimented for considering a variety of alternative approaches to the regulation. The City of Vero Beach Power Plant is encouraged that the EPA proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that affect the technical practicability of meeting the proposed standards. Specifically, the EPA recognizes that there may be situations where the costs of meeting the proposed standards at a specific facility may be significantly higher than the costs considered by the EPA in establishing these standards. In those instances the proposal provides the facility with the opportunity to justify an alternative technology selection.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.079.004

Author Name Jim Stevens

Organization Vero Beach Power Plant

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

The EPA proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific-factors that indicate that the costs of meeting the performance standards are not warranted by the projected benefits at that facility. This is potentially very good. The proposed rule allows facilities to select an alternative level of compliance where the costs of compliance with the EPA's performance levels would be significantly greater than the expected benefits of achieving these levels. This explicitly recognizes the site-specific variations in the water bodies (with varying ecological conditions) and can help account for controls already in place at many facilities.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.079.005

Author Name Jim Stevens

Organization Vero Beach Power Plant

Subject Matter Code 7.01.03

Option 3--Site-specific determination

The EPA has chosen a flexible approach to compliance that allows facilities to meet the performance standards through a number of options, including creation or voluntary restoration of habitats and other non-traditional approaches. This approach allows for continued innovation in addressing the potential adverse environmental impacts associated with impingement and entrainment at power generating facilities. This also leaves significant discretion in determining how best to comply with the standards to state permitting authorities and facilities managers who have developed a great deal of expertise on these issues over the past 25 years. The City of Vero Beach Power Plant has a good working relationship with the state and believes in deferring, where possible, to the state regulators.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule. This rule preserves an important role for states.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

For information on the role of restoration, please refer to sections VII and VIII in the preamble to the final rule.

Subject Matter Code 22.06
UMRA/Impacts on local governments

Criticism:

The EPA has underestimated the impact on public power systems. The City of Vero Beach Power Plant believes that the EPA should consider these impacts on local government.(See section titled Assessment of Unfunded Mandates Analysis on Public Power in the Comments submitted by the American Public Power Association).

The City of Vero Beach Power Plant agrees with the APPA that the EPA should encourage states to implement the new 316(b) requirements coordinating with states to ensure reliable grid operations.

The City of Vero Beach Power Plant is very concerned with the unintended consequences of downtime in the utility industry when 316(b) requirements are implemented. If the EPA and states attempt to do these too quickly or at the same time, there may be electricity price spikes as public power generators purchase power from IOUs or other public power entities during a one to three month down time.

The final rule should encourage state flexibility in setting sensible deadlines for 316(b) retrofits when the utility would have scheduled outage, maintenance or have lower demand. The EPA's proposed rule ignored this potential consequence that could be serious in a region (or watershed) where several utilities face NPDES permit renewal, imposition of 316(b) requirements, and planned outages in the same year. If not timed wisely, the region's customers could face unexpected utility bill increases-particularly during a peak use time such as mid summer or mid winter.

The EPA and states should take a common sense approach to new 316(b) requirements. This common sense approach would minimize potential cost spikes and energy disruptions and would avoid placing too high a demand on the few dozen consulting engineering firms that have considerable expertise in biological studies and the various intake technologies.

EPA Response

For a response to comments on potential impacts on public power systems, please refer to comment 316bEFR.028.008 in subject matter code 22.03.

For a response to comments on implementation of new 316(b) requirements, please refer to comment 316bEFR.028.007 in subject matter code 21.09.

UWAG definition of "adverse environmental impact"

Author Name Jay Hudson

Organization South Carolina Public Service Authority (Santee Cooper)

As defined beginning on page 17163 of the Preamble, Santee Cooper supports the UWAG alternative definition and approach for determining "Adverse Environmental Impacts" over the EPA approach. The EPA's approach referring to "significant numbers or percentages" lacks specificity while UWAG's approach provides protective physical and biological decision criteria that are attributable to the operation of the cooling water intake structure.

EPA Response

Please see the response to comment 316bEFR.002.019 for the discussion on the definitions EPA rejected for adverse environmental impact in this rulemaking.

Comment ID 316bEFR.080.003

Subject Matter Code 18.02.02

UWAG recomm. for using previous studies

Author Name Jay Hudson

Organization South Carolina Public Service Authority (Santee Cooper)

Also, we believe the EPA should adopt the UWAG approach and allow use of previous Section 316(b) Demonstration Studies unless there has been a change in the species of concern (Representative Indicator Species) at the intake location. UWAG's approach, as noted on page 17165, is the most practical in that it allows for all "relevant costs" to be considered as true costs of the impact that the particular technology proposed would cause to the permittee.

EPA Response

EPA has disallowed the use of historical determinations of BTA in today's final rule; however, existing data that is reflective of current conditions may be used to support the required studies. Please see response to comment 316bEFR.040.001 for details.

Additionally, in today's final rule, EPA offers a site-specific compliance alternative (see 125.94(a)(5)) in which an applicant may receive a determination of BTA from the Director for its facility provided it meets one of two cost tests. EPA believes that this alternative will provide additional flexibility for facilities who may find that the other compliance alternatives are not suitable for their site.

Comment ID 316bEFR.080.004

Subject Matter Code 21.03
Monitoring requirements

Author Name Jay Hudson

Organization South Carolina Public Service Authority (Santee Cooper)

At pages 17179 and 17180 of the Preamble, the EPA notes that permittees would have to perform verification monitoring to demonstrate compliance with the requirements of minimizing adverse environmental impact. Santee Cooper recommends that the EPA consider that compliance be "demonstrated" upon initial operation of those technologies that will be approved by the Director during the permit renewal process and satisfactorily constructed by the permittee. Once the permittee has installed the technology, in lieu of monitoring, he should only be required to operate and maintain that technology for the life of the intake.

EPA Response

Please see EPA's response to comment 316bEFR.074.023. EPA has included in today's final rule several alternatives for achieving compliance, including demonstrating compliance with a Technology Installation and Operation Plan in place of numeric performance requirements. Please see EPA's response to comment 316bEFR.017.003 for an explanation of what constitutes compliance with today's performance requirements. Also please see the final rule preamble section IX for a discussion of the Technology Installation and Operation Plan.

Comment ID 316bEFR.080.005

Author Name Jay Hudson

Organization South Carolina Public Service Authority (Santee Cooper)

Subject Matter Code 7.02

Performance standards

Santee Cooper understands the "calculation baseline" is an estimate which the EPA intends to use as the basis to "verify" the level of protection that should be provided by the permittee's proposed technology(ies). The EPA's proposed "benchmark" ranges for nationwide compliance are reductions of 80 to 95 percent and 60 to 90 percent from the calculation baseline for impingement and entrainment, respectively. While Santee Cooper advocates the EPA's approach, we are not sure the range is optimum or correct for all sites. In Chapter 5 of the EPA's own Technical Development Document(as referenced in the New Facilities Phase I Rule), the EPA notes the performance of the various technologies was found to vary based on site-specific conditions and recognizes the practicality or effectiveness of alternative technologies are not uniform under all conditions. We therefore ask if it is reasonably possible to predict with certainty whether other ranges only 10 percent lower than the stated benchmark ranges would not also be equally protective of a species of concern at a particular site.

Santee Cooper believes the state Directors would be more informed whether a national standard should be applied for compliance, or whether a lower range, which would provide adequate protection for a particular waterbody, should be applied. Santee Cooper has a good working relationship with the state and believes in deferring, where possible, to the state regulators. Santee Cooper recommends leaving significant discretion in determining how best to comply with the standards to state permitting authorities and facilities managers who have developed a great deal of expertise on these issues over the years.

Consequently, we believe EPA's stated benchmark ranges should not constitute "absolute compliance" ranges; instead, they should be benchmark goals. If the ranges were considered goals, the state Directors would be given the latitude and discretion to determine whether a permittee that has installed the technologies they approved to reduce impingement actually met the compliance criteria. Consider the hypothetical case where a permittee installed the approved technology for reductions in impingement, but were to find through monitoring he actually achieved a reduction of 78 percent - only 2 percent shy of the "low benchmark." In this case, if the ranges were goals, Directors would have the flexibility to determine whether the actual percentage for that facility was close enough to the goal to be in compliance.

Similarly, consider the case for a facility which installed the technologies that were designed to meet both the impingement and entrainment ranges and subsequently finds through monitoring that one range is met while the other range falls short by only a few percent. It would seem unreasonable and impractical to require that permittee to install additional technologies to improve just a couple of percent. Simply put, should the EPA not adopt the approach we are proposing in comment no. 4 above, we believe the EPA should provide the Directors more flexibility in the determination for BTA compliance based on the reasonableness of the proposed technologies to meet "goals," not absolute compliance ranges.

EPA Response

EPA disagrees. The national performance standards adopted in today's rule are both appropriate and supported by the record. EPA believes that today's rule maintains a desired flexibility for both the permittee and the Director in determining the most appropriate and cost-effective means to meet the requirements. EPA adopted performance ranges rather than single value limits in recognition of the inherent variability that may exist between waterbodies and facility configurations.

For a discussion on the Technology Installation and Operation Plan and how it relates to compliance with today's rule, please see the preamble to today's final rule.

EPA has decided to give the Director the authority to determine methods of evaluating compliance. Thus, the Director will specify species and life stages of concern. The Director may choose to require evaluation of all species or of certain indicator species; or the Director may elect to verify compliance using biomass as a metric. EPA believes that as each situation will be somewhat unique, it should be left to the Director to determine whether biomass or actual numbers are a more appropriate unit.

RFC: Proposed use of restoration measures

Santee Cooper recommends the proposed rule should allow permittees restoration credits for cooling ponds that were constructed to operate the facilities, particularly if the cooling ponds did not exist before the facility was constructed.

EPA Response

For an activity to be considered a restoration measure, it must meet all of the requirements described in the final rule.

Comment ID 316bEFR.080.007

Author Name Jay Hudson

Organization South Carolina Public Service Authority (Santee Cooper)

Subject Matter Code 21.01.04

Comprehensive demonstration study (7 parts)

At §125.95 on page 17222, as well as at §125.98 on page 17224, it is evident the EPA intends that permittees be required to submit a Comprehensive Demonstration Study upon each renewal application. Santee Cooper believes that BTA demonstrations should be a one-time demonstration unless there are significant changes within the waterbody where the intake structure is located.

Santee Cooper recommends the EPA clarify that Comprehensive Demonstration Studies are not required at each renewal.

Additionally, in §125.95 there is a requirement the Comprehensive Demonstration Study must be submitted with the renewal application at least 180 days before the permittee's permit expires. This is an unreasonable requirement as proposed. The EPA must factor in additional time for permittees whose permits are set to expire approximately coincident with the date the rule becomes final. The EPA simply must allow permittees sufficient time to perform the field studies which are necessary prerequisites to compiling the Comprehensive Demonstration Study.

EPA Response

EPA disagrees that the Comprehensive Demonstration Study should, in its entirety, be a one-time submittal. For an explanation of EPA's position, please refer to the final rule preamble section VIII.E.4., Comprehensive Demonstration Study (CDS). EPA recognizes that in many cases, this information cannot be developed, analyzed and submitted prior to the time a facility's current permit expires. EPA has attempted to accommodate this situation in § 125.95(b). Please refer to the preamble to today's rule and EPA's response to comment 316bEFR.034.066 for a clarification of timing requirements for the submittal of studies and permit compliance issues in today's final rule.

Sample facilities/technologies

Consumers Energy has been a leader in developing innovative technologies to minimize fish impingement and entrainment in a variety of Great Lakes situations. CE was the first in the Great Lakes to design and install an off-shore wedge-wire screen intake for the JH Campbell Plant on Lake Michigan. This system has no impingement, minimizes entrainment and has been demonstrated in Michigan to be the best technology available for the JH Campbell Unit 3 Plant. CE was one of the first companies in the country to install and operate a fish deterrent net at the JR Whiting Plant on Lake Erie which has reduced fish impingement by 90%. Finally, CE has successfully installed and operated the largest barrier net in the county at the Ludington Pumped Storage Project on Lake Michigan, which also annually reduces fish loss by about 90%. Our experience with the installation, operation, evaluation and maintenance of such a variety of intake systems has shown that site-specific consideration of technologies and impact is the most effective way to attain agency and facility agreement on the best technology to minimize adverse environmental impact.

EPA Response

Today's rule maintains the flexibility for a facility to determine the most appropriate design and construction technologies, operational measures, and/or restoration measures suitable to its location that can best achieve requirements of today's rule.

EPA acknowledges the success achieved at both the JR Whiting facility and JH Campbell with their respective technologies and notes their inclusion in Chapter 3 of the Technology Development Document.

Proposed standards for Great Lakes

THE GREAT LAKES STANDARDS

The proposed Great Lakes requirement of a technology to reduce fish entrainment by 60 - 90% in the Great Lakes is not justified and limits the number of technologies available for consideration. Years of past intake study demonstrations and lake assessments have clearly shown that entrainment is a relatively small factor of potential cooling water impact and that impingement reductions yield the most cost-effective environmental benefit. While the Great lakes are a unique resource, they do not require more protection than other lakes and reservoirs. Elimination of the entrainment standard would allow facility owners and Great Lakes regulators the needed flexibility to select for technologies that are cost-effective and maximize net benefits.

EPA Response

Please refer to the response to comment 316bEFR.025.013 for a discussion of the Great Lakes as sensitive waterbodies.

Subject Matter Code 18.02

RFC: Use of previous demonstration studies

FLEXIBILITY FOR PREVIOUSLY APPROVED INTAKES

Consumers Energy has invested considerable time and resources in evaluating installing and demonstrating cooling water intake technologies that have been approved as BTA. It would be very helpful if the final rule would allow states to re-approve a previously approved intake as best technology available either as they are or with some level of revalidation up to and including a new study under the new 316(b) rule. There are many electric generating facilities in the Great Lakes for which there is already a high degree of confidence that the facility is not creating “adverse environmental impact” and there should be a simpler process for their approval.

EPA Response

EPA has disallowed the use of historical determinations of BTA in today’s final rule; however, existing data that is reflective of current conditions may be used to support the required studies. Please see response to comment 316bEFR.040.001 for details. EPA has also added many streamlining efficiencies to reduce burden in today's final rule, please see response to comment 316bEFR.034.005 for a discussion.

RFC: Test: benefits should justify the costs

ALTERNATIVE SITE-SPECIFIC APPROACHES

As proposed, the EPA only allows site-specific alternatives to be considered if the cost of achieving the standard is significantly greater than the expected benefits of compliance. We believe the best decision criteria allow facilities to select technologies or mitigation measures that maximize net benefits. Therefore, we encourage EPA to adopt either of the two site-specific approaches as proposed by UWAG and PSEG.

EPA Response

See the preamble to the final rule. See also response to comment #316bEFR.075.065. For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Comment ID 316bEFR.081.006

Subject Matter Code 21.04

Determination of compliance

Author Name Jon W. Allan

Organization Consumers Energy

COMPLIANCE ASSESSMENT

Facility owners and agencies will need to expend considerable time and resources to determine if a given technology installed on a cooling water intake achieved the percentage reductions in impingement and entrainment that are specified in the draft rule. In order to reduce implementation costs, speed permitting and prevent unnecessary permit backlog for both States and facilities, the EPA should allow State permitting agencies to waive the requirement for baseline monitoring, study and modeling for facilities that install any of the approved BTA technologies. Compliance monitoring should be focused to that which is necessary to demonstrate proper operation of the technology and not of further biological determinations.

EPA Response

EPA has included in today's final rule five alternatives for achieving compliance, and an option to demonstrate compliance with a Technology Installation and Operation Plan in place of numeric performance requirements. For a discussion of how compliance is to be determined, please see the preamble to the final rule and EPA's responses to comments 316bEFR.017.003 and 316bEFR.063.005. For EPA's explanation of EPA's monitoring requirements, please refer to EPA's response to comment 316bEFR.307.027. Also please see the final rule preamble section IX for a discussion of the Technology Installation and Operation Plan.

Comment ID 316bEFR.081.007

Author Name Jon W. Allan

Organization Consumers Energy

Subject Matter Code 10.07

RFC: Cost: benefit ratio for site-specific BTA?

COST-BENEFIT TEST

The cost-benefit test is a critical element of the proposed rule. In its current form, the proposed rule lacks a sound benefit assessment approach, overstating the benefits because of inappropriate inputs in biological assumptions, statistical methods, and resource valuation methodologies. In particular, the EPA use of the habitat replacement cost as a means to value benefits is inappropriate and greatly overstates potential benefits. Consumers Energy urges EPA to broaden their consideration of benefit options to include other mitigative actions such as habitat preservation, fishery recreational items and settlement agreements. Again, this is to build in the flexibility to allow regulators and owners to reach agreements on 316(b) determinations in an efficient and cost-effective manner.

EPA Response

As described in sections 125.94(c) and 125.95(b)(5) of the final rule, facilities may use restoration projects that produce and result in increases of fish and shellfish to meet the rule's performance requirements.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

EPA disagrees with the commenter's assertion that "the proposed rule lacks a sound benefit assessment approach." EPA's approach to benefit cost analysis of the proposed and final Section 316(b) Phase II rule is consistent with principles outlined in the EPA's Guidelines for Preparing Economic Analyses, United States EPA (EPA 240-R-00-003, DCN #6-1931).

For EPA's responses to specific comments on commercial fishing methods please see comment # 316bEFR.323.016.

For EPA's responses to specific comments on recreational fishing methods presented at proposal and the NODA please see comments # 316bEFR075.504 regarding the benefits transfer approach used at proposal, comments # 316bEFR.041.452, #316bEFR.337.010, and #316bEFR.306.320 regarding the RUM analysis.

The HRC method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see comment # 316bEFR.005.035."

As stated in the NODA, the "rule of thumb" is not used for estimating non-use benefits for the final Section 316(b)rule. Due to uncertainty in monetizing non-use values at the national level, EPA has not included quantitative measures of nonuse values The Agency, however, has provided several measures that indicate the potential magnitude of non-use values, including peer-reviewed meta-analysis, the benefit transfer method, and break-even analysis. For detail see Chapters A12, Non-Use Meta-Analysis Methodology, and A15, Habitat Based Methodology for Estimating Non-Use Values, of the final Phase II Regional Studies Document (DCN #6-0003) and Chapter D1 (break-even analysis) of the final Phase II EBA document (DCN #6-0002).

EPA also disagrees with the assertion that EPA's I&E analysis is flawed. Please see EPA's responses to Comment 316bEFR.029.105 regarding the age of impingement, Comment 306.092 regarding the detection of ecological impacts, Comment 316bEFR.074.101 regarding EPA's calculation of production foregone, Comment 316bEFR.074.042 regarding multiple conservatisms, Comment 316bEFR.005.009 regarding fish population modeling, and Comment 316bEFR.025.015 regarding compensation.

Role of States and Tribes (alt./equiv. programs)

Author Name Russell J. Harding

Organization Michigan Dept of Environmental Quality

Michigan has implemented a 316(b) program for a number of years. Design, construction, and operation of intake structures have been evaluated on a case-by-case basis to minimize adverse environmental impacts for a majority of the intake structures tar existing regulated facilities in Michigan. We believe it may not be necessary to require new studies or demonstrations for all those facilities with site-specific approvals.

EPA Response

EPA agrees that historical study data may be useful provided that it is reflective of current conditions at the facility. However, EPA also believes that historical BTA determinations must be re-examined against today's rule. See response to 316bEFR.040.001 for a discussion on the use of historical BTA determinations.

General statement of support

However, outstanding issues still remain for a number of facilities, and promulgation of the 316(b) regulations will assist us in resolving those issues. Therefore, we support the proposed performance-based standards to help resolve remaining intake issues for existing facilities in the state.

EPA Response

EPA notes the comment. No response necessary.

Burden on permitting agencies (general)

We are concerned, from a regulatory standpoint, about the impact of the proposed regulations on the National Pollutant Discharge Elimination System (NPDES) permitting process. We recommend the regulations provide flexibility for the states to exempt facilities with previously approved 316(b) demonstrations from further study, rather than require every facility to conduct new studies and demonstrations. The states should have the option to require the additional studies or demonstrations if conditions have significantly changed or if special concerns warrant a reevaluation of impacts. We believe this approach will streamline the NPDES permit process and allow us to devote limited resources to facilities that need the attention. This approach will benefit permitting authorities faced with permit backlogs.

EPA Response

Please see response to comment 316bEFR.040.001 for a discussion on the use of historical BTA determinations.

RFC: Proposed use of restoration measures

Author Name Russell J. Harding

Organization Michigan Dept of Environmental Quality

Regarding the restoration (mitigation) provisions of the proposed rules, we recommend that any such provision allow the states to decide what mitigation is appropriate.

EPA Response

The final rule gives permitting authorities the flexibility to determine the feasibility of restoration measures on a site-specific, case-by-case basis. All restoration measures must meet all of the requirements described in the final rule.

RFC: Appropriate spatial scale for restoration

We recommend that a hierarchy of mitigation approaches be described to first implement on-site, in-kind mitigation, and that failing that option, mitigation on a broader scale within the watershed or lake basin be considered. For the most part, we would expect that restoration efforts would occur in the watershed or lake basin affected and be specifically designed to address the resource affected. However, there may be unique circumstances that would justify restoration measures outside the waterbody that would benefit the environment.

EPA Response

For a discussion of the appropriate scale on which to conduct restoration measures, see EPA's responses to comments 316bEFR.212.001 and 316bEFR.059.008.

RFC: Cost: benefit ratio for site-specific BTA?

The proposed rules allow for approval of site-specific best technology available for minimizing entrainment/impingement. Approval must be based on a determination that the cost of compliance with the promulgated performance standards would be "significantly greater" than either the costs considered by the EPA in establishing those standards or the benefits of complying with those standards. We recommend that the regulations be revised to add greater clarity in carrying out this cost/benefit comparison. Such improved clarity should be designed to maximize net environmental benefits and to reduce uncertainty for both the regulatory agency and the regulated parties.

EPA Response

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

See response to comment 316b.EFR.410.001 for further discussion of clarity and uncertainty in the cost tests.

See response to comment 316bEFR.006.003 for further discussion of significantly greater.

Seabrook

In the Seabrook Station Case Study Chapter G1-1 there are also several errors that are identified and corrected below.

-Seabrook Station is a single-unit generating station. The second unit was cancelled in 1986 and was never completed.

-The circulating water system draws water from the Atlantic Ocean coastal waters off the state of New Hampshire and not Ipswich Bay (Massachusetts).

-The ocean intake consists of three velocity caps (not one).

-The circulating water system discharge is located 5,500 feet offshore in the ocean and not 5,500 feet from Seabrook Station (note: The plant is located two miles inland. An intake tunnel and a discharge tunnel each about three miles long and more than two hundred feet below sea level, deliver cooling water to the inland generating station and return it to the ocean.

EPA Response

EPA regrets these errors. However, EPA wishes to note that this information was never used in EPA's analysis and is no longer included in any documents submitted by EPA in support of the final rule.

1.0 INTRODUCTION

The EPA's case study for Seabrook Station uses the Production Foregone model to evaluate fish losses at the plant due to impingement and entrainment. The Production Foregone model attempts to estimate the total biomass which could have been produced by the population had the effects of power plant operation not occurred (EPRI 1999). This model requires impingement and entrainment estimates, and life history parameters as input. The following review of the EPA's case study includes a critique of the application of the Production Foregone model, a review of the life history parameters, and a review of the input impingement and entrainment estimates used in the model.

2.0 APPLICATION OF THE PRODUCTION FOREGONE MODEL

As expressed in Chapter A5 of the case study, the approach used by EPA was to first present the raw impingement and entrainment losses at the plant derived from annual Seabrook Station Environmental Monitoring Program reports. Next, these losses were expressed as foregone Age 1 equivalents using Adult Equivalency (AE) methodology. Age 1 equivalents were then converted to foregone fishery yields in terms of biomass using the Thompson and Bell model. Finally, foregone biomass production was converted to a monetary estimate. Specific comments on the application of the Production Foregone model referencing the section numbers of EPA case study, are presented below.

Section A5-2.1 Facility I&E (Impingement and Entrainment) Monitoring

EPA assumed all fish killed by impingement were Age 1 at the time of death. For those species for which impingement occurs at older ages, foregone production and fishery yield will be overstated, because unrealized production of younger fish is greater than that of older fish. A more accurate approach would have been to calculate production foregone for each age class, and then sum the production foregone across age classes.

Section A5-2.2 Species Evaluated

This section begins by stating that “EPA conducted detailed species-specific loss analyses for species that were most predominant in facility collections or had special significance (e.g., threatened or endangered status).” In fact, species were aggregated for analysis. Application of species-specific life history parameters to multiple species amplifies uncertainty in the appropriateness of the parameter values. This problem is exacerbated when selected life history parameters correspond to a species that is a minor component of the aggregate.

Labeling of species aggregates to match available life history information obscures this major source of error. In the case of Seabrook Station, an aggregation of six species was reported by EPA as winter flounder, but winter flounder was only a small portion of the aggregate entrainment for that group of species. In addition, this situation exists with EPA’s lumpfish analysis, which is dominated by Atlantic seasnail. In the EPA’s analysis of impacts to red hake, several species are grouped, including silver hake. Further discussion of inappropriate species groupings appears in Section 4.0.

These inappropriate groupings of species increased both the imprecision and inaccuracy of the impact assessment to an unknown degree through inappropriate application of life history parameters of individual species to aggregated species groups. While this may be justifiable for closely related fishes with similar life histories, it cannot be justified in many cases. This is especially true for winter flounder, where it appears that the overwhelming majority of the eggs assigned to winter flounder were cunner, a completely unrelated fish.

Section AS-3.1 Modeling Age-1 Equivalents

In section A5-3.l of the case study EPA states: “The age of equivalency can be any life stage of interest”. Mathematically, this is true; however, not all ages are equally appropriate for interpreting impacts or as input to other models. For evaluating potential impacts to a fishery, the age of equivalency should be the age of recruitment to the fishery. This age will differ depending on the life history of the species and the fishery. EPA uses the results of the equivalent adults analyses as inputs to the Thompson and Bell model to estimate foregone fishery yield. The Thompson and Bell model assumes that the fish have recruited to the fishery; however, Table G1-35 indicates only 1% of winter flounder are vulnerable to the fishery at Age 1+, 29% at Age 2+, and 80% at Age 3+. This indicates that Age 1+ is not an appropriate age of presumed recruitment to the fishery and therefore not an appropriate age of equivalency for equivalent adult analysis. Appendix G1 indicates that Age 2+ or 3+ would be a more appropriate age of equivalency for many species given the empirical information on age of recruitment to the fishery.

Section A5-3.2 Modeling Foregone Fishery Yield

This section states that the Thompson and Bell model "provides a simple method for evaluating a cohort of fish that enters a fishery ..." . This statement reflects the fact that the Thompson and Bell model is based on recruits. For many species, Age 1+ fish have not recruited to the fishery as seen above for winter flounder. Age 2+ or 3+ is a more appropriate age of equivalency for the harvested species in this case study.

Section A5-3.3 Modeling Foregone Production

Production foregone should not be calculated as if fish were impinged at a younger age than actually occurred. EPA has assumed that all impinged fish were impinged at Age 1+. In doing so, EPA has included production that accrued from Age 1+ to the actual age of impingement as production foregone, thereby overstating production foregone by this amount.

In Table G3-4, EPA adjusted upward the number of impinged fish to account for mortality during the Age 1+ life stage under the assumption that impingement was distributed over the entire interval. This represents an equivalent number of impinged fish, had all of the impingement occurred at the start of the year. EPA's methodology is not entirely clear, however, if EPA used the impingement numbers from Table G3-4 to calculate production foregone, EPA has amplified the error described in the preceding paragraph by applying an inflated number of impingement mortalities in the calculation of production foregone.

Section A5-3.4 Evaluation of Forage Species Losses

The trophic transfer model implicitly assumes that production of harvested species is limited by availability of forage. This assumption is not necessarily true, especially for stocks that are depleted or otherwise below carrying capacity.

Figure A5-2 presents a trophic transfer model for valuation of foregone production of forage species. An explanation for this figure presents an estimate of trophic transfer for high efficiency (prey to predator transfer) and low efficiency (prey through intermediates to recreationally or commercially important species) trophic pathways. The model assumes a coefficient of transfer efficiency (k) of 0.09 for the high efficiency pathway and 0.009 for the low efficiency pathway. Furthermore, the model assumes that 20% of the forgone production will pass through the high efficiency pathway and 80% through the low efficiency pathway. There is no justification given for these assumptions. No literature in either the form of field or laboratory studies is cited. While all models have some assumptions, justification of assumptions is required, usually through reference to the scientific literature

Section A5-4.2 Parameter Uncertainty

The second paragraph asserts parameter uncertainty leads to imprecision rather than inaccuracy, because of offsetting effects of inaccuracies. While errors in individual parameters may offset each other to some degree, the analyses utilize fixed parameter values. The deterministic results exhibit inaccuracy rather than imprecision.

Section A6 – Fish Population Modeling

The citation of Strange et al. (2002) on page A6-7 is not really relevant, because in the examples cited, the entire population is directly exposed to the stressor (i.e., the habitat is altered). The analogous individual-level endpoint for 316(b) would be survival of entrained or impinged individuals. Clearly, however, not all organisms in the habitat are entrained or impinged.

Section G3-4 - Seabrook's Annual Impingement and Entrainment

Table G3-3, which table presents the annual impingement at Seabrook Station expressed as Age 1 equivalents is cited on page G3-14. The estimate of Age 1 equivalents is usually larger than the raw estimate of impingement due to an assumption that is explained in a note at the bottom of the table. This note states: "...ages of impinged fish are assumed to be distributed across the interval between the start of year 1 and the start of age 2.. ."

Calculation of the equivalent number entrained at the start of the year (see Table G3-3 note) is more sensitive, in absolute terms, to error in the mortality rate estimate than is conventional equivalent adults analysis that calculates the equivalency at an older age. Furthermore, the metric is conceptually flawed as a measure of impact, because it has no ecologically meaningful interpretation.

3.0 REVIEW OF LIFE HISTORY PARAMETERS

The output from any model is only as good as the input data. For the Production Forgone model used by EPA, life history data are important input parameters to the model. Appendix G1 presents the life history data used by EPA to estimate the Age 1 equivalents, fishery yields, and production foregone. The models are sensitive to these values, because these parameters are exponents in the models used. Extrapolation across species is a major source of potential error.

A review of all the life history parameters in Appendix G would result in a document almost as long as Appendix G. The following is a discussion of the weaknesses in the estimates of some of the life history parameters presented in Appendix G.

Natural Mortality (per stage)

Eggs

The reference, Stone and Webster (1977), is used as a source for estimates of egg mortality for several different species. This reference apparently contains an estimate of Atlantic silverside egg mortality. Footnotes to tables in Appendix G1 indicate that the Atlantic silverside egg mortality estimate is used to estimate egg mortality of many fishes including American plaice, American sand lance, bluefish, lumpfish, northern pipefish, sculpin spp., scup, striped killifish, and threespine stickleback. The Atlantic silverside is an estuarine spawner with a relatively large egg (1.0-1.5 mm) (Able and Fahay 1998). Eggs are deposited in the intertidal zone and apparently are attached to vegetation by adhesive tendrils (Martin and Drewry 1978). The use of the egg mortality estimate for Atlantic silverside for other species that may have smaller and in many cases pelagic eggs cannot be justified because of the differences in life history among the species.

Larvae

Larval mortality for several species including American plaice, American sand lance, Atlantic cod, bluefish, butterfish, fourbeard rockling, grubby, hogchoker, little skate, lumpfish, northern pipefish, radiated shanny, rock gunnel, sculpin scup, searobin, threespine stickleback, windowpane, were calculated using the expression:

(natural mortality) = -LN (survival) — (fishing mortality)

Fishing mortality on larvae is 0, so we are left with the expression:

(natural mortality) = -LN(survival)

This expression is not informative because no value for survival or citation for the assumed value is provided. Given the values for larval natural mortality in the tables, one can solve for —LN (survival). However, this does not provide any biological justification for the assumed value.

Juveniles

The estimates of natural mortality of Age 0+ fish (larval stage to Age 1+) for several species including American plaice, Atlantic herring, American sand lance, Atlantic menhaden, Atlantic silverside, butterfish, fourbeard rockling, grubby, (longhorn sculpin), little skate, lumpfish, northern pipefish (broad-nosed pipefish), radiated shanny, rainbow smelt, rock gunnel (radiated shanny), sculpin spp. (longhorn sculpin), scup, searobin, threespine stickleback, and windowpane, appear to be derived from either NOAA (2001) or Froese and Pauly 2001.

Natural mortality estimates derived from NOAA (2001) appear to be for older life stages that are commercially exploited and at least partially recruited to the fishery. For most species, natural mortality usually decreases with age. EPA apparently assumed that natural mortality rates were constant from Age 1+ through the remainder of a fish’s life. Therefore, the use of natural mortality estimates of commercially exploited stages for younger life stages is a clear underestimate of natural mortality of the younger life stages. The underestimated natural mortality for these young fish will overstate production foregone and foregone fishery yield. EPA’s assumption that all impinged fish were Age 1+, amplifies the significance of error in mortality rates for Age 1+ and 2+ fish. Other data sources, including Able and Fahay (1998) and other life history papers, present data that could be used to estimate natural mortality for Age 0+ and Age 1+ fish for several of these species.

The source, Froese and Pauly (2001), refers to an internet site (FishBase) where many life history parameters are presented for many fishes. Natural mortality estimates from this site are used for fourbeard rockling, grubby, lumpfish, northern pipefish, radiated shanny, rainbow smelt, rock gunnel, sculpin spp., scup, searobins, threespine stickleback and windowpane. Natural mortality (m) as defined by FishEase "refers to the late juvenile and adult phases of a population" (Froese and Pauly 2001). Therefore, the use of these estimates for the early juvenile stages underestimates the actual natural mortality, especially for longer lived fishes, and overstates the production foregone and foregone fishery yield.

Weight Estimates

Estimates of weight at various lifestages are presented in the tables in Appendix G. These estimates of weight are factors in the estimates of growth rates, which are important in the calculations of foregone production and yield. Weight estimates for each life stage are generally estimated from length-weight relationships. These length-weight relationships should be specific for each lifestage as there are major changes in the body form and the relationship between length and weight among life stages. However, it appears that EPA may have used length-weight relationships for larvae to estimate the weight of eggs based on their diameter. This will tend to underestimate the weight of eggs and thereby overstate production during the transition from egg to larvae. This is potentially significant given the relative portion of individuals entrained as eggs. Furthermore, there can be a reduction in weight between the egg and yolk sac larvae stage, which could be termed negative production. Production cannot begin until the fish commence exogenous feeding.

4.0 REVIEW OF ENTRAINMENT AND IMPINGEMENT REPRESENTATIONS

Table G3-6 of EPA's case study presents estimates of entrainment of eggs and larvae at Seabrook Station derived from the annual monitoring reports. EPA apparently grouped some species based on apparent similarities in life history. North Atlantic takes exception to some of these grouping as explained below.

Entrainment Data

Lumpfish

Data presented in Table G3-6 appear to be a combination of lumpfish and snailfishes. However, these ecologically and taxonomically diverse fishes have different life histories and should not be grouped. Furthermore, snailfish comprise the majority of this group and the application of life history parameters for lumpfish to snailfishes is not appropriate. Egg diameters for lumpfish range from 2.2-2.6 mm while egg diameters for Atlantic seasnail and inquiline seasnail range from 0.8-1.4mm (Collette and Klein-MacPhee 2002). Application of lumpfish egg diameter data to seasnail eggs will result in an overestimate of the biomass of this group.

Red hake

Data presented in Table G3-6 appear to be a combination of hake spp., red hake, white hake and silver hake. The life histories of these fishes are different and they should not be grouped. Estimated natural mortality of silver hake and red hake is 0.4, but 0.2 for white hake (NOAA 2001). Egg diameters for red hake (0.64-0.78 mm) and white hake (0.70-0.79 mm) are similar, but egg diameter for silver hake (1.04-1.24mm) is larger (Collette and Kiein-MacPhee 2002), which affects the estimates of egg biomass.

Sculpin spp.

Data presented in Table G3-6 appear to be a combination of longhorn sculpin, shorthorn sculpin and sea raven. Although sea raven eggs and larvae are rarely entrained, their egg diameters (3.9 mm: Collette and Klein-MacPhee 2002) are much larger than the sculpins and they should not be included in this group.

Winter Flounder

Data presented in Table G3-6 appear to be a combination of Atlantic cod/witch flounder, cunner/yellowtail flounder, Pleuronectidae, winter flounder, witch flounder, and yellowtail flounder. While all of these taxonomic groups appear to be part of the family Pleuronectidae, the inclusion of cunner/yellowtail flounder and Atlantic cod/witch flounder with winter flounder is not justified. Corrected estimates of winter flounder entrainment are presented in Table 1. EPA's overestimate of winter flounder entrainment ranged from 500,000 in 1994 to 790,000,000 in 1991.

Table 1. ERRORS IN EPA's PRESENTATION OF WINTER FLOUINDER ENTRAINMENT ESTIMATES.

Year	Data from Table G3-6 (EPA)	Data from Seabrook Station Annual Reports	EPA Overestimate
1990	520,479,242	3,200,000	510.000,000
1991	800,030,734	9,000,000	790,00,00
1992	242,018,538	6,200,000	232,000,000
1993	62,666,462	2,900,000	59,800,000
1994	500,000	0	500,000
1995	60,200,044	8,000,000	52,000,000
1996	172,100,000	10,300,000	162,000,000
1997	199,800,000	2,200,000	198,000,000
1998	138,521,000	4,700,000	134,000,000

Cunner/yellowtail flounder eggs are among the most numerous groups entrained each year, and the largest single component of EPA's winter flounder group (Figure 1). However, none of the cunner/yellowtail flounder eggs are likely to be winter flounder eggs. Winter flounder eggs are distinguished from cunner/yellowtail flounder eggs by theft irregular shape and thicker and grainy membrane (Collette and Klein-MacPhee 2002). Furthermore, winter flounder eggs are demersal and adhesive and therefore, are rarely entrained at the mid-water intakes of Seabrook Station.

The cunner/yellowtail flounder group is not likely to contain many yellowtail flounder eggs. It is explicitly stated in the annual monitoring reports that "A comparison of cunner and yellowtail flounder larval abundance indicated that most of the eggs in the cunner/yellowtail flounder group were likely cunner, assuming a relatively similar hatching rate between the two species (NAT 1999: p 4-45). The ratio of cunner to yellowtail flounder larvae is variable but can be as large as 408:1 (1997: NAT 1998a), indicating that in some years the percentage of yellowtail flounder eggs in the cunner/yellowtail flounder group may be less than 1%.

Given the dominance of cunner in this species grouping, the cunner/yellowtail flounder group should be split out and addressed separately as cunner, rather than grouped with winter flounder. The inclusion of cunner/yellowtail flounder eggs with winter flounder eggs greatly increases the estimate of winter flounder entrainment, and the potential monetary value of losses due to impingement and entrainment at Seabrook Station.

Atlantic cod/witch flounder eggs were also included with winter flounder. However, this group does not contain any winter flounder eggs. Atlantic cod/witch flounder eggs are distinguished from winter flounder eggs by their spherical shape and larger size (Atlantic cod: 1.20-1.69 mm; witch flounder 1.07-1.45 mm; Collette and Klein-MacPhee 2002).

Impingement Data

North Atlantic has stated in recent annual Environmental Monitoring Reports that not all impingement estimates prior to the last quarter of 1994 are reliable because plant personnel were not adequately sorting fish from impingement debris. Impingement monitoring was improved in late 1994. Since 1998, an outside contractor has been conducting impingement counts and estimates are considered to be reliable. Therefore, any projections of impingement impacts using data prior to 1995 are inaccurate and probably are underestimates.

Table G3-2 in EPA's case study presents estimates of impingement at Seabrook Station, apparently derived from the annual monitoring reports. However, several of the impingement estimates are in error or represent inappropriate groupings of species. Most of these errors are numerically small, and probably do not affect the assessment of the impacts of entrainment and impingement. Errors observed, and corrections are presented in Appendix A.

5.0 CONCLUSIONS

The EPA's case study on the impacts of entrainment and impingement at Seabrook Station is flawed due to improper application of the Production Foregone model and inappropriate input data. EPA's method of scaling the number of entrained and impinged fish to Age 1 rather than the age of recruitment to the fishery is conceptually flawed and, combined with understated rates of natural mortality, results in a systematic overestimate of production foregone. Furthermore, misapplication of the Thompson-Bell model assigns an inflated portion of the estimated foregone production to lost fishery yield.

Input parameters for the model are not always well supported by the scientific literature, or there are no good data available. The estimates of trophic transfer (k) used in the model are not supported by literature citations. Many of the life history parameters, including mortality and weight estimates, are inappropriate. Specifically, the use of natural mortality estimates of adult fish for juvenile fish is inaccurate, as well as the apparent use of length-weight regressions of larval fish for estimating weight of fish eggs.

The apparent grouping of species resulted in inaccurate estimates of the number of organisms entrained. The EPA's winter flounder aggregation included two taxonomic groups that contained few if any winter flounder eggs or larvae. This inappropriate grouping inflated the estimates of winter flounder entrainment by orders of magnitude.

It is EPA’s responsibility to either use the data that is accurate, or to acknowledge that the life history data are lacking and it is not possible to accurately estimate monetary losses due to impingement and entrainment. The use of dubious estimates of life history parameters simply because they are the best data available, results in inaccurate and imprecise estimates of monetary losses. A complete discussion of the weaknesses of the life history parameter estimates and the implications of the weaknesses of these estimates is lacking in the case studies. Species for which accurate life history data are lacking should be clearly identified so that the accuracy of the monetary losses can be evaluated.

Despite years of study, many life history parameters for some fishes are not well known. However, these uncertain estimates of life history parameters are used to calculate a monetary loss due to impingement and entrainment. When monetary losses are presented, there is an implied accuracy to the estimate. There is the real risk that monetary losses will be taken out of the context of the discussion of parameter uncertainty, and presented as absolute numbers with little error associated with the estimates.

EPA Response

The commenter proposes an alternative procedure for tabulating production foregone among impinged fish. EPA believes that the proposal may have merit but maintains that the practical effect of using the alternative procedure would be negligible, for reasons described in response to Comment 316bEFR.305.003 on EPA's production foregone analysis. The commenter's suggestion is based in part on the fact that EPA’s analysis for proposal used an assumption that all impinged fish were age 1. EPA notes that this assumption has been changed, as described in response to Comment 316bEFR.029.105.

The commenter discusses the possible effects of the species aggregation methods employed by EPA. EPA used species aggregation to reduce the total number of distinct species requiring individual parameter sets because of the lack of life history data for many species, particularly survival rates of early life stages. EPA believes that the aggregations are reasonable and do not introduce significant biases. In the Regional Analysis Document (DCN# 6-0003), EPA noted which species were included in the aggregations.

The commenter asserts that EPA has improperly used age 1 equivalents in the context of estimating foregone harvest. EPA maintains that the estimates of foregone harvest do not suffer from the kinds of flaws suggested by the commenter. The commenter seems to improperly equate the technical term "age of equivalency" with "age 1 equivalent." EPA did not estimate, nor did it report, "age of equivalency" which, as the commenter correctly notes, refers to the age at which fish enter a fishery. EPA did not use its estimates of age 1 equivalents as if they were the same as "age of equivalency" equivalents. EPA's estimates of foregone harvest were based on the best available information about the age at which fish become vulnerable to the fishery which, as the commenter notes, is frequently greater than age 1.

The commenter raises concerns about survival rates and fish weights, including certain values employed and EPA's reporting methods used to document them. The Regional Analysis Document (DCN# 6-0003) includes revisions that were motivated by earlier public review and references to additional source material (see EPA’s response to Comment 316bEFR.305.003 on production foregone for additional information. EPA maintains that some degree of uncertainty is unavoidable and that the parameter sets used by EPA reflect a good faith effort to obtain the best available data.

Option: UWAG's recommended approach

CP&L & FPC preferred site-specific approaches.

CP&L and FPC believe that the environmental impacts associated with CWIS are highly site-specific and that the determination of best technology available (BTA) for minimizing adverse environmental impacts (AEI) at existing facilities should be made on a site-specific basis. Accordingly, we have concluded that any of the site-specific alternatives described in 67 Fed. Reg. 17159-166 is more appropriate and scientifically defensible than the proposed option. More specifically, we support "The Utility Water Act Group (UWAG) Approach" described starting on 67 Fed. Reg. 17162. We believe that this site-specific approach optimizes all resources and considerations for determining BTA.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Option: Site-specific based 1977 Draft Guidance

It should be noted that the reason the EPA is undergoing this rulemaking is because of the absence of a rule to implement § 316(b) of the Clean Water Act. EPA issued final § 316(b) regulations in 1976, which referred the permit writer to a "Development Document" that described various intake technologies, and factors to be considered in choosing the BTA for a site-specific CWIS. The 1976 site-specific rule was remanded [Appalachian Power Co. v. Train, 566 F.2d 451 (4th Cir. 1977)] on procedural grounds and not technical grounds. Therefore the site-specific technical concept was left intact and has been continued via a draft guidance document for 25 years. Examples of successful site-specific 316(b) determinations include CP&L's Brunswick Nuclear Plant, which has successfully implemented BTA technologies, and FPC's Crystal River Plant, which has successfully employed mitigation measures.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Burden on permitting agencies (general)

Author Name Charles K. Wakild

Organization Progress Energy

CP&L and FPC recognize that EPA has rejected site-specific approaches, in part, due to the implementation burden that is presumed to be greater on State and Federal permitting agencies than the burden imposed by EPA's proposed option. CP&L and FPC believe that this concern is unfounded and that when all requirements are considered, site-specific approaches are not more burdensome than EPA's proposed option. The current site-specific decision-making process generally requires each regulated facility to develop and conduct studies that characterize or estimate potential AEI. If AEI is determined to be occurring, the guidance presents a basis for determining the BTA for minimizing the AEI. The state regulatory and resource agencies are partners in approving the studies and conclusions. EPA's proposed rules require similar efforts. EPA's proposed option requires a characterization of the subject waterbody (including impingement and entrainment information) and a design and construction technology plan. Again state regulatory and resource agencies are partners in approving the studies and conclusions. In both scenarios, studies are conducted on the specific waterbody and compliance plans are developed. There is a possibility that the site-specific approach could even be less burdensome. Most of the site-specific options described in 67 Fed. Reg. FR 17159-1766 would target certain species ("representative indicator species" or "critical aquatic organisms") and consequently would focus state resources rather than causing the state resources to diverge in an attempt to address all species in the waterbody. Additionally with the site-specific approach, it will be determined in some cases that certain facilities are not causing AEI and no further efforts will be needed.

Lastly, CP&L and FPC do not believe that all State and Federal permitting agencies view site-specific approaches as overly burdensome. As support for our opinion, we have attached letters froth the Honorable Michael F. Easley, Governor, North Carolina (February 22,2002) and the Honorable David B. Struhs, Secretary, Florida Department of Environmental Protection (February 27, 2002) wherein both states have indicated their preference for site-specific regulatory approaches for CWIS that emphasize flexibility for state decision-making.

EPA Response

EPA has included the site-specific determination of BTA in today's final rule in addition to four other compliance alternatives. Please see response to comment 316bEFR.019.014 for a discussion of site-specific considerations.

RFC: Use of previous demonstration studies

CP&L and FPC support the use of previous §316(b) demonstrations.

CP&L and FPC encourage EPA to adopt a process that would allow for the use of previous §316(b) demonstrations that have determined whether or not AEI is occurring and the BTA for minimizing AEI, if needed. We believe that states should be given the flexibility to reaffirm the findings of previously conducted demonstrations if specified conditions are met. The specified conditions could include acceptable data collection and analytical methods and documentation that there have been no significant changes to either the aquatic populations affected by the CWIS or to the design, construction or operation of the permitted facility. CP&L and FPC have successfully performed several site-specific 316(b) demonstrations wherein impacts were accurately assessed and mitigative measures were appropriately deployed. Studies for the Brunswick Plant and Crystal River Plant are excellent examples.

EPA Response

EPA has disallowed the use of historical determinations of BTA in today's final rule; however, existing data that is reflective of current conditions may be used to support the required studies. Please see response to comment 316bEFR.040.001 for details.

Author Name Charles K. Wakild

Organization Progress Energy

Subject Matter Code 7.02

Performance standards

The proposed performance standards (80-95% reduction of impingement mortality and/or 60-90% reduction in entrainment) should not be included as numerical limits in permits. Instead CP&L and FPC believe it would be more appropriate to use the performance standards as guidelines for selecting technologies, operational measures, and restoration measures to address impingement and entrainment issues. Once the facility submits, and the agency approves, the Design and Construction Technology Plan (technologies and/or operational measures) and any proposed restoration measures, the approving agency could include a condition in the permit requiring the proper design, installation, operation and maintenance of approved technologies, operation measures, and restoration measures, rather than compliance with a numeric performance standard.

EPA's proposed option for implementing §316(b) consists of establishing performance requirements expressed as percentage reductions in impingement and entrainment compared to a baseline value. A performance requirement expressed as a percentage reduction is not realistic for either a baseline calculation or a compliance determination. A percentage by function is a ratio of one value to another. Due to the variability of the biological dynamics for fish and shellfish populations, each value in this ratio is a variable subject to diel, seasonal, and yearly fluctuations. The number of species that are to be considered further complicates this process. EPA did endeavor to address this issue of variability by assigning a range of performance percentages (e.g. reduction in impingement mortality by 80—95%). However, even a range of performance that is relative to a ratio of two variables, each of which has a large degree of variability, is impractical. To impose such requirements will lead to the need for determinations of confidence intervals around the values (be they a value of central tendency or a percentile). This can only lead to statistical complexity when determining baseline calculations and compliance with the performance standards. It is envisioned that much energy and resources will be expended arguing statistics of a somewhat arbitrary performance standard rather than determining true impacts to the environment.

EPA Response

Please see responses to comments 316bEFR.307.064, 316bEFR.311.002, 316bEFR.009.040 and 316bEFR.063.005. EPA agrees with the statistical observations in this comment. For this and other reasons, EPA has authorized, with the approval of the Director, compliance to be demonstrated pursuant to the implementation of Technology Implementation and Operation Plan rather than in relation to the performance standards.

Author Name Charles K. Wakild

Organization Progress Energy

Subject Matter Code 12.03

RFC: Entrainment vs. entrainment mortality

The proposed performance standard for entrainment should be modified such that the standard is applicable to entrainment mortality and not all entrainment. Based on studies CP&L and FPC have conducted, we are convinced that entrained organisms can and do survive. Consistent with our reasons for preferring site-specific regulatory approaches, CP&L and FPC have observed that survival rates are species- and site-specific.

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards. Please see response to comment 316bEFR.002.015 regarding the inclusion of entrainment survival estimates in site-specific benefit analysis.

Performance standards

The proposed performance standard for impingement mortality should be modified such that the standard is applicable to representative indicator species (RIS), as discussed at 67 Fed. Reg. 17,162-64, and is not applicable to all species. We believe it is not practical or desirable to design and operate an intake technology that attempts to ensure protection of all impingeable species. The identification of RIS should be done in consultation with natural resource management agency personnel who understand how the potentially impacted ecosystem functions.

EPA Response

Please see response to comment 316bEFR.063.005.

Permit applications/implementation schedule

CP&L and FPC encourage EPA to allow sufficient time for permitted facilities to achieve compliance.

To accommodate existing facilities whose NPDES permit renewal application is due soon after the final rules are adopted, CP&L and FPC recommend that the effective date of the final rule be structured to allow sufficient time for permitted facilities to conduct adequate studies, develop compliance plans and construct any technology measures that may be needed. The proposed rule states that permitted facilities must comply with the rule "when an NPDES permit containing requirements. . .is issued..." The proposed rule further states that certain study information must be submitted with the NPDES permit application. EPA also presumes at 67 Fed. Reg. 17208 that the information collection activities may take as long as three years. Also, in the Economic and Benefits Analysis document on page B1-13 it is stated that facilities have to come into compliance with the proposed Phase II rule during the year their first post-promulgation NPDES permit is issued. Obviously there is a need for EPA to recognize the time (in some cases possibly years) needed by a permitted facility to complete their NPDES permit application and to come into compliance with the proposed rule. The activities involved in compiling an application include developing a study plan, obtaining approval of the plan, conducting the planned monitoring, evaluating the monitoring data, determining appropriate measures to comply with the applicable requirements, and obtaining approval of proposed compliance measures from State and Federal permitting agencies. This process could easily take three or more years. Next, the permitted facility will need time for construction of any technologies. CP&L and FPC encourage EPA to factor into the final rule, sufficient time for permitted facilities to achieve compliance.

EPA Response

See response to comment 316bEFR.045.007.

Comment ID 316bEFR.084.012

Subject Matter Code 18.02

RFC: Use of previous demonstration studies

Author Name Charles K. Wakild

Organization Progress Energy

CP&L and FPC do not support the reevaluation of previous §316(b) demonstrations at each permit renewal.

CP&L and FPC are opposed to the-proposed rule where it suggests a “comprehensive reevaluation” of the §316(b) demonstration every time a permit is renewed. We recommend that after a successful demonstration has been completed, the permit writer should accept the initial demonstration at each subsequent permit renewal, unless there have been significant changes in plant operations or adverse changes to the aquatic populations.

EPA Response

EPA agrees that a comprehensive demonstration study may not need to be conducted each time a permit is renewed. Please see response to 316bEFR 041.126 for a discussion.

Withdrawal threshold of 50 MGD

CP&L and FPC believe that the design flow of emergency service water intakes should not be included in determining the applicability of the rule.

CP&L and FPC suggest that EPA distinguish between primary cooling water intakes and emergency service water intakes. For example, at one of CP&L's facilities, a closed cycle recirculating cooling water system (natural draft wet cooling tower) is employed as the primary means of cooling. The facility also uses an emergency, once-through service water system, which normally operates a nominal amount of time to ensure that the system is in working order. However, this emergency intake has a design capacity greater than 50 MGD. CP&L and FPC believe that the design flow of an intake that is used nominally for reliability testing should not be included when determining whether a facility is subject to the § 316 rule.

EPA Response

Documented facility examples of CWIS impacts

CP&L is concerned that certain statements found in the preamble of the proposed rule misrepresent current impacts at its Brunswick Nuclear Plant

CP&L believes that EPA's discussion of impingement and entrainment impacts found at 67 Fed. Reg. 17137-38 contains misleading statements regarding its Brunswick Nuclear Plant. EPA asserts that "impacts attributable to impingement and entrainment at individual facilities may result in appreciable losses of early life stages of fish and shellfish (e.g., three to four billion individuals annually)." EPA also states that "a modeling effort evaluating the impact of entrainment mortality on a representative fish species in the Cape Fear estuarine system predicted a 15 to 35 percent reduction in the species population." In support of both statements, EPA cites Brunswick Station's "Historical Summary and Review of Section 316(b) Issues" prepared by EPA Region IV (1979). This information, which dates from the early stages of Brunswick operation, is out of date. CP&L took several steps many years ago to address the alleged impacts. Although it is doubtful that an adverse environmental impact would have occurred at the Brunswick facility even without mitigation, CP&L installed mitigation measures in the l980s. These include a diversion fence at the mouth of the intake canal (installed in 1982), fine mesh screens with a fish return system (1983 and 1987), and a seasonal flow-reduction schedule. Studies conducted since the installation of these mitigation measures indicate that they have significantly reduced impingement mortality and entrainment. Reductions in impingement mortality have ranged up to 97%, based on organism density, for all species. Reductions in entrainment of total organisms as a result of the combination of voluntary flow minimization and fine-mesh screens have ranged up to approximately 90 percent, depending on species and life stage. Additionally, it should be noted that recent studies show that there have been no significant changes over the past 25 years in the population densities in the Cape Fear estuary for several species allegedly impacted by the Brunswick Plant's cooling water system.

EPA Response

EPA used the data available to the agency when compiling examples of environmental impact associated with cooling water intakes for the preamble to the proposed rule. EPA thanks the commenter for the submission of this update on environmental impacts related to the Brunswick facility.

Sample site-specific rule (p.17159-61)

Encourage the use of existing data to minimize rule's cost impact.

Regulatory Reference: Preamble VI. Best Technology Available for Minimizing Adverse Environmental Impact at Phase II Existing Facilities

C. Site-Specific Based Options Under Consideration

1. Sample Site-Specific Rule (p. 17159-17160)

EPA also invites comment on site-specific approaches for determining the best technology available for minimizing adverse environmental impact at existing facilities.

125.94 (a) (2) A previously conducted section 316(b) demonstration may be used to determine whether the location, design, construction and capacity of the facility's cooling water intake structure reflect best technology available for minimizing adverse environmental impact if it reflects current biological conditions in the water body and the current location and design of the cooling water intake structure. A previously conducted section 316(b) demonstration generally would reflect current conditions or circumstances if:

(i) The previous section 316(b) demonstration used data collection and analytical methods consistent with guidance or requirements of the permitting agency and/or the Administrator;

(ii) The available evidence shows that there have been no significant changes in the populations of critical aquatic species; and

(iii) The owner or operator can show there have been no significant changes in the location, design, construction, and capacity of the facility's cooling water intake structure that would lead to a greater adverse environmental impact.

DOMINION COMMENTS: If a facility has data showing that there is: (1) minimal entrainment and impingement and no discernable harm to the aquatic community, or (2) the environmental impact of entrainment and impingement is of so little economic and environmental significance that the costs of a comprehensive § 316(b) study would be significantly greater than its likely benefits, then there should be no need for either further intake evaluation or installation of additional intake technology. A provision should be added to the rule to allow a facility to make a justification that one of the conditions has been met and thus a 316(b) study is not required.

EPA Response

EPA did not adopt the sample site-specific rule language in the proposed rule. While EPA rejected a purely site-specific approach, EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

The rule does not require a determination of whether an adverse environmental impact is occurring is a preliminary step in implementing 316(b). Please refer to the response to comment 316BEFR.313.001 for more information on EPA's position on minimum impacts at existing facilities.

Author Name Pamela F. Faggert
Organization Dominion Generation

Subject Matter Code 21.05
Role of States and Tribes (alt./equiv. programs)

Successful state § 316(b) programs should be continued.

Regulatory Reference: Preamble VI. Best Technology Available for Minimizing Adverse

Environmental Impact at Phase II Existing Facilities

C. Site-Specific Based Options Under Consideration

Section 125.96 Will Alternative State Requirements and Methodologies for Determining the Best Technology Available for Minimizing Adverse Environmental Impact Be Recognized? (p.17160)

Notwithstanding any other provisions of this subpart, if a State demonstrates to the Administrator that it has adopted alternative regulatory requirements that will result in environmental performance within a watershed that is comparable to the reductions of impingement mortality and entrainment that would otherwise be achieved under this subpart, the Administrator shall approve such alternative regulatory requirements.

DOMINION COMMENTS: In the proposed rule, EPA proposes to allow States to continue to use “alternative regulatory requirements” they have adopted, if they can show these requirements are “functionally equivalent” to the new federal rule - that is, if within each relevant watershed they would result in environmental performance that is comparable to the reductions in impingement mortality and entrainment that would be achieved under EPA’s proposed § 125.94(67 Fed. Reg. 17,180 col. 1-2).

EPA’s proposal appears to require that a State show that its program achieves the same percentage reductions in entrainment and impingement mortality as EPA’s performance standards (60-90% and 80-95% respectively). But a successful State program may have focused on larger-scale effects, such as impacts on fish populations or the aquatic community, and the State may know that its program has successfully protected local aquatic communities but not necessarily be able to demonstrate that, for example, entrainment has been reduced by 60-90 percent. EPA should allow States to retain proven successful programs without having to force-fit them into EPA’s new performance standards.

Many States have incorporated § 316(b) into their water permit programs by adopting the federal §316(b) language and then writing regulations or guidance that references EPA’s 1977 draft § 316(b) guidance. If a State has complied with its administrative laws and procedure in developing and implementing its § 316(b) program, the program should be eligible for consideration as “functionally equivalent” to proposed §125.94.

EPA Response

Comment ID 316bEFR.085.006

Subject Matter Code 7.01.03

Option 3--Site-specific determination

Author Name Pamela F. Faggert

Organization Dominion Generation

Site specific determination of Best Technology Available is preferred.

Regulatory Reference: Preamble VI. Best Technology Available for Minimizing Adverse Environmental Impact at Phase II Existing Facilities

A. What Is the Best Technology Available for Minimizing Adverse Environmental Impact at Phase II Existing Facilities?

4. Site-Specific Determination of Best Technology Available (p. 17145)

Under today's proposed rule, the owner or operator of an Phase II existing facility may demonstrate to the Director that a site-specific determination of best technology available is appropriate for the cooling water intake structures at that facility if the owner or operator can meet one of the two cost tests specified under § 125.94(c)(1).

DOMINION COMMENTS: Dominion strongly supports EPA's recognition that a site-specific alternative approach is needed to establish intake requirements at sites where the costs of intake technologies are excessive, or where meeting the performance standards with the technologies is not practicable.

The process of designing impingement and entrainment monitoring programs and selecting impact assessment methodologies is inherently site-specific. Site-specific factors are very important in determining the best approach to minimize adverse CWIS effects. Technologies that work at one location are frequently found not to work at another. The only way to accurately and appropriately select best technology available is on a site-specific basis. Site-specificity maximizes the ability to achieve the most environmentally effective and cost-effective reductions in adverse environmental impact.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Streamline the workload for evaluating site-specific applications.

Regulatory Reference: Preamble VI Best Technology Available for Minimizing Adverse Environmental Impact at Phase II Existing Facilities

A. What Is the Best Technology Available for Minimizing Adverse Environmental Impact at Phase II Existing Facilities?

13. Cost Benefit Test (p. 17153)

EPA is also concerned about the potential for members of the public who object to the authority's site-specific determinations to raise challenges that must be resolved in administrative appeals that can be very lengthy and burdensome, followed in some cases by judicial challenges. An ongoing State study of permitting workloads estimates that appeals of NPDES permits issued to major facilities require 40 hours to resolve in a simple case and up to 240 hours for a very complex permit. EPA Region 1 estimates that one year is required to resolve a complex administrative appeal, involving significant amounts of technical and legal resources. Should the permit appeal be followed by a judicial challenge, EPA Region 1 estimates an additional two years or more of significant investment of technical and legal resources in one decision, with additional time and resources needed if the initial judicial decision is appealed. Again, however, EPA notes that these burdens may be small compared to the potential costs of complying with presumptive performance standards. EPA invites comments on ways to incorporate site-specific consideration of costs and benefits without undue burden on the Director. In particular, EPA invites comment on decision factors and criteria for weighing and balancing these factors that could be included in regulation or guidance that would streamline the workload for evaluating site-specific applications and minimize the potential for legal challenges.

B. Other Technology-Based Options Under Consideration

3. The Utility Water Act Group (UWAG) Approach (p. 17162)

The Utility Water Act Group (UWAG), an association of more than 100 individual electric utility companies and three national trade associations of electric utilities, provided EPA with a recommended site-specific regulatory framework, entitled "316(b) Decision Principles for Existing Facilities." UWAG's recommended approach for decision-making under section 316(b) includes the following components:

A definition of "Adverse Environmental Impact";

-Use of Representative Indicator Species (RIS) for the assessment of adverse environmental impact;

-Making decisions under section 316(b) that complement, but do not duplicate, other Federal, state, and local regulatory programs;

-Use of de minimis criteria to exempt small cooling water users that pose no appreciable risk of causing adverse environmental impact because only a small amount of cooling water is withdrawn from a water body at a location that does not require special protection;

-Determination of adverse environmental impact or its absence using the facility's choice of three methods, either alone or in combination: (1) Use of previously conducted section 316(b) demonstrations that are still valid in light of current circumstances; (2) use of ecological risk assessment by means of demonstration of no appreciable risk of adverse environmental impact using conservative decision criteria; or (3) assessment of risk using a structured decision making process consistent with EPA's Ecological Risk Assessment Guidelines;

-A "maximize net benefits" approach for selecting the best technology available for minimizing adverse environmental impact;

-At the option of the permittee, recognition of voluntary enhancements such as fish stocking or habitat improvements; and

-Providing data or information with NPDES permit renewal applications if new information shows that previously conducted section 316(b) demonstrations are no longer scientifically valid.

DOMINION COMMENTS: Dominion supports UWAG's 316(b) Decision Principles, because it will provide technical, legal and policy tools that will ultimately streamline the workload for evaluating site-specific applications.

EPA is concerned that site-specific decisions on environmental impact will require burdensome, time and effort by permitting agencies and therefore proposes to simplify the § 316(b) decision process by setting a numerical criterion. However EPA's criterion merely prescribes a reduction in the number of individual animals lost and thus fails to address the complexities of aquatic communities.

Without question, State and federal regulators face resource constraints. EPA's proposal makes the goal (60-90% reduction, for example) more numerically precise, to be sure. But proving that the goal is met will require permit writers to consider the effects of the same site-specific factors that have always been considered. Most of the burden of implementing a site-specific approach, conducted in accordance with a clear and consistent decision-making process like that described in UWAG's 316(b) Decision Principles, would fall on regulated facilities, not regulators. Dominion is prepared to perform studies reasonably necessary to allow scientifically and environmentally sound § 316(b) decisions. A streamlined process will provide the technical, legal, and policy tools for decision-making that were lacking in the past and as a result minimize the burden on EPA and states.

UWAG definition of "adverse environmental impact"

EPA should adequately define adverse environmental impact.

Regulatory Reference: Preamble VI Best Technology Available for Minimizing Adverse Environmental Impact at Phase II Existing Facilities

C. Site-Specific Based Options Under Consideration

5. Discussion of Site-Specific Approach Issues and Associated Questions for Comment a. Determination of Adverse Environmental Impact

(3) Discussion of UWAG Recommendation for Determining Adverse Environmental Impact (p. 17163)

UWAG offers the following definition: Adverse environmental impact is a reduction in one or more representative indicator species (RIS) 61 that (1) creates an unacceptable risk to a population's ability to sustain itself, to support reasonably anticipated commercial or recreational harvests, or to perform its normal ecological function and (2) is attributable to operation of the cooling water intake structure.

DOMINION COMMENTS: Section 316(b) cannot be implemented effectively unless there is a definition of "adverse environmental impact." "Adverse environmental impact" cannot mean harm to a single fish or a single egg; it must mean harm at the population or community level. Dominion supports UWAGts recommended definition of "adverse environmental impact": Adverse environmental impact is a reduction in one or more representative indicator species that (1) creates an unacceptable risk to the population's ability to sustain itself, to support reasonably anticipated commercial or recreational harvests, or to perform its normal ecological function and (2) this negative impact is attributable to the operation of the cooling water intake structure.

At many electric generating facilities, there is already a high degree of confidence that the facility is not creating "adverse environmental impact" or has already installed BTA. Examples would include (1) where a facility already has performed a § 316(b) demonstration before the new § 316(b) rule I promulgated and has shown to the satisfaction of its regulatory agency that the facility complies with § 316(b), or (2) where operating experience and knowledge of the local fishery provide regulatory authorities with confidence that fish populations are not being harmed by impingement and/or entrainment.

The statute calls for minimizing "environmental impact," not eliminating entrainment and impingement mortality, so technologies should be evaluated accordingly. Fisheries should be viewed as a resource that can be managed and sustained. EPA should recognize that some losses of individual fish are not harmful to the fishery resource as a whole and that there is no reason to view losses caused by cooling water intake structures as fundamentally different from losses caused by any other human activity or natural occurrence. Great losses occur as a result of commercial fishing industry, and a rebound of striped bass populations has been witnessed upon initiation of a fishing moratorium.

EPA's § 316(b) rule should use the lessons of fisheries management science. If the impact of a facility's CWIS is in the range of impacts known by fisheries managers to be within normal variation or not of concern to the viability of the fishery, the facility is not creating "adverse environmental impact."

RFC: Definition of "adverse environmental impact"

EPA should define the term "minimal" as it pertains to entrainment and impingement losses and adverse environmental impact.

Regulatory Reference: Preamble V. Environmental Impacts Associated With Cooling Water Intake Structures

A. Facility Examples (p. 17137)

In some cases, the number of organisms impinged and entrained by a facility can be substantial and in other examples impingement and entrainment may be minimal due to historical impacts from anthropogenic activities such as stream or river channelization.

A. Facility Examples (p. 17138)

At this facility, fish impingement and entrainment by cooling water intakes were found to be minimal.

VI. Best Technology Available for Minimizing Adverse Environmental Impact at Phase II Existing Facilities

C. Site-Specific Based Options Under Consideration

13. Cost Benefit Test (p. 17153)

EPA notes that at some sites, impingement and entrainment losses are minimal.

DOMINION COMMENTS: Dominion proposes that the rule include a definition for the term "minimal" since the term is often used in discussions of environmental impacts, entrainment and impingement losses (mortality) and adverse environmental impact (this is consistent with the previous comment - EPA should adequately define adverse environmental impact).

-Minimal = SMALL = Environmental effects are not detectable or are so minor that they will neither destabilize nor noticeably alter any important attribute of the resource, i.e. population structure.
