EPRI has reviewed EPA's concerns with past survival rate data, and UWAG understands that EPRI's comments will address this issue. But whether or not EPA's concerns about past studies are well-founded, they should not disqualify other studies, especially those that may be done in the future, from being used to select intake technologies. In the Phase II Case Study Analysis, § A7-4, A7-4.1, EPA has tried to identify the characteristics of a sound entrainment survival study. Without necessarily agreeing in every respect with EPA's view of what constitutes an adequate study, UWAG believes that, at the least, a survivability study that meets EPA's standards should be usable for selecting BTA and measuring compliance with the performance standards.

In short, the entrainment performance standard should allow survival to be taken into account where usable data on survival exist. Facilities might choose to conduct survival studies, which would allow the baseline to start at a lower numerical value. Alternatively, the percentage reduction could be reduced on a site-specific basis from the 60-90% that otherwise applies to entrainment.

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards. Please see response to comment 316bEFR.002.015 regarding the inclusion of entrainment survival estimates in site-specific benefit analysis. Please see the response to comment 316bEFR.306.506 for the discussion regarding EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule.

Performance standards

For Compliance Purposes, the Performance Standard for Impingement Mortality Should Be Applied Either to “Representative Indicator Species” (RIS) or to Total Fish of All Species

1. One Alternative Is to Use RIS

In determining for compliance purposes whether a technology will reduce impingement mortality by 80-95%, the analysis in many cases should not be applied to all impingeable species in the waterbody. Consistent with long practice, it should be acceptable to apply the 80-95% reduction standard only to certain species that are impingeable and representative of species in the waterbody that need to be protected. UWAG has called these “Representative Indicator Species” (RIS).

At many sites it may not be feasible to design an intake technology that will ensure protection of every impingeable species to the same extent, because there are too many potential species, and their occurrence and distribution are too variable. Also, survival rates change over time. A technology that has a certain survival rate for one species in one season may have a different effect on another species in a different season.

Moreover, fisheries experts agree that not all species are of equal biological value. The loss of large numbers of some species will not harm the aquatic community. Impingement of forage species, for example, may be far less biologically significant than impingement of commercial or recreational species. And exotic species, especially nuisance species, may not be valuable to a waterbody at all.

2. As Another Alternative, Compliance Can Be Measured by Total Number (or Mass) of Fish Lost by Impingement

The rule should allow as an alternative, however, that the permittee may choose to measure compliance with the performance standard for impingement mortality by simply measuring (counting or weighing) the combined impingement losses of all species together. This should be allowed if the permit applicant can satisfy the permitting agency that it is justified at a particular site. Even where it is justified, however, threatened or endangered species would have to be considered separately.

EPA Response

See the preamble to today's rule for a discussion of monitoring requirements as well as methods of demonstrating compliance.

Subject Matter Code 7.02

Performance standards

The Performance Standards Should Not Apply to Nuisance Species

For both impingement and entrainment, exotic species that are regarded as a "nuisance" should not be subject to the percent reduction standards. Indeed, many State agencies have rules against placing nuisance species back in a waterbody once they are removed. Some exotic species, like zebra mussels, are highly invasive and offer no commercial or recreational benefit. Entrainment or impingement of these species should not be considered an "adverse impact" at all. Some species, such as the common carp or Asiatic clam, are viewed as nuisance species by natural resource managers for some State waters but not all. At least where they are considered a nuisance, the entrainment and impingement performance standards should not apply.

Zebra mussels and Corbicula (Asiatic clam) can be entrained in great numbers. At least one utility has problems entraining and impinging an exotic snail (the Chinese or Japanese Mystery Snail), which was introduced to the United States as a food source in California and more recently for use in aquariums. These snails are taken by water intakes in significant numbers and can even clog condenser cooling water tubes. Given State fishery resource managers' often extensive efforts to get rid of these species and EPA's own express concerns about their effects, cropping by CWISs should not be considered "AEI" <FN 32> or in setting the "baseline" (though they might be considered in assessing net benefits when benefit-cost analysis is used).

One way to handle nuisance species in a § 316(b) analysis would be by a benefit-cost analysis that assigns an appropriate valuation, on a site-specific basis, to losses of such species. If a nuisance species is unwanted because it harms other, more desirable fish, its value should be considered small or even negative. If on the other hand an exotic species has some value, even a small one, then a technology that protects it should have that value added to its "benefits" for purposes of § 316(b) benefit-cost analysis.

Also, EPA should write the § 316(b) performance standards to accommodate fish that are moribund or dead before they arrive at the cooling water intake. For example, weather-related phenomena like winter fish kills or kills associated with sudden temperature drops and other site- and waterbody-specific episodic biological and physical phenomena can kill or injure fish, which may then be carried to the intake. If a facility has reliable data on the rate of arrival of such dead or moribund fish, the measurement of the reduction of impingement mortality should be adjusted accordingly.

Footnotes

32 EPA has warned about the problem of exotic species. See "Invasive Non-Native Species," <http://www.epa.gov/OWOW/watershed/wacademy/acad2000/invasive.html>; U.S. Biennial Report on Exotic Species in the Great Lakes, <http://www.epa.gov/grtlakes/glwqa/ usreport/part5.html>.

For Entrainment, the 60-90% Reduction Standard Can Be Applied to Either Total Biomass or Total Numbers of Organisms (Either Identified by Species or Not) Entrained

The 60-90% reduction standard for entrainment, where it applies, can be applied either in terms of total biomass or in total numbers of organisms entrained. For the existing plant as presently configured, the entrained biomass could be measured by collecting entrained organisms from the outfall or other appropriate monitoring location where a representative sample can be taken. This mass would be compared to the mass of eggs and larvae that would have been entrained at a shoreline intake with no entrainment reduction controls (or other baseline) to determine if there is a 60 percent reduction or better.

For the "baseline" plant configuration and the future plant with new intake technology installed, sampling could be done near the intake (the hypothetical shoreline intake for the baseline plant and the existing or relocated intake for the future complying plant). The density of entrainable organisms then might be used to calculate the mass of organisms that would be entrained, both by the shoreline intake without any protective technology and by whatever new proposed intake technologies are being assessed. As always, the element of time must be taken into account, for entrainable organisms will be present at some times and not at others, and this differs from species to species.

On the other hand, in freshwater rivers and streams in the past, entrainment traditionally has been measured by counting the number of organisms entrained. This produces either a total number of undifferentiated eggs and larvae entrained, or, to the extent possible, an identification of the entrained eggs and larvae by species or family. UWAG supports use of either total biomass or total numbers of organisms (whether identified to the species level or not) as a basis for calculating entrainment losses. If eggs and larvae can be identified, the analysis should focus on RIS.

It is important, however, not to require a permittee to prove that he has reduced entrainment of every entrained species by 60%. EPA has no data to support species-by-species permit reduction or monitoring. In some cases, the difficulty and cost of taxonomic classifications makes species-specific monitoring unreasonable, and classification is not even possible for early life stages of some species. Therefore, measurement of entrainment through total biomass or total of all species combined must remain an option.

EPA Response

For a discussion of the calculation baseline, please see response to comment 316bEFR.063.022. For a discussion of determining compliance with the final rule, please see response to comment 316bEFR.063.005 and the preamble to the final rule.

Averaging Times Should Be Long Enough to Accommodate Natural Fluctuations

EPA also needs to clarify the averaging period for the percent reduction. A short-term averaging period cannot be justified because of the significant natural temporal and spatial variability in fish abundance and distribution. In months when there are no entrainable organisms near the intake, entrainment may be near zero, and percent reduction will probably also be low (or at least meaningless, given the low "baseline"). Thus, an average of entrainment reduction over a single month would be unrepresentative. Moreover, the density of aquatic populations can vary naturally over the longer term, from year to year. Accordingly, the percent reductions should be applied as an average within certain confidence intervals over several years.

Elsewhere in these comments, UWAG has proposed that once a new intake technology is installed, the permittee may have to monitor for two years (or less) at some sites and perhaps up to five years at estuarine sites to verify that the technology is achieving reductions within the ranges specified by EPA's performance standards. It would be sensible to measure the percent reductions over the entire monitoring period, which could be less than <FN 33> two years or up to five years in length.

This does not mean, if the permittee discovers at the end of the five-year period that his average did not meet the performance standard, that he suddenly and unexpectedly is subject to penalties for five years' worth of violations. This would be unfair in light of the variability of fish communities and the permittee's limited control over what animals approach his intake. The rule should state that a permittee that has done everything it agreed to do but nevertheless does not meet the standard is not deemed to be in noncompliance for two years' or five years' worth of daily violations.

Footnotes

33 EPA should clarify that less than two years of verification monitoring may be acceptable in some cases. Proposed § 125.95(b)(7) (67 Fed. Reg. 17,224 col. 2) requires a permit applicant to include in the Comprehensive Demonstration Study a plan to conduct, at a minimum, two years of monitoring. But that is a requirement only for planning and for review by the permitting authority, not for actual monitoring.

Proposed § 125.96, which addresses what monitoring must actually be performed, says that actual monitoring must be as specified by the Director to demonstrate compliance with § 125.94 (67 Fed. Reg. 17,224 col. 3). How much monitoring is enough to demonstrate compliance is site-specific, and UWAG does not believe it is EPA's intent to require two full years of monitoring whether it is needed or not. UWAG asks EPA to clarify that the monitoring necessary may be less than two years' worth in some cases.

EPA Response

Please see response to comment 316bEFR.063.005 for a discussion on the methods of determining compliance with today's final rule.

EPA Should Clarify What Is "Entrainable"

EPA needs to clarify the difference between impingeable and entrainable organisms, which depends on screen mesh size. A larger mesh means, other things being equal, that there are more "entrainable" organisms and fewer impingeable ones. Reducing the mesh size means that some organisms that would have been entrained now may be impinged. Thus, a fine mesh screen might be installed to reduce entrainment, with the result that formerly entrainable fish or larvae are now impinged against the screen. As screen mesh size becomes smaller, survival rates of impinged smaller organisms may drop.

EPA should resolve this issue by defining an "entrainable" organism as one that will fit through a standard 3/8-inch intake screen. This will lend certainty and consistency to the rule.

Monitoring requirements

EPA Should Clarify that Annual Monitoring Is Not Required for Facilities with Cooling Towers

Although having cooling towers (reducing intake capacity to a level commensurate with a closed-cycle, recirculating cooling system, in the words of proposed § 125.94(b)(1)) is one way to satisfy the proposed rule, EPA points out that cooling towers were not used as a basis for the numerical performance standards. 67 Fed. Reg. 17,142 col. 2. Since EPA has determined that cooling towers are not "BTA," UWAG concludes that a permittee cannot be required to install them. The main value of § 125.94(b)(1), in UWAG's view, is that a facility that has already installed cooling towers will unquestionably be in compliance with the rule. As a practical matter, in most or all instances, retrofitting a cooling tower to an existing facility built without one would fail the benefit-cost test, because the high cost of building a tower at an existing facility would be so much larger than the benefit it would offer in terms of reducing entrainment and impingement.

The proposed monitoring requirements reflect how conservative cooling towers are compared to the numerical performance standards. Section 125.95(b) says that all facilities except those that satisfy § 125.94(b)(1) (that is, those that have flow commensurate with closed-cycle cooling) must submit a comprehensive demonstration study, including information on the "calculation baseline." Since facilities with cooling towers do not have to calculate a "baseline," clearly the proposed rule does not contemplate that a cooling tower will have to be monitored to determine how much reduction in impingement mortality and entrainment it is accomplishing. Section 125.94 provides that the facility must monitor only as specified by the Director to demonstrate compliance with § 125.94.

It is curious, and possibly misleading, then, that EPA's Technical Development Document appears to assume that facilities with cooling towers will spend $75,000 a year for annual monitoring. See Technical Development Document for the Proposed Section 316(b) Phase II Existing Facilities Rule, App. A (EPA 821-R-02-003 April 9, 2002). EPA should state clearly that this is not required. At most, a facility with a cooling tower would have only to show that its intake capacity was commensurate with a closed-cycle, recirculating system; no annual monitoring would be required for that purpose.

EPA Response

In today's final rule, EPA has determined that facilities that choose compliance alternative 1, flow commensurate with closed cycle cooling, will not need to submit any components of a Comprehensive Demonstration Study and will not be required to monitor further to verify compliance with the performance standards (see § 125.94(a)(1)(i)).

OPERATIONAL MEASURES MUST BE VOLUNTARY

Although EPA lists seven specific technologies on which it bases its cost and benefit estimates, EPA also says in the preamble that its conclusion is based on use of "one or more of these technologies with operational controls in some cases." Whatever this means, it should not mean that EPA can require operational controls (meaning, typically, cutting back on cooling water flow, and thus on electricity production).

EPA Response

EPA has not determined any specific technology to be BTA and does not require any facility to use any particular technology, or suite of technologies, to comply with today's rule. Rather, it leaves the determination of the appropriate controls to be implemented up to the facility itself subject to the approval of the permitting authority.

Subject Matter Code 7.02

Performance standards

Some Facilities Cannot Adjust Flow

From a purely mechanical standpoint, many existing power plants are severely limited in their ability to “adjust” (control) cooling water flow. Most circulating water pumps that supply once-through cooling water are not variable speed pumps; they operate either full on or full off.

In addition, some facilities have legal restrictions on their ability to adjust flow. Several Florida facilities are required, as part of their Florida Industrial Wastewater (SPDES) Permits, to develop “manatee protection plans.” A required component of these plans is to ensure an adequate supply of warm water if the ambient water temperature drops below 61oF in order to ensure manatee survival. This means that utilities sometimes have to operate a facility even when it is not economically beneficial. While this “running out-of-economics” scenario is infrequent (because when water temperature drops below 61oF usually the facilities are operating anyway because the air is cold), it would be a problem if reducing flow were required by a permit condition. In such a case, a permit requirement to restrict flow for § 316(b) purposes would conflict with the requirement to provide heated discharge water to protect manatees.

EPA Response

In today's final rule, EPA has not designated any particular design and construction technology or operational measure as Best Technology Available (BTA), with the exception of facilities eligible for compliance alternative 4. This includes flow reduction technologies such as variable speed pumps, which would allow a facility to moderate its intake flow based on generating needs. EPA believes that the numerous physical and biological variables that exist at each facility, coupled with economic concerns, justify a site-specific determination of the most appropriate design and construction technology, operational measures, and/or restoration measures. Reducing intake flow remains an option, however, for those facilities that wish to implement it.

Comment ID 316bEFR.041.079

Subject Matter Code 2.04

EPA's legal authority to:

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Congress Did Not Authorize EPA to Regulate Levels of Operation

Congress did not authorize EPA to regulate, by § 316(b) or other provision of the Clean Water Act, the level of operation of power generating facilities. This is evident from the language of § 316(b): operational controls are not, by any stretch of the language, aspects of the "location," "design," "construction," or "capacity" of the intake structure, and so they cannot be required under authority of § 316(b).

Leaving aside § 316(b), nowhere else in the Clean Water Act did Congress so much as suggest that EPA should regulate how dischargers operate or how much product they are allowed to produce. Thus, EPA is not authorized to regulate pollutant levels in a facility's internal waste stream, <FN 34> and all the more can it not direct a facility to cut production. <FN 35>

Footnotes

34 American Iron and Steel Inst. v. Environmental Protection Agency, 115 F.3d 979, 996 (D.C. Cir. 1997).

35 Operating restrictions are costly. Whenever a facility is prohibited from operating for any reason, it is incapable of generating revenue. In a "regulated" market, such as Florida, a utility is required by the Public Service Commission to supply enough electricity to meet all the customers' needs as well as to maintain an agreed-upon reserve. If units are not available to operate and the demand for power exceeds the utility's ability to supply it, the power must be purchased from other suppliers (assuming there is power available to be purchased). Under these circumstances, the cost of the power purchased is often greater than the price would have been if the utility had generated it, and the revenues go to the seller of the electricity.

In an unregulated market where purchased-power agreements are in place, the same principles apply. Utility A commits to have a certain number of megawatts of electricity for sale to Utility B at all times. If for any reason Utility A cannot meet its commitment (e.g., if a unit has mandatory operating restrictions because of § 316(b) compliance issues), it must pay Utility B for "replacement power" to meet the contract demand. Again, this replacement power is often more expensive than the cost of the Utility A's generating it.

In a true "merchant" scenario, the economic facts are simple, because there are no replacement power issues: the generator earns money only when it makes electricity.

EPA Response

See preamble to the final rule, particularly sections III, VII, and VIII. The final rule does not directly regulate the level of operation of Phase II existing facilities. The rule allows, but does not require, the use of operational measures as one of several means of meeting applicable performance standards. See Riverkeeper v. EPA, slip op. at 33 (2nd Cir. Feb. 3, 2004) ("We also think the statute allows the EPA to regulate the operation of cooling water intake structures, as the word "design" can reasonably be read to embrace the methods used in running a structure as well as its layout and technical specifications.")

Organization obo Utility Water Act Group

Subject Matter Code 3.03

Definition: Waters of the U.S.

THE RULE'S TREATMENT OF COOLING PONDS AND LAKES NEEDS TO BE CLARIFIED

A. Ponds Created Specifically for Cooling Are Treatment Systems Are Excluded from the Definition of "Waters of the U.S."

EPA's regulation, 40 C.F.R. § 122.2, exempts "waste treatment systems" from the definition of "waters of the United States." The definition reads as follows:
Waters of the United States means:

(a) All waters which are currently used, were used in the past, or may be susceptible to use in interstate or foreign commerce, including all waters which are subject to the ebb and flow of the tide; . . . Waste treatment systems, including treatment ponds or lagoons designed to meet the requirements of CWA (other than cooling ponds as defined in 40 CFR 423.11(m) which also meet the criteria of this definition) are not waters of the United States.

Thus, thermal treatment systems, including ponds and lagoons designed to meet CWA requirements (which cooling ponds clearly are), are specifically exempted from the NPDES permit requirement. <FN 36> Because a cooling pond is a part of a plant's treatment system, the make-up water intake point should be considered the jurisdictional intake for the purposes of § 316(b).

Disturbingly, EPA's proposed definition of "once-through cooling water system" says that such systems sometimes use "ponds." Proposed § 125.93, 68 Fed. Reg. 17,221 col. 1. This definition may give the wrong impression, since cooling "ponds" are clearly "treatment systems" instead of "waters of the United States."

In the preamble to the proposed rule, EPA says that it "interprets 40 C.F.R. § 122.2 to give permit writers discretion to regulate cooling ponds as 'waters of the United States' where cooling ponds meet the definition of 'waters of the United States.' To the best of UWAG's knowledge, EPA has never issued any such interpretation on a national basis, and the only EPA memorandum on point of which UWAG is aware says that reference to cooling ponds in § 122.2 may be interpreted as having no legal force or effect, thereby taking cooling ponds wholly outside the definition. Letter from Robert Perciasepe, Assistant Administrator of EPA's Office of Water, to W. Ray Cunningham, Director, Water Management Division (EPA Region IV) (December 13, 1993). In any case, for purposes of implementing § 316(b), UWAG believes strongly that EPA should find that cooling ponds (and, as discussed below, other man-made impoundments created solely or primarily for supplying cooling water) are closed-cycle cooling systems and not "waters of the United States" subject to § 316(b).

Footnotes

36 Such systems, if created in waters of the United States, were at one time brought back within the application of the other criteria in the definition by the restrictive provision at the end of the treatment system exemption; however, that restriction was suspended in 1980 and no longer has any legal effect. Cooling ponds "as defined in 40 C.F.R. 423.11(m)" also fall outside the treatment system exemption. But the rule containing the definition of "cooling ponds" cited in that parenthetical, which served as the basis for that restriction, was set aside by the Court of Appeals in Appalachian Power Co. v. Train, 566

F.2d 451 (4th Cir. 1977). Thus, as a matter of law, the cooling pond exclusion from the treatment system exemption no longer has any force or effect.

Comment ID 316bEFR.041.081

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 8.02

Proposed standards for lakes and reservoirs

EPA Should Consider Cooling Lakes and Reservoirs to Be Closed-Cycle Cooling Systems

Cooling "ponds," then, are expressly excluded from waters of the U.S. Cooling "lakes," formed by damming rivers or streams that are waters of the U.S., should be treated the same for § 316(b) purposes. EPA has long asserted broad authority to define waters of the U.S. and to include and exclude waters from the definition of "waters of the U.S." where necessary to achieve the purposes of the Clean Water Act, although this authority has been narrowed by the SWANCC case, Solid Waste Agency of Northern Cook Co. v. U.S. Army Corps of Engineers, 531 U.S. 159 (2001).

As a matter of policy, EPA should treat both cooling ponds and cooling lakes, built in whole or in part to supply cooling water, as closed-cycle cooling systems that achieve the requirements of § 316(b). <FN 37> Cooling lakes do not need additional intake technology, both because minimizing "adverse environmental impact" was considered when the impoundment was constructed and because experience shows that adverse environmental impacts generally do not occur in cooling lakes, which usually have thriving populations. <FN 38> It makes no sense to expose existing facilities to the possibility that they will have to construct additional fish protection technologies on impoundments that, in the first place, were designed and constructed primarily to provide cooling water.

Footnotes

37 The same can be said of some reservoirs, which typically are manmade, highly engineered systems that in some cases were constructed primarily to supply cooling water and heat treatment. For example, many reservoirs in Texas and other parts of the Southwest were built primarily or solely for this purpose. See Appendix 11 to these comments. Thus, UWAG believes that States should have the authority to deal with reservoirs just as they do cooling lakes or ponds and treat them as part of a closed-cycle system where the reservoir is constructed primarily for cooling water supply and thermal treatment.

38 See generally Parkhurst and McLain 1978.

EPA Response

Comment ID 316bEFR.041.082

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 8.02

Proposed standards for lakes and reservoirs

EPA does not appear to have made any attempt to identify either (1) the number of facilities with cooling lakes or thermal treatment reservoirs that would be required to retrofit additional technologies, or (2) the costs and benefits of such additional controls. In fact, a review of the information EPA provides on in-scope facilities suggests that EPA assumed that all or most of these facilities would not be required to retrofit any additional technologies or do any additional studies.

EPA Response

EPA agrees in part and disagrees in part. As noted in the definition for a closed-cycle recirculating cooling system at § 125.93, a facility with a cooling pond may be considered as employing closed-cycle recirculating cooling. EPA agrees that any facility that is designated as using closed-cycle recirculating cooling would be exempt from further requirements, as stated in § 125.94(a)(1)(i).

However, as stated in Section II.C of the preamble and in the response to comment 316bEFR.006.001, EPA does not intend to change the regulatory status of cooling ponds and acknowledges that a determination of whether a cooling pond is to be considered a "water of the United States" and whether a cooling pond can be considered as a closed-cycle recirculating cooling system will be made on a case by case basis by the Director.

Given the site-specific nature of this decision and the inherent difficulty in predicting the outcome of such a decision, EPA did not attempt to identify the number of facilities with cooling ponds that would have additional requirements under the final rule. Similarly, EPA did not attempt to identify the costs and benefits of any additional requirements.

Special definitions

The "Annual Average Retention Time" in the Definition of "Lake or Reservoir" Is Not the Most Appropriate Metric and Might Be Misinterpreted

EPA's proposed definition of "lake or reservoir" requires an annual average hydraulic retention time of more than seven days. See 67 Fed. Reg. 17,130 col. 3. In order to more accurately reflect the biological principle and purpose sought by this criterion, the metric should be based on the average hydraulic retention time during the period when entrainable life stages of important species are present.

Also, EPA is not clear about how the retention time is to be calculated, and the definition does not discuss how inflows from make-up water sources, return flows from recirculating cooling water systems, evaporation, and infiltration should be accounted for in calculating the retention time. Therefore, particularly in the arid Southwest where overland outflows are very small and evaporation/infiltration rates are high, hydraulic retention times might be inappropriately described as shorter than the seven days required to be defined as a lake or reservoir. EPA should clarify that wet circulating cooling system flows are not to be included in the calculation, only the natural hydraulic residence time.

It is possible that the proposed rule might be misinterpreted to require inflows and outflows generated by a recirculating cooling water system to be considered in calculating hydraulic retention time. If so, many hydraulically isolated waterbodies designed and constructed as closed-cycle cooling water ponds and reservoirs would incorrectly be defined as "rivers" under the proposed rule. EPA should clarify that only inflows from and outflows to a "water of the United States" should be used in the calculation of hydraulic retention time.

EPA Response

Please refer to EPA's response to comment 316bEFR.015.006.

EPA's Proposed Prohibition Against Altering the Natural Thermal Stratification of Lakes and Reservoirs Is Legally and Technically Flawed

If a facility proposes to increase its design intake flow on a lake or reservoir, EPA's proposed rule would not allow the increased flow to disrupt the natural thermal stratification or turnover pattern, except where the disruption is determined to be "beneficial to the management of fisheries." See proposed § 125.94(b)(4)(ii), 67 Fed. Reg. 17,221 col. 3. This provision is unwise, but, if it is to be included in the rule at all, a better formulation would be "must not disrupt . . . if such disruption is determined to be an adverse environmental impact to fish or other aquatic life." Apart from that, the "disruption" standard has several problems.

1. EPA Has Not Evaluated Technologies for Avoiding Destratification

Nowhere does EPA provide any indication of what CWIS technology might meet the "disruption" standard. EPA may feel that intake location, and not a specific technology, is adequate to meet it. If so, EPA may in effect be requiring the relocation of CWISs in some lakes and reservoirs without even considering possible technological solutions.

2. Altered Stratification Ordinarily Is Not a Problem

In any case, there is good reason to conclude that altered thermal stratification is not a problem. The issue of altered thermal stratification in lakes and reservoirs due to power plants has been addressed by the Nuclear Regulatory Commission (NRC) as part of the development of its Generic Environmental Impact Statement for License Renewal of Nuclear Stations (GEIS 1996). Section 4.2.1.2.3 of the GEIS, which is concerned with thermal effects, indicates that thermal stratification occurs in two ways: by the discharge of heated water (not a consideration under § 316(b), which applies only to intake structures) or by the altered circulation patterns caused by pumping cooling water in and out of the power plant. Surface discharge of heated water can intensify stratification, whereas enhanced circulation (as may be caused by facilities with once-through cooling systems) may break down stratification.

a. Destratification May Be a Benefit

In many cases, destratification of a lake or reservoir is desirable. The Tennessee Valley Authority has installed fans on the surface of one of its reservoirs to destratify it, thereby allowing the otherwise anoxic hypolimnetic waters to receive oxygen. In other cases, as appropriate, TVA releases greater-than-planned or greater-than-normal flow through reservoirs to create mixing and prevent or disrupt stratification, which can lead to hypoxia. The only cases where disrupting stratification would cause an adverse environmental impact would be where the disruption led to a release of toxicants in toxic amounts or of excessive nutrients in a form available to algae, or where a cool or cold lower-waters fishery was adversely impacted.

The NRC GEIS cites a study in Illinois where an unheated flood control reservoir (Lake Shelbyville) was compared with a cooling lake (Lake Sangchris). GEIS 1996, p. 4-54 (citing EPRI, "Evaluation of a Cooling Lake Fishery," Introduction, Water Quality and Summary, Vol. 7 (1980)). In contrast with the unheated lake, Lake Sangchris did not stratify in the summer. As a result, largemouth bass had a longer growing season and greater annual growth in Lake Sangchris, the cooling lake.

b. Altered Thermal Stratification Has Never Been a Problem at Most Plants

The GEIS also notes that the common practice of using cool hypolimnetic water from deep intakes for power station cooling, with surface discharge, may increase the size of the warm epilimnion and decrease the amount of habitat available to coolwater fish. The NRC GEIS uses the example of thermal discharges from the Oconee Nuclear Station, which increased the annual heat load of Keowee Reservoir by one-third and lowered the thermocline from between 5 and 15 meters to as low as 27 meters. As another example, the McGuire Nuclear Station withdraws cool hypolimnetic water from Lake Norman and discharges the heated water at the surface. As at Oconee, this has the effect of increasing the size of the upper layer of warm water and decreasing the habitat available for coolwater fishes (e.g., striped bass) in the hypolimnion of Lake Norman.

Temperature modeling of Lake Norman indicated that increasing the maximum upper discharge temperature from 95 to 99ºF during July, August, and September would conserve coolwater fish habitat in the Lake by allowing smaller withdrawal rates of hypolimnetic waters. This would lower the average heat content of the lake by allowing more heat to dissipate to the atmosphere from the warmer localized area. After consultation with the North Carolina Department of Health and Natural Resources, the NPDES permit was modified to allow the higher temperatures. Modeling reservoir heat budgets allows effects of thermal discharges on stratification to be predicted and used by utilities and regulatory agencies to develop the best heat dissipation scheme.

The GEIS also says that altered thermal stratification has never been a problem at most plants. At a few plants (e.g., McGuire and Oconee), the issue has been periodically re-examined and mitigated as needed by adjusting thermal discharges through the NPDES permit renewal process. Based on a review of the published literature and operational monitoring reports, the GEIS concludes that operation of the cooling system has not altered thermal stratification at most power plants with once-through cooling systems. At the small number of plants where changes in thermal stratification have occurred, monitoring and modeling studies have been used to adjust the thermal discharges, thereby mitigating adverse impacts. As appropriate, these models can take into account other thermal inputs to the receiving waterbody and therefore consider cumulative as well as individual plant effects. Consultation with the utilities and regulatory agencies during preparation of the draft GEIS, as well as their comments on the draft GEIS, revealed no concerns about the individual or cumulative impacts of cooling systems on thermal stratification. GEIS 1996, p. 4-8.

c. The Nuclear Regulatory Commission Concludes That the Effects of Cooling Systems on Thermal Stratification Are Not Significant

The NRC concluded that the effects of cooling system operation on thermal stratification are a Category 1 issue with a "small" level of significance. In order for the NRC to list an issue as Category 1, the analysis in the GEIS had to find that (1) the environmental impacts associated with the issue have been determined to apply either to all plants or, for some issues, to plants having a specific type of cooling system or other specified plant or site characteristics; (2) a single significance level (i.e., small, moderate, or large) has been assigned to the impacts; and (3) mitigation of adverse impacts associated with the issue has been considered in the analysis, and it has been determined that additional plant-specific mitigation measures are likely not to be sufficiently beneficial to warrant implementation. GEIS 1980, p. 4-8. The issue is classified as a small level of significance if the environmental effects are not detectable or are so minor that they will neither destabilize nor noticeably alter any important attribute of the resource.

The NRC findings in the GEIS, then, demonstrate that thermal de-stratification due to cooling water intake is a non-issue.

3. EPA Has Not Defined "Disrupt"

Also, EPA nowhere defines what "disrupt" means. In a lake or reservoir, stratification results from natural physical processes that result in a layer of warmer surface water separated from a cooler (and therefore more dense) layer by a thin boundary called the thermocline. In nature, many factors influence the formation and dissolution of the stratified waterbody (e.g., seasonal temperature changes and wind). When a power plant is situated on the waterbody, additional factors are introduced that affect the relative heat balance of the system. The degree to which a cooling water withdrawal and corresponding thermal effluent discharge contribute to "disrupting" the stratification is largely a function of the volume of water withdrawn, the zone from which it is withdrawn, the delta T across the condenser, and the location and depth of the discharge.

EPA Response

EPA disagrees that the standard is flawed. EPA believes the natural thermal stratification of a lake, if present, influences the physical and chemical cycles of lakes, which, in turn, strongly govern their production, utilization, and decomposition. A facility with a disproportionally large water intake can adversely impact both primary and secondary production. EPA believes the intake capacity standard for lakes and reservoirs is economically practicable and technologically achievable for existing facilities, and will result in an acceptable level of source water protection.

A facility located on a lake or reservoir that wishes to increase its design intake flow is required to establish a maximum intake capacity that will not disrupt the natural thermal stratification or turnover pattern of the source waterbody where such stratification or turnover pattern is determined to be beneficial. EPA believes an "across-the-board" limit is unworkable for lakes and reservoirs since the concept of flow is inapplicable to a lake. In addition, EPA believes preserving some degree of the natural thermal stratification, if present, is desirable because of the increased cooling efficiency that can result. The thermal stratification standard, while different from the flow-based standards for estuaries and freshwater rivers, does limit a facility to an intake capacity that will achieve an acceptable level of protection for the source water.

EPA acknowledges that it has not identified any technologies to avoid the disruption of the thermal stratification of lakes. As stated earlier in this response, EPA believes that the disruption of thermal stratification is best prevented by limiting changes in intake capacity and not by installing intake technologies.

EPA has chosen not to further define the term "disruption." EPA expects facilities located on a lake or reservoir to work in conjunction with the Director to correctly determine what constitutes an unacceptable disruption of any natural thermal stratification or turnover pattern.

EPA's legal authority to:

EPA Lacks Authority under § 316(b) to Regulate Stratification

Any power plant intake and discharge located on a lake or reservoir will change or affect the stratification in some way. The real issue is the degree of the alteration, which will vary based on site-specific differences in the factors mentioned above. As discussed elsewhere in these comments, minimizing unacceptable alterations requires a careful balancing of factors relating to the waterbody, the intake structure, and the discharge. Section 316(b) gives EPA authority over only the CWIS, not over discharges or other factors. Thus, a limit on stratification, which not only may be impossible to meet but also implicates an aspect of the facility regulated under other sections of the CWA, is inappropriate and, for the reasons discussed above, wholly unnecessary.

Providing an exception in cases where the permittee can show the change in stratification is beneficial (see 67 Fed. Reg. 17,221 col. 3) does not solve the problems inherent in the proposed rule. Between "harmful" and "beneficial" lies a range of neutral effects. EPA has no real evidence that changes in stratification are likely to be harmful, and yet the proposed rule would require studies to prove the negative. This is the opposite of administrative efficiency and cannot be justified.

EPA Response

Disrupting the natural thermal stratification or turnover pattern of a lake (other than the Great Lakes) or reservoir indicates a cooling water structure intake's substantial effect on a waterbody. Under the rule, EPA has determined that a commensurate level of entrainment, an adverse impact, must be reduced. For a discussion of EPA authority to implement section 316(b), see the preamble to the final rule, particularly sections III, VII, and VIII.

Proposed standards for Great Lakes

GREAT LAKES FISH ARE NOT UNIQUELY SENSITIVE TO ENTRAINMENT, AS EPA'S PROPOSAL IMPLIES

EPA proposes to require Phase II facilities situated on the Great Lakes to meet the same entrainment reductions it has proposed for facilities on estuaries and oceans (which it claims are sensitive to entrainment by virtue of the greater density of entrainable organisms that EPA alleges occurs throughout estuarine and ocean waters <FN 39>). Even if UWAG agreed with EPA's views on the sensitivity of estuaries and oceans (which we do not), EPA has not, and cannot, offer any similar justification for requiring entrainment controls on Great Lakes facilities.

EPA has not offered any evidence that entrainable organisms are particularly at risk in the Great Lakes, and the evidence suggests just the opposite, as we will show in the discussion below. Instead, EPA claims that entrainment controls are necessary because the Great Lakes represent a "unique system that should be protected to a greater extent than other lakes and reservoirs." 67 Fed. Reg. 17,141.

EPA says that it provided additional details in the Phase I proposal and NODA that support special treatment for the Great Lakes. 67 Fed. Reg. 17,141 col. 2, citing 65 Fed. Reg. 49,060 and 66 Fed. Reg. 28,853. As UWAG's comments on both of those Phase I documents showed, EPA's support amounts to little more than conclusory statements without any factual backing. UWAG, by contrast, submitted ample facts during the Phase I rulemaking to show that the Great Lakes are not particularly sensitive to entrainment and do not warrant special protection. Because EPA ultimately decided to apply across-the-board technology requirements for new facilities, it deleted its special protection for the Great Lakes and never otherwise defended it. Thus, EPA's previous proposal provides no real support for its current one.

UWAG recognizes that the Great Lakes represent a unique and important resource. However, with regard to impingement and entrainment, EPA confuses uniqueness with sensitivity. The Great Lakes are unique, and they do have a unique fish assemblage, but that does not mean the fish are uniquely sensitive. To the contrary, the aquatic communities in the Great Lakes are probably less sensitive than in many other lakes and reservoirs. Generally speaking, the naturally occurring freshwater species in the Great Lakes are the same species found in smaller lakes in the north central United States. Moreover, the five Great Lakes themselves are not all alike, and lumping them together into a single "sensitive" category is a gross oversimplification.

A. Salmonids in the Great Lakes Normally Are Not Vulnerable to Entrainment

From a fisheries perspective, what sets the Great Lakes apart from most smaller lakes and reservoirs is the presence and active management of large numbers of both native and introduced salmonids (i.e., Pacific salmon, trout, and coregonids, primarily bloater and white fish) (Becker 1983, Tanner 2000). At first glance it might appear that this unusual resource would need more protective regulations. But because of the life history of these species, the opposite is true.

As coldwater species, most of these species are fall/winter spawners that spawn in relatively deep, often offshore areas (particularly reefs and shoals) (Becker 1983, Tanner 2000). Thus, the larvae of most salmonids are not at particular risk of entrainment. Also, many of the trout and salmon populations in the Great Lakes are primarily the result of stocking. Thus, there are few or no trout or salmon eggs or larvae to be entrained. Also, the size of the populations is actively managed by resource agencies.

This assessment is supported by data EPA provided in the § 316(b) Phase I rule. Only one salmonid (lake trout) appears in EPA's entrainment table (Phase I EA Table 11-6), it was at a single plant (out of 25 plants on Lake Michigan alone (Kelso and Milburn 1979)), and it was entrained in low numbers. Therefore, given the life history characteristics of the group of fishes of most concern in the Great Lakes (i.e., salmonids), no special level of concern is warranted. EPA has no basis for imposing entrainment control requirements on facilities in the Great Lakes when no such requirements are warranted for other lakes or reservoirs.

B. Because of their Spawning Behavior, Non-Salmonids in the Great Lakes Are Not Ordinarily at Risk

Among non-salmonids, most of the highly valued recreational Great Lakes fishes also are relatively insensitive, again because of their life histories. Besides salmonids, four species provide most of the Great Lakes sport catch: yellow perch, smallmouth bass, northern pike, and walleye.
Yellow perch is of particular concern in Lake Michigan now because their population is very low. Yellow perch lay their eggs in long gelatinous strips, which greatly reduces the likelihood that their eggs will be entrained. Some yellow perch populations spawn well offshore, further reducing the likelihood of entrainment losses.

Smallmouth bass are nearshore nest builders. After the eggs hatch, the male guards the fry for several days. Because of this nest guarding, non-drifting behavior, smallmouth bass larvae are not frequently entrained, even where adult populations may be abundant (EA 1987).

Northern pike are restricted primarily to shallow embayments along the Great Lakes (which is not where the power plants are). They spawn in very shallow areas over dense aquatic vegetation. No intakes are located in any such areas. Walleye are uncommon in the open areas of the Great Lakes, except Lake Erie; thus, entrainment of walleye is low compared to non-recreationally important species. Walleye, as well as yellow perch, are actively managed by resource agencies through quotas on recreational and commercial harvests.

In summary, the fishes that make the Great Lakes unique (the salmonids) or constitute the non-salmonid recreational fishery (yellow perch, smallmouth bass, northern pike, and walleye) are not, by reason of their life history characteristics and agency management, particularly at risk. Therefore increased levels of entrainment control are not warranted for Great Lakes intakes. Instead, the Great Lakes should be subject to the same requirements as other lakes and multi-purpose reservoirs.

Footnotes

39 As UWAG showed in its comments on the Phase I rule, EPA's assumption that estuaries and oceans are inherently more sensitive to entrainment than are other waterbody types is not warranted. UWAG 2000 Phase I Comments, pp. 129-34, 148-52.

EPA Response

RFC: Test: benefits should justify the costs

Author Name Hunton & Williams

Organization obo Utility Water Act Group

THE ONLY DEFENSIBLE STANDARD FOR "BEST" TECHNOLOGY IS THAT WHICH HAS THE MAXIMUM NET BENEFIT

EPA's performance standards, which would require an 80-95% reduction in impingement mortality and a 60-90% reduction in entrainment, raise many questions. Several technical questions about how to apply the standards are addressed in Section VIII above. In addition, the standards raise important issues about the role of cost in selecting BTA. In the preamble to EPA's proposal, the Agency says permittees should choose the most cost-effective technology for achieving a level of reduction within the 80-95% or 60-90% performance range. 67 Fed. Reg. 17,142 col. 1. UWAG agrees that this is appropriate. EPA also says that cost plays a role in deciding when the standards should not apply at all and a site-specific analysis be done instead.

EPA's proposed test for departing from the performance standards and using a site-specific analysis instead is that the cost of meeting the standards be "significantly greater than" either the benefits or the costs that EPA itself considered in making the rule. See proposed § 125.94(c)(1)-(2), 67 Fed. Reg. 17,221 col. 3. What EPA should use instead is the only cost test that has a rational basis in economic theory: the "best" technology is that which maximizes net benefits.

EPA Response

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020. See also preamble to the final rule.

RFC: Test: benefits should justify the costs

The Way to Choose the "Best" Technology Is to Abandon Performance Standards and Instead Select the Technology that Maximizes Net Benefit

NERA's analysis of the Phase I rule (Appendix 12 to these comments) shows that the correct way to choose the best technology is to select the one that maximizes net benefits. Comments by other experts support this fundamental principle. See, e.g., comments prepared for PG&E National Energy Group by Professor Robert Stavins of Harvard University.

The maximum net benefit criterion is the only criterion that is consistent with the basic economic principle of efficiency. In its most basic form, benefit-cost analysis seeks to find the technological alternative or other social investment that provides the most benefit for the smallest possible cost, thereby maximizing the net benefit (benefit – cost) of the improvement. <FN 40> Thus benefit-cost analysis is a framework for determining which alternative will enhance economic efficiency the most. Efficiency addresses two broad considerations:

-In a world of limited natural, human, and financial resources, it is desirable to achieve any given goal at the least possible cost.

-When faced with multiple goals, we should allocate our scarce resources among these goals so as to achieve the greatest total benefit for any given expenditure of scarce resources.

Maximum net benefit is the preferred economic criterion for evaluating the efficiency of decisions. It is the only criterion that identifies the alternative that will yield the highest potential gain in efficiency, that is, the alternative that will yield the largest gain in benefits to society.

Maximum net benefit is preferred to maximizing the benefit-cost ratio because it reflects the scale of alternative projects. For example, a project could have a high benefit-cost ratio but not produce the maximum net benefits simply because it is a low-cost alternative that produces relatively large benefits. Another project could involve higher costs, but produce larger total benefits and subsequently have a higher net benefit.

The maximum net benefit criterion has several important strengths and is especially well-suited to address the regulatory matters related to the § 316(b) regulations. In particular, the criterion, when it is implemented as part of a benefit-cost analysis, organizes important information about the large number of potential CWIS investments in a logical form that allows for trade-offs and relates directly to a rule for identifying BTA. It also systematically incorporates considerations of uncertainty about both costs and benefits. Comparisons about uncertain benefits and costs are based on expected outcomes.

Clearly, because of a lack of information or the limits of available methodologies, it may not be possible to accurately monetize all possible benefit or cost categories. In such cases, the benefit-cost analysis will qualitatively describe the benefits and costs in question. In cases where monetized benefits fall short of costs, decisionmakers may decide whether or not the likely value of identified, nonmonetized net benefits is large enough to justify the investment. <FN 41> Thus, benefit cost analysis is sufficiently flexible to address both monetized and non-monetized benefits.

Benefit-cost analysis critics assert that such emphasis on human-use values neglects the value of ecological services. However, accurately measured human-use values incorporate values for ecological services. These ecological services provide benefits to humans even if they are not consumed directly by humans. For example, food-chain services provided by benthic organisms are analogous to factor inputs in production processes. These organisms derive their values from the value of the outputs they produce, which are quantified using nonmarket valuation techniques. Such benefits can be quantified and included in the analysis, even if they cannot be reliably monetized.

The criticism sometimes heard that benefit-cost analysis is overused or that subjective, nonmonetary factors are neglected in public policy decisions are unfounded. Both OMB and EPA have issued guidance that requires careful accounting of uncertain and unquantified values and outlines established methods for doing so.

However, evaluating nonmonetized net benefits should not be confused with a “wholly disproportionate” cost test, which would mandate CWIS investments the measured costs of which exceeded measured benefits by a substantial margin. Such a test is arbitrary and tends to overcompensate for uncertainty. The net effect would be to waste scarce public and private resources. The “wholly disproportionate” approach seems motivated by the unjustified assumption that measured benefits are consistently and significantly understated relative to costs. For cooling water intake structures, both costs and benefits include components that are difficult to measure and thus involve some degree of uncertainty. Benefit-cost analysis of CWIS alternatives should incorporate OMB and EPA guidance on accounting for uncertainty and risk in both expected cost and expected benefit calculations.

Finally, some might argue that benefit-cost analysis is expensive and unnecessarily complicated. Economists have developed the benefits transfer approach as a cost-effective way to implement the benefit-cost analysis framework. This approach uses the available data and models developed in the professional literature as a way to control the costs of the analysis. Nevertheless, the transfer is performed using sound economic principles and is based on the maximum net benefit criterion.

Additionally, the transfer can be tailored to meet the needs of a particular situation. In simple cases, the transfer is likely to be straightforward. More complicated cases may involve a mixture of targeted data collection and analysis, but this is still less expensive than a full-scale original study. Even those studies may be warranted in cases where the potential investment costs are sizeable and there is substantial uncertainty. Appendix A of the TER report appended to these comments summarizes how the benefits transfer approach can be implemented cost-effectively.

But EPA may insist on retaining its performance standards. For that reason, the rest of this section discusses how EPA might use cost to signal when a site-specific analysis should be used instead of the performance standards.

Footnotes

40 An early definition states that benefit-cost analysis is a “technique that measures impacts in dollars or other quantified values and that also provides systematic recognition of unquantifiable values and significant qualitative impacts” Liroff

1982. More recently, Arrow et al. 1996 provide eight principles on the appropriate use of benefit-cost analysis.

41 Where substantial risks are involved, decision makers may be able to quantify the monetary value of the risks and include it as a cost associated with that alternative. This approach is the way financial markets absorb information about investments with varying risks.

EPA Response

Please refer to the response to comment 316bEFR.005.020 for a discussion of the application of the cost-benefit test to assessing the value of alternative approaches.

RFC: Test: benefits should justify the costs

If No Technology Will Meet the Performance Standards at a Reasonable Cost, Then a Different Analysis Is Needed

Suppose, then, that EPA retains the performance standards but that for a certain site there is no technology that can achieve them at a reasonable cost. Because the costs will vary from site to site, UWAG agrees with EPA that there should be an alternative approach where deploying the technologies is not practical or the costs are excessive (though UWAG cannot agree with EPA's "significantly greater" cost test, because it is not based on sound economic principles).

EPA Response

In response to comments regarding situation where there may be no technology that can achieve the performance standards at a reasonable cost, please see the preamble for discussion on site-specific determination of best technology available for minimizing adverse environmental impact. The final rule allows for a comparison between the facility's projected costs of compliance to the costs considered by the Agency. If the facility's costs are significantly greater than the costs considered by the Agency then the Director may make a site-specific determination of the best technology available for minimizing adverse environmental impact.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

For EPA's response to comments on application of the "significantly greater than" test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.006.003.

Performance standards

EPA's Designation of a Limited Set of BTA Technologies and the Percentage Reduction Standards Based on Those Technologies Are Defensible Only Because of the Flexibility Provided by the Cost-Cost and Benefit-Cost Tests

EPA's performance standards (80-95% reduction in impingement mortality and 60-90% reduction in entrainment) are based on very general site-specific estimates of what a limited set of technologies (wedgewire screens etc.) can achieve in a few individual cases. But many site-specific factors influence whether a technology can be deployed as a practical matter and what level of performance it can achieve. <FN 42>

Footnotes

42 This is true even for cooling system technologies such as wet recirculating cooling towers, which EPRI studies have shown will not produce predictable reductions in entrainment and impingement corresponding with flow. As an ongoing Oak Ridge National Laboratory study for EPRI demonstrates, there does not seem to be a consistent dose-response pattern between volume of water withdrawn and effects on fish populations. EPRI 2002a.

EPA Response

EPA notes that today's rule, with the exception of compliance alternative 4, does not designate any specific determination to be considered Best Technology Available (BTA).

Please see response to comments 316bEFR.307.064, 316bEFR.311.002 and 316bEFR.063.005.

Intake structure technology costs (e.g., screens, etc)

EPA's Cost Estimates Are Not Clearly Explained or Supported

The variability of cost and performance of technologies at different sites is shown in a report by Edward P. Taft and Thomas C. Cook of Alden Research Laboratory, Inc., who also authored EPRI's 1999 Fish Protection Report. The report (Appendix 13 to these comments) reviews EPA's estimates of the costs of intake technologies.

As that review shows, EPA's cost estimates are very general, focusing on a few selected technologies (for impingement, retrofitting fish buckets and return systems to reduce mortality or reducing through-screen velocity to 0.5 feet per second; for entrainment, retrofitting fine mesh screens and fish buckets/return systems, reducing through-screen velocity to 1.0 feet per second, or "fanning" (i.e., expanding) the intake to accommodate the resulting increase in screen area).

EPA's cost estimates, while not necessarily incorrect, are in some cases not clearly explained or supported. For example:

-EPA does not clearly specify whether the design velocity it considered in costing fine mesh screening/fanning (1.0 ft/sec) was the through-screen velocity or the screen approach velocity, nor does it appear to have provided the data from which UWAG could assess whether the 1.5 ft/sec median velocity EPA assumed for existing facilities reflects through-screen or approach velocity. EPA also does not say whether the 1.0 ft/sec design value is a maximum or an average value.

-It is not clear whether EPA included costs for constructing fish handling compliance technology.

-In Box 2-1 of the TDD, costs for underwater installation of t-24 passive intake screens are presented. While these costs may be accurate, it is not clear how they were applied to estimate underwater traveling water screen installation costs.

-EPA does not explain why construction factors for fine mesh screens with fish handling systems are lower than for fine mesh screens alone.

EPA Response

EPA clarified and expanded the set of compliance costs based on intake technologies for the NODA. See comment 316b.EFR.041.651. The Agency provided many more technologies for costing in the NODA, clarified the basis for the cost derivations, and addressed the subject of site-specific factors through the application of the varied technologies.

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 9.05

Intake structure technology costs (e.g., screens, etc)

Site-Specific Factors Will Affect Costs

Many site-specific factors will affect the costs of intake technologies in practice, including the following:

-The possible need to rearrange or relocate pumps and associated piping or to build a new screen array and construct cut-off walls to channel flow so as to achieve the design velocity;

-The possibility that sheet piling may not be possible in some cases, necessitating construction of cofferdams instead;

-The possibility that retrofitting a backwash system requires raising the head shaft/ sprocket in some cases;

-Possible costs to excavate in order to install piping to convey water from screens to an onshore screenwell;

-Possible factors that could increase O&M costs, which EPA calculated as a percentage of capital costs, using a factor taken from the new facility rule.

EPA itself recognizes the importance of site-specific factors and the variability they create. See Phase II TDD at 3-1. But EPA concedes that it did not undertake a systematic data collection effort with consistent data collection procedures, which might have allowed it to develop a performance standard that would account for the site-specific factors. (Similarly, EPA has not collected data to document the reductions in impingement mortality and entrainment achievable by one of the other alternatives it considered, wet recirculating cooling towers.) Nor does EPA claim that requirements that vary slightly based on waterbody type will account for these factors. Instead, EPA has conducted a general analysis that relies mostly on the 1999 EPRI Fish Protection Report, as well as other fairly limited (and largely qualitative) information developed by EPA's contractors.

EPA's proposed performance standards cannot be met at every facility, <FN 43> or cannot be met at a reasonable cost at every facility, because fish populations are not under the exclusive control of plant operators and are subject to wide and unpredictable natural variations in behavior and abundance. The percent reduction in impingement mortality and entrainment that a particular technology will achieve in practice depends on natural environmental conditions, ranging from drought (low river flows) to floods (abnormally high river flows), which routinely occur during prime spawning periods (such as those for game fish like smallmouth and largemouth bass and walleye). The impact and significance of these factors can be determined only by a site-specific analysis.

Site-specific factors influence both (1) where the technology can be located and (2) whether it can be operated so as to maximize biological benefits or even meet the performance standards. As such, these factors determine how effective a technology will be in protecting organisms. Consider, for example, the use of wedgewire screens to achieve optimum hydraulic conditions for fish protection at an existing shoreline CWIS on a river. Such screens need to be placed in an area where ambient currents will carry organisms and debris away from the screens. At one site this might be accomplished easily, at another, a suitable location may not be available due to navigation or other site-specific constraints. See Appendix 14, which is a report by Edward P. Taft of Alden Research Laboratory, Inc., describing the performance of intake technologies in light of EPA's proposed performance standards.

EPA should consider when establishing performance standards that the database of experience with wedgewire screens, fine mesh screens, and aquatic fabric filter systems is biased toward success. The reason is that the database is a research database and not a "compliance" database. That is, the intake technologies were generally tested under near-perfect (and short-term) conditions (including painstaking O&M), thereby optimizing performance. Had long-term testing been conducted, subjecting the technologies to all the challenges of nature, performance would likely have been lower. Because of this bias, it is inappropriate to conclude that the high performances recorded in the past can be standardized for the industry.

This is not to say that fine mesh screens, wedgewire screens, and aquatic filter barriers will not work. It means only that they will not meet the performance standards for all existing facilities and may be very expensive at some sites. <FN 44> EPA recognizes this, to some extent, by setting ranges rather than single-number criteria.

Footnotes

43 Other than fine mesh screens, the proposed technologies have not been proven, or even tested, in Gulf Coast estuaries. Very high aquatic productivity, heavy sediment loading in the water column, intense biofouling communities, and shallow waters can limit the application of fabric filter systems and wedgewire screens in Gulf estuaries. Fine mesh screens (typically 5-10 mm openings) are successful only where limited biological productivity, limited biofouling, and minimal sediment loading permit.

Very high aquatic productivity levels in Gulf Coast estuaries result from long growing seasons, an abundant food supply, freshwater inflows, and prolific intertidal marsh and reef habitats. This intense productivity, although seasonally and diurnally variable, is seen virtually year-round with a myriad of phytoplankton and zooplankton assemblages, abundant nekton species, and invertebrate and mollusk species. These estuaries, where recruitment levels of eggs, larvae, and juveniles are extremely high, are not conducive to the application of fine mesh filtration associated with a cooling water intake structure.

Equally significant are the abundant biofouling communities of American oyster, barnacle species, assorted mussel species, and colonial hydroids present in these habitats, which quickly colonize mechanical equipment that is submerged even for a brief period of time.

In addition, the heavy loading of organic materials, very common in the water columns of these flood-prone estuaries, adds significantly to the problem of restricting water flow through fixed or revolving mechanical devices. Add in the numerous species of comb jellies, other assorted jellyfish species, and the periodic influx of sargassum weed, and two things become clear: (1) aquatic fabric barriers and wedgewire screens may not be functional technologies in Gulf Coast estuaries, and (2) site-specific alternatives are essential for compliance.

44 The desirability even of cooling towers is site-specific, since cooling towers differ greatly in both their cost and their environmental impact from site to site.

EPA Response

EPA recognizes the site-specific factors that are important for consideration of costs. See the Technical Development Document for a further discussion of how the Agency utilized a variety of site-specific construction and operation and maintenance costs in estimating the compliance costs of the rule.

For discussion of the performance standards in the final rule, see the preamble to the final rule.

For a discussion of how the Agency accounts for the implications in cost uncertainty in performance of a range of technologies in varied conditions, see Section X of the preamble to the final rule and the Technical Development Document.

Performance standards

Because of the Site-Specific Nature of Costs, Feasibility, and Performance, an Alternative to the Performance Standards Is Necessary

More important, EPA recognizes the variability of technology performance at different sites by providing an alternative approach where costs are excessive. It is extremely important to have such an alternative. UWAG itself has said that intake technologies like wedgewire screens, fine mesh screens, and aquatic filter barriers can achieve 90% or better reduction in entrainment and impingement. <FN 45> But UWAG's statement was qualified by the caveat that this level of protection cannot be accomplished at all sites, and that there is not yet a large body of experience using some of these technologies.

Thus, under the proposed rule, if none of the intake technologies EPA used for its performance standards (or other intake technologies or, at the permittee's option restoration projects) would in fact meet those standards, or such measures would achieve the standards only at a cost that is "significantly greater" than the benefits, the permit writer would be entitled to seek site-specific alternative requirements. To make this showing, the permittee would do a site-specific analysis demonstrating the costs and benefits of the alternative technologies, and identifying those that are feasible and the costs of which would not be significantly greater than benefits. The permit writer would set alternative requirements based on this demonstration.

Indeed, UWAG believes that, without an alternative for excessive cost situations, the proposed rule would be insufficient as a matter of law. The evidence in the record to support the use of wedgewire screens, fine mesh screens, and aquatic fabric filter barriers and the type of technology assessment that EPA has performed would not be good enough to establish a pure technology-based effluent limitation guideline under § 301 of the Clean Water Act or a new source performance standard under § 306, which EPA has required be applied uniformly by industry category and subcategory.

Nevertheless, the analysis that underlies EPA's performance standards is not necessarily inadequate as a matter of law, because § 316(b) is not a pure technology-based requirement <FN 46> like §§ 301 and 306, because the interaction between a cooling water intake structure and a waterbody is different from the "discharge of a pollutant" regulated by §§ 301 and 306, and because EPA has provided an alternative for excessive cost situations. Without such an alternative, EPA's analysis would not be adequate under the Clean Water Act or the Administrative Procedure Act. (A requirement for closed-cycle cooling at most or all facilities also would not be justifiable, for the same reason.)

EPA has, in fact, allowed for a site-specific analysis where the costs of meeting the performance standards are too high – in EPA's words, where the costs are "significantly greater" than either the costs EPA considered or the benefits of the technology. But UWAG does not agree that the "significantly greater" test makes sense in terms of economic theory.

Footnotes

45 For example, on page 37 of UWAG's 2000 Phase I Comments, UWAG pointed out that, for the Brunswick Station,

seasonal flow minimization and fine-mesh traveling screens had reduced entrainment by almost 90% for some species and life stages. The fish diversion structure had reduced the density of larger organisms impinged at the plant by 43% and weight by 67%. On page 39, UWAG said that the screens at the Surry Station resulted in a survival rate of over 90%.

46 A technology-based approach looks first at the available treatment technology and how effective it is across an entire industry category, considers its cost, and picks a technology that is "best" for the entire industry category. A water quality-based approach, by contrast, looks first at the desired goal in the water (a water quality standard or, in the case of § 316(b), the goal of minimizing environmental impact) and requires the permittee to find a technology to accomplish the goal. In this sense, § 316(b) is neither purely technology-based nor purely water quality-based. Like water quality-based requirements, § 316(b) begins with a standard of quality in the receiving waters, namely that adverse impact be minimized. This is why UWAG has always insisted that EPA must first define what "adverse environmental impact" is, just as EPA must set instream water quality criteria before water quality-based permit limits can be set plant-by-plant.

EPA Response

For a discussion of the site-specific compliance alternative, please see the preamble to today's final rule.

Available I&E technologies

Technologies that Are Not Feasible at a Particular Site Should Not Have to Be Analyzed in Detail

One case where a cost test should not be necessary, however, is where a technology simply will not work at a site. EPA should clarify that an intake technology that is not feasible at a particular site need not be analyzed in detail. A brief explanation of why the technology will not work at the site should be sufficient.

By not "feasible" we mean that technology, for engineering reasons, simply will not work at a particular site or that there is not enough room at the site to construct it. <FN 47> "Infeasible" would apply, for example, where a particular type of screen would interfere with navigability. Such technologies are not in any meaningful sense "available" for a site and therefore cannot be "best technology available."

For example, in 2002, PG&E NEG was informed by Gunderboom, Inc., that its fabric filter barrier technology could not be installed in either Salem Harbor, where the Salem Harbor Station is situated, or in Mount Hope Bay, where the Brayton Point Station plant is situated, because of interference with navigation and other reasons. Plainly, no purpose would be served by requiring PG&E NEG to do more than simply report this fact to the agency.

The same result might be reached by recognizing that a technology that will not work at a particular site will also fail any benefit-cost test. Certainly it will not maximize net benefits. It will also fail EPA's cost-cost and benefit-cost tests; one might say that the "cost" of meeting the performance standards with a technology that does not work is very large or that the "benefit" is very small, even zero.

But the cost-cost and benefit-cost analyses should not be necessary to eliminate an infeasible technology. When a facility's engineers can show that a technology simply will not work at a site, the facility should not have to do a cost analysis. It should be enough to state concisely to the permitting authority the reason why the technology will not work.

Footnotes

47 The California Environmental Quality Act defines "feasible" as "capable of being accomplished in a successful manner within a reasonable period of time, taking into account economic, environmental, social, and technical factors." Cal. Env. Qual. Act § 21061.1.

EPA Response

Today's rule maintains the flexibility for a facility to determine the most appropriate design and construction technologies, operational measures, and/or restoration measures suitable to its location that can best achieve requirements of today's rule. EPA does not require the evaluation of any particular technology for use at a particular facility. Rather, the Agency relies on the best professional judgment of the facility personnel to determine which technologies might be successfully deployed to meet the requirements of today's rule and therefore warrant further investigation.

RFC: "Significantly greater" for eval. alt. req.

Author Name Hunton & Williams

Organization obo Utility Water Act Group

A Site-Specific Benefit-Cost Test Is Essential

Leaving aside clear-cut cases where a technology will not work, EPA's decision to include a benefit-cost test exception is the key to making the rule viable. However, EPA's test that costs must be "significantly greater" than benefits cannot be supported.

There is no question that costs must be considered when determining BTA. <FN 48> This suggests that principles of economics should be consulted in making the rule. To the economist, the "best" intake structure technology for a given site is the one that maximizes net benefit. The "maximize net benefit" formula is supported by the work of UWAG's consultant NERA, as documented in UWAG's comments on the new facilities rule, and by economics literature generally. See Appendix 12 to these comments; Arrow 1996.

One could write the § 316(b) rule, then, to provide for a site-specific alternative whenever the technology that would maximize net benefits was not one that would meet the performance standards. But this would, in effect, nullify the performance standards and replace them with the "maximize net benefits" test. <FN 49> While that would be a good idea, we are assuming here that the performance standards remain in the final rule and have some teeth as a technical restraint on the economic analysis.

EPA could use the test of costs that exceed benefits by any amount for exempting a facility from the performance standards: no additional technology would be required unless the benefits of using it (mostly in terms of saving fish) would exceed the costs (mostly in terms of dollars spent, but also of adverse environmental impacts of the technology). A technology would not be required if its costs were greater than its benefits by even a small amount, because installing such a technology would decrease the net benefit to society; the public is worse off when a company incurs, say, \$100.01 to provide \$100 worth of benefits. <FN 50>

Footnotes

48 Section 316(b) uses "best available" to describe the technologies Congress wanted EPA to consider for minimizing AEI. Wherever Congress used these words in other parts of the CWA, such as §§ 301 and 306, it meant for costs to be considered. Indeed, §§ 301 and 306 are referenced in § 316 itself as the basis for identifying the dischargers subject to § 316(b) (i.e., those point source dischargers otherwise subject to effluent limitations guidelines and new source performance standards). Moreover, one of the few things the legislative history says about BTA is that it means best technology available "at an economically practicable cost." 118 Cong. Rec. H9130 (daily ed. 33,762, 1972), Leg. Hist. at 264 (remarks of Congressman Clausen for House Conferees).

49 The only difference might be in whether the permittee has the burden of invoking the benefit-cost test. EPA could leave the performance standards in place to apply wherever the permittee did not ask to be relieved from complying with them, leaving the burden on permittees to invoke the benefit-cost test.

50 Although "the public" receives the benefit of more fish, it is also the public that pays the \$100.01 cost in the form of higher prices for electricity or lower return on investments in utility companies.

RFC: Appropriateness of "wholly disproportionate"

The "Wholly Disproportionate" Standard Is Irrational

One test that clearly can not be supported is the "wholly disproportionate" test. This test says that a facility need not meet the performance standards, and may do a site-specific analysis instead, if the cost of meeting the standards is "wholly disproportionate" to the benefits. This is irrational, because it would require technologies the costs of which were much greater than their benefits, leaving society much worse off than before.

The "wholly disproportionate" test is not consistent with the economic objective of maximizing the net benefits from BTA determinations. It appears to be motivated by an unsupported assumption that measured benefits are consistently and significantly understated compared to costs, perhaps because of perceived limitations in the methods of assessing benefits. Whatever the motivation, improvements in benefit assessment methodologies and empirical studies in the last two decades provide ample bases for using an appropriate benefit-cost test (see Appendix 12 at 66).

How big would costs have to be to be "wholly disproportionate" to benefits? This can be inferred from a handful of court decisions, not all of them in the area of environmental law. A few cases interpret "wholly disproportionate" or similar terms. In State of Ohio v. U.S. Department of the Interior, 880 F.2d 432, 444 (D.C. Cir. 1989), reh. denied en banc, 897 F.2d 1151 (1989), the D.C. Circuit suggested in dictum that "grossly disproportionate" might mean, for example, that damages were three times the amount of use value, that is, a ratio of 3:1. In General Railway Signal Co. v. Washington Metropolitan Area Transit Authority, 875 F.2d 320, 326 (D.C. Cir. 1989), cert. denied, 494 U.S. 1056 (1990), the court concluded that line item figures of $1.3 million were "grossly disproportionate" to estimates of actual costs ranging from $566,000 to $650,000, a ratio of 2.3:1 or less. The court also said that a 161.5% markup to cover profits and indirect costs was "wholly disproportionate" to the relatively modest in direct costs and the 9.73% profit figure contained in an estimate of the costs of the work that included these elements.

UWAG is aware that individuals, perhaps even some at EPA, have speculated that costs might have to go as high as 10 times benefits to be "wholly disproportionate." But so far as we know these statements were oral, unofficial, and unsupported by anything in statute, regulation, or written guidance. From the above-cited precedents it appears that a better guide is that a cost is "wholly disproportionate" if it is 2 or 3 times benefits. That is certainly consistent with plain English; most people asked to pay twice what a house or car was worth would agree that the price was wholly disproportionate.

RFC: Appropriateness of "significantly greater"

The "Significantly Greater" Standard May Not Be as Bad as the "Wholly Disproportionate" Standard, But It is Still Irrational

EPA proposes to use costs "significantly greater than" benefits as the test for when the performance standards may be abandoned in favor of a site-specific analysis. Clearly EPA intends this to require technologies with costs greater than benefits, but not so much greater as the "wholly disproportionate" test. 67 Fed. Reg. 17,145 col. 3 - 17,146 col. 1.

"Significantly greater than" is an improvement over "wholly disproportionate." But to the extent "significantly greater than" allows choices with negative net benefits, it too is irrational, because it leaves society worse off than before.

RFC: Test: benefits should justify the costs

A “Benefits Greater than Costs” Test Would Be Better than “Significantly Greater,” Though Still Not Optimal

A better test for deciding when to abandon the performance standards and resort to a site-specific analysis would be to do so if all the technologies that can achieve the performance standards have negative net benefits (that is, costs greater than benefits). <FN 51> This would not be as good as maximizing net benefits, but it would at least be rational, in the sense that it would not require a facility to choose technologies that make society worse off overall. It would be equivalent to allowing a site-specific analysis if the benefit-to-cost ratio of meeting the performance standards was less than 1:1, though we have tried to avoid using ratios for decisionmaking.

As a legal matter, “positive net benefit” as a decisionmaking standard can be said to grow directly out of § 316(b). Section 316(b) calls for minimizing environmental impacts that are “adverse.” A loss of fish cannot be said to be “adverse” if the alternatives for reducing it would have no net benefit to society.

At least one State implicitly endorses, in effect, a cost-benefit ratio of 1:1. In the Maryland regulations, COMAR 08.03.05.D, Maryland calculates the value of the impingement species lost by estimating the number of each species destroyed and multiplying by values listed in COMAR 08.02.09.01. These factors are weighted by an adjustment factor (1.0 for recreational species, 0.75 for forage species). Dischargers then must install and operate functional modifications to mitigate impingement loss if the additional cost of installation of modifications to intake structures and of operation modifications over a five-year period does not exceed five times the estimated annual value of impingement loss. These approved modifications are defined as BTA. COMAR 08.03.05.D(1)-(2). (Maryland deals with entrainment in a different provision, Regulation .04.)

Footnotes

51 In other words, this formula would merely eliminate the word “significantly” from the test, which introduces a bias based on the unsupported assumption that benefits are typically measured too low or costs too high.

EPA Response

See the preamble for a discussion of the site-specific compliance alternative.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

How a "Benefit-Cost" Test Should Work in Practice

In short, UWAG believes that a sound benefit-cost test would work as follows. Regardless of the numeric performance standards, the § 316(b) rule should require the intake technology (including if appropriate the status quo) that maximizes net benefits.

If EPA retains its numeric performance standards, however, a benefit-cost test should be provided, as it is in EPA's proposed rule, to provide relief from excessive costs. The permittee should have to consider all "available" intake technologies for the site. These would not include technologies that were not feasible for engineering reasons, because these would not be "available" in any real sense. Absent such engineering reasons, though, the permittee would have to assess each of the technologies that EPA has based its rule on – that is, fine- and wide-mesh wedgewire screens, aquatic filter barrier systems, barrier nets, modified screens and fish return systems, fish diversion systems, and fine mesh traveling screens and fish return systems.

If all the technologies that could meet the performance standards were too costly, then the permittee should be allowed to use an alternative, site-specific analysis. For deciding what is "too costly," the "wholly disproportionate" test would be irrational and counterproductive, because it allows decisions that make society not just worse off but considerably worse off. The "significantly greater" test is better, but still irrational and unjustified by the principles of economics. Only a test that would allow a site-specific analysis whenever the cost of meeting the performance standards exceeded the benefits would pass the minimum threshold of rationality.

By whatever test, once a site-specific analysis is allowed, EPA's proposal is that the Director select a less costly technology "to the extent justified by the significantly greater cost." Proposed § 125.94(c)(2), 67 Fed. Reg. 17,221 col. 3. In UWAG's view this should be taken to mean that the technology selected should be the one that maximizes net benefits. That might be the status quo. As EPA has acknowledged, in some cases "no action" may be the appropriate decision.

In any case, it should not be necessary to analyze (1) cooling towers, (2) restoration measures, or (3) operational measures, because they cannot be required under the new rule, only offered voluntarily.

EPA Response

See the preamble for a discussion of the site-specific compliance option.

RFC: Test: benefits should justify the costs

The Rule Should Allow Consideration of "Equity"

The "maximize net benefits" formula is the only one that satisfies economic theory for serving the public interest. But it is based on maximizing utility to society, and legal standards are about fairness as well as efficiency. In two respects the test may need to be modified in cases where fairness demands. One is in considering money already spent to protect fish before the rule was promulgated. The other is where a net benefit could be obtained for the public but only by a very large expense to the operator of the facility.

1. Past Expenditures May Have to Be Considered in Some Cases

EPA has appropriately recognized that many facilities in states with established § 316(b) programs have already installed protective technologies or taken restoration measures. Just as EPA has allowed credit for such efforts by establishing a "baseline," so EPA should allow the counting of past expenditures in the cost-cost and benefit-cost tests where necessary for fairness.

Benefit-cost analysis considers costs going forward, not costs already incurred. To an economist, the analysis of the efficient protection of fishery resources requires a forward-looking analysis rather than a historical one. It is irrelevant to the economist what costs or benefits have been incurred in the past, and the focus is exclusively on potential actions and the marginal benefits and marginal costs of such actions.

But regulators should have authority to consider, in appropriate cases where fairness requires it, fish protection costs incurred in the past. If the costs of screens already installed before the § 316(b) rule becomes final were "significantly greater" than the costs EPA considered, for example, then the threshold for applying a site-specific analysis may already have been crossed. As noted above, these costs should include the monitoring and studies needed to comply with § 316(b).

Consider, for example, the following hypothetical:

	Cost	Benefit
Baseline	0	0
Existing screens (already installed before the § 316(b) rule)	100	30
Proposed additional new screen or filter to satisfy new rule	10	15
EPA's estimated cost	50	–

Suppose the rule provided for a site-specific analysis if the incremental cost of technology to meet the performance standards was two times (or less) the benefits. By that test, the original screens in the above scenario, having cost $100 to save $30 worth of fish, would not be justified, but in this example they have already been installed. The proposed new modifications, in contrast, are cost-justified (at least by the irrational 2:1 test), because they would cost only $10 to buy $15 worth of benefits. But because the total costs and benefits ($110 versus $45) fail the 2:1 test, the proposed new screens should not be required, out of fairness.

For the same reason of fairness, permitting agencies should be allowed to give credit for the benefits of restoration projects undertaken in the past that reduce the impacts of cooling water intake structures. Under appropriate circumstances, the beneficial effects of restoration projects, both during the permit term and beyond, should be counted toward satisfying the numerical performance standards of § 125.94(b)(2) and (3). Where the performance standards cannot be met by intake technologies without costs "significantly greater" than either EPA's costs or the benefits of the technologies, past restoration projects should, as fairness requires, be counted in the site-specific analysis toward deciding what measures, past and future, are "justified by the significantly greater costs."

2. Regulators Should Be Allowed to Reject a Proposed Technology that Will Impose Inordinate Costs on the Facility

Another exception to the pure "net benefits" test might need to be made where the benefit is small in proportion to the burden on the permittee. The strict "maximize net benefits" test would call for the alternative that produces the most net benefit to society, even if the cost to an individual facility or company is very high, and even if the second-best alternative has a much lower cost and almost as great a net benefit. Consider the following hypothetical:

	Benefit	Cost	Net	Ratio
Baseline	0	0	0	–
Technology A	500	400	100	1.25
Technology B	100,000	99,800	200	1.002

Assume that in both A and B cases the cost is incurred entirely by the facility paying for protective technology, while the benefits are entirely in terms of saving fish, with the benefits accruing to the public generally. In this case Technology B has a greater net benefit to society than Technology A (twice as great, in fact), but it also costs the utility an enormous amount more. In this case some departure from the "maximize net benefits" test is desirable and should be allowed by the proposed rule. (Using a benefit-cost ratio would provide relief in this case, but we have said already that using ratios for decisionmaking is not favored.) EPA's rule should allow regulators to deal with "distributional" issues like this one.

EPA Response

See Comment ID 316EFR.005.020 for EPA's response on "maximize net benefits".

In regard to the comments that past expenditures should be considered in the cost tests, EPA disagrees because the purpose of the rule is to reduce impingement mortality and entrainment from what is the status quo today. Therefore, the baseline for assessing costs associated with the requirements of the rule starts with this final rule. However, in the final rule there are several compliance alternatives where existing design and construction technologies, operational measures, and/or restoration measures are considered for meeting the performance standards. See the preamble to the final rule for additional information on cost tests and compliance alternatives.

RFC: Test: benefits should justify the costs

Costs and Benefits Should Be Counted in Their Entirety

Whatever benefit-cost test is used, it will be valid only if the costs and benefits it considers are accurate and complete. EPA would do well to provide guidance on techniques for valuing costs and benefits.

1. Costs Should Be Counted Completely

In calculating the costs of an intake technology, the permit writer should take into account the unique aspects of the site, its size, its proximity to population, and local ordinances that affect cost. Most of the costs could be covered by a specific set of non-water quality impact cost factors. Additional capital costs and O&M costs must first be considered. Schedule-related issues on brownfield or site-limited sites should be considered, because if construction limitations call for a longer construction schedule, the cost of construction funds can increase project cost by up to $80 million for a 1200 MW gas-fired combined-cycle plant. Costs should also include noise abatement costs, visual protection/landscaping, loss of land value, and purchase of emission credits. Finally, the costs of sampling and studying the waterbody should be included.

In the preamble to the proposed rule EPA discusses how rigorous and “empirical” any cost estimate should be. 67 Fed. Reg. 17,152. It is not clear what EPA means by “empirical.” If it means that permittees should use reasonably reliable sources of cost data, such as the experience of the permittee or other companies, vendor estimates (which EPA itself relies on heavily), and supportable engineering studies, then EPA’s point is well-taken. But if EPA is attempting to suggest some sort of standard for the quality of cost data, it should say exactly what it means.

EPA Response

In response to the comment on the meaning of the word "empirical", used by the Agency in the preamble to the proposed rule, please see Merriam-Webster's Collegiate Dictionary.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Author Name Hunton & Williams
Organization obo Utility Water Act Group

Subject Matter Code 10.07.03
RFC: Test: benefits should justify the costs

EPA Should Clarify How "Benefits" Should Be Determined

To apply a benefit-cost test, the "benefits" of a technology must be quantified. In essence, this means determining the value of the fish or larvae that are saved from entrainment or impingement mortality.

Unfortunately, some of the methods used in EPA's own analysis of the "benefits" of the proposed rule are unsound. EPA should correct the impression that these methods are appropriate for benefit-cost analyses in individual cases. The most egregious example is the use of the habitat replacement cost (HRC) method to use costs as a proxy for benefits. This error is discussed above. <FN 52>

In addition, EPA should provide guidance on the use of contingent valuation (CV) methods, since badly designed CV studies can be seriously misleading. Contingent valuation is a controversial methodology, especially for § 316(b) purposes. The contingent valuation method for estimating the value of natural resource services involves a direct survey of individuals to elicit their willingness to pay (WTP) for different levels of services. For example, the survey might ask respondents the maximum amount they would be willing to be pay for a 25% increase in fish catch at a particular site. The CV method requires that people be able to express their value for marginal changes in fishery services and, furthermore, that their responses to hypothetical questions indicate their actual valuations of the changes described in the questions.

For determining non-use values (the satisfaction people derive from the mere existence of a fish, even if they never intend to use it), <FN 53> CV may be the only available method. However, CV presents great methodological challenges, and a CV study must be carefully designed if it is to be useful. In the context of § 316(b), it is very hard to believe that there are high non-use values for marginal improvements in fish populations such as are at issue in most § 316(b) cases. It is one thing to believe that people value the very existence of an endangered species, and quite another to conclude that they value a one percent increase in a population of gizzard shad or menhaden.

The main shortcoming of the CV method is that it relies on responses to hypothetical questions instead of observations of actual behavior. When people are asked the amount they would hypothetically be willing to pay for some commodity, they have little incentive to answer carefully. Economists have long felt that observations of actual behavior more accurately reflect preferences than responses to hypothetical questions. For non-use values, though, there are no behavioral trails to be followed (Arrow 1993 at 3).

Moreover, CV fish evaluation studies typically include both use and non-use values, focus on highly valued game fish, and use a policy that results in a large increase in the fish population. CWIS applications, in contrast, typically involve only use values, common sport fish species, and relatively small changes in fish populations. Therefore, using estimates from CV fishing studies for a CWIS-related cost-benefit analysis may require careful interpretation.

Elsewhere in these comments UWAG has recommended ways in which benefits of fish protection should be determined. EPA might do well to clarify the following points:

-The valuation of benefits must take into account that some species have lower values than others. Appropriate models are available to value noncommercial and nonrecreational species (i.e., forage species).

-The "benefits" of a technology should not include organisms that are spared entrainment if they would have survived entrainment unharmed. Rather, benefits should be adjusted to reflect survival rates where data on survival rates are available.

-Benefits should be reduced to reflect density dependence in fish populations. If the lower density resulting from the loss of a thousand larvae would cause the population to produce, say, 750 additional larvae, then the benefit of preventing a loss should be adjusted accordingly.

-"Benefits" of a technology should include providing protected habitat or warm water for manatees, shore birds, etc.

Footnotes

52 In describing UWAG's proposal for the existing facilities rule, EPA erroneously states that "UWAG believes use of existing EPA cost-benefit calculation methodologies, such as those used for natural resource damage valuation under CERCLA and NEPA would be sufficient." 67 Fed. Reg. at 17,165. UWAG cited to EPA's natural resource damage valuation process, and EPA's BEN model, only as examples of tiered approaches to developing site-specific cost-benefit information. See UWAG Phase I NODA Comments, pp. 103-08. UWAG explicitly stated that it did not endorse use of EPA's natural resource damage valuation process or the BEN model in § 316(b) determinations.

53 See K. Arrow et al., Report of the NOAA Panel on Contingent Valuation (Jan. 11, 1993).

EPA Response

The comment states that EPA has used unsound methods in its benefits analysis. This comment refers to EPA's proposed rule analysis. For the final rule analysis, EPA has made significant changes in its methods and applications.

The HRC method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see the response to comment # 316bEFR.005.035.

The comment states that EPA should provide guidance on the use of CV methods. For EPA's discussion of the appropriateness of using stated preference methods in the context of the 316(b) regulation see the Notice of Data Availability (67 FR 38752). The Agency notes, however, that its benefits analysis does not rely on original CV studies, so there is no need to explain the shortcomings of CV studies.

The comment says that it is hard to believe that there are high non-use values for marginal improvements in fish populations. However, no empirical evidence is presented to support this belief. For EPA's response to comments regarding evidence for non-use values for temporary losses to common species, please see the response to comment #316bEFR.306.302.

The comment states that the analysis must take into account differences in values for different fish species. EPA does account for differences in value for different species of fish. The RUM models estimate values for different species or species groups, and the benefit transfer for the Inland Region uses different values for different species groups. See Chapter 4 in Parts B through H in the regional study document prepared for the analysis for the final Phase II rule (DCN #6-0003).

The comment mentions that appropriate models are available to value forage species, but does not give a specific example of such models. EPA does use a trophic transfer model to translate foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. This method, however, allows to estimate indirect use value of forages species. There may well be nonuse values that still pertain to all forage fish, and especially to the forage fish that are not adding to biomass in landed fish (as the latter are overlooked in the current valuation context). Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule (DCN #6-0003). See Chapter A5: Methods Used to Evaluate I&E.

For additional information on EPA's conclusions about entrainment survival, please see response to Comment #316bEFR.306.506 and Chapter A7 of Part A of the Regional Study Document for the Phase II rule.

For a discussion of density dependence in the context of the 316b rulemaking, please see EPA's response to Comment #316bEFR.025.015.

The final regulation does not require technologies that will change water temperatures. For a discussion of the effect of hot water discharges and manatees, please see EPA's response to comment #316bEFR.051.016.

General: cost tests

Author Name Hunton & Williams

Organization obo Utility Water Act Group

A Cost-Cost Test is Appropriate

In addition to the benefit-cost test for departing from the performance standards, EPA proposes a cost-cost test: A site-specific analysis could be used if the cost of meeting the performance standards was "significantly greater" than the costs EPA considered in making the rule.

The "significantly greater" test here is not necessarily irrational, as it is when applied to costs and benefits. Here it is analogous to the "fundamentally different factors" exception to national technology-based effluent limitations. As such, UWAG cannot say it is unreasonable, so long as the difference between projected cost at the site and EPA's estimated cost that is required to meet the test is not too great.

However, EPA needs to clarify how permit writers should identify the costs EPA considered in setting the rule. According to the preamble, the permittee interested in using the cost-cost test would "consider the model plants presented in EPA's Technical Development Document, determine which model plant most closely matches its fuel source, mode of electricity generation, existing intake technologies, waterbody type, geographic location, and intake flow and compare its engineering estimates to EPA's estimated cost for this model plant." 67 Fed. Reg. at 17,144 col. 1-2. According to the Phase II TDD, the costs developed for 539 plants and presented in Appendix A to the TDD would form the basis of comparison. Phase II TDD, p. 2.1. It is not clear how the permit writer is to distinguish among 539 plants to find the one that most closely matches the permittee's facility. UWAG applauds EPA's attempts to provide a wide range of model plants, and this method may provide appropriate flexibility for comparing complex engineering costs, since such costs are affected by a variety of site-specific factors. But further clarification of the model plant selection process is warranted. <FN 54>

Footnotes

54 UWAG notes that Appendix A to the Phase II TDD does not provide the geographic locations of the 539 listed plants. EPA says that geographic location is "an important factor for the consideration of installation capital costs" but explains that the Agency "could not reconcile a means to protect a limited amount of confidential business information claimed by respondents to the questionnaire and the need to provide this data to the public for the purposes of evaluating this proposed cost test option." Phase II TDD, p. A-1. Apparently EPA intends to release the geographic location information at a later date. Id. UWAG reserves the right to comment more fully on this cost test when this information becomes available.

EPA Response

The Agency agrees with the commenter's assessment of the reasoning behind the cost-cost test, the cost benefits test and the term "significantly greater."

The Agency addresses the issue of implementing the cost-cost test in section IX.H of the preamble to the final rule and in response to comment 316b.EFR.410.001.

RFC: Proposed use of restoration measures

EPA'S PROPOSAL TO PERMIT RESTORATION ON A VOLUNTARY BASIS IS GOOD POLICY

UWAG agrees that restoration should be one way of satisfying § 316(b). Restoration activities might include, among other things, fish hatcheries and stocking, wetlands restoration or creation and other types of habitat improvement, removing barriers to fish migration, and creating artificial reefs. Restoration projects created in the past, as well as those undertaken after the rule becomes final, should all count toward compliance with the new rule. On a site-specific basis, such measures may have more potential to achieve net environmental benefits for the waterbody than intake technologies and operating restrictions.

A. Experience with Restoration Projects Has Been Good

Clearly restoration projects are good for the environment. For example, fish stocking as a restoration effort is practiced by Quad Cities Station as a means to offset fish impingement. Biological monitoring and trending of standing crop estimates in the Mississippi River pools that are stocked by Exelon have demonstrated a 30% recruitment in certain game species resulting from these stocking efforts. The Illinois and Iowa departments of natural resources have acknowledged this remarkable accomplishment and continue to be strong supporters of the fish-stocking program on the Mississippi River. Restorations achieve measurable results and are also well received by the public and by government agencies.

It is sometimes argued that the language of § 316(b) forbids consideration of environmental enhancements in place of CWIS technological modifications. UWAG agrees that environmental enhancements are not "intake structure technologies" and thus that § 316(b) does not authorize regulators to require them. However, § 316(b) does require the regulator to determine, in the first instance, whether AEI is occurring. Because past restoration measures directly affect the AEI determination, they enter the § 316(b) determination process well before the regulator reaches the question of what CWIS technologies are the "best available" for minimizing AEI. Thus, that existing environmental enhancements are not CWIS technologies does not make them irrelevant to the AEI inquiry.

As for proposed environmental enhancements offered during the BTA assessment phase of § 316(b), EPA has considered and accepted voluntary environmental enhancements in several § 316(b) permitting decisions. See, e.g., In the Matter of Florida Power Corp., Crystal River Power Plant, Units 1, 2, and 3 Findings and Determinations, NPDES Permit No. FL0000159 (Sept. 1, 1988) (authorizing a fish hatchery program "in an attempt to replace fish and shellfish eggs, larvae, and juveniles entrained" by the facility); Fact Sheet for John Sevier Decision (Application No. TN0005436) Region IV (1986) (finding fish stocking and monitoring program were "appropriate measures for compliance with Section 316(b)"). Other examples are provided by the Salem and San Onofre stations.

There is no principled reason to change this approach in the § 316(b) rule, and there are good policy reasons to allow regulators the flexibility to evaluate environmental enhancements that will offset impingement and entrainment losses. Where a permittee's operation of a CWIS causes effects that otherwise would constitute AEI and those losses either can be addressed or significantly offset by restoration measures that benefit not only the species of interest but also the ecosystem as a whole (such as wetlands restoration, fish ladders, and aquaculture activities), it makes little or no sense from a public policy perspective to automatically require installation of an intake technology instead. This is especially true where the cost of upgrading CWIS technology (together with other relevant factors such as the remaining useful life of the facility) weigh against requiring an investment in technology.

EPA Response

In the final rule, EPA allows use of restoration measures to minimize or help to minimize the adverse environmental impacts that derive from impingement and entrainment of aquatic organisms. All restoration measures must meet the requirements described in the final rule, including those under sections 125.94 and 125.95. For a discussion of EPA's authority to include restoration measures as a compliance option in the final rule, see the preamble to the final rule.

For a discussion of the use of existing restoration projects and of the role of ancillary benefits from restoration measures, see EPA's response to comment 316bEFR.032.011.

RFC: Info. to include in a restoration plan

A Permittee Should Be Able to Propose a Restoration Project After the Permit Application Is Submitted

UWAG is concerned that EPA's proposed rule may, albeit unintentionally, preclude permittees from developing and submitting restoration projects after their permit applications have been submitted. Proposed § 125.95(b)(5), 67 Fed. Reg. 17,223 col. 3, implies this when it says that "if you propose to use restoration measures to meet the performance standards in § 125.94, you must submit the following information with your application for review and approval . . . ." This could be read to suggest that a permittee has only one chance – when it puts together its study plan and submits its permit application – to propose restoration. This is neither practical in all cases nor necessary. Such a limitation would serve only to constrain unnecessarily the development of useful projects and, ultimately, of trading that might use such projects.

UWAG does not believe that EPA intended to propose such a limitation. Rather, we think it is an artifact of inconsistencies and problems inherent in EPA's proposed framework for permit application and compliance. UWAG has identified many such issues, described elsewhere in these comments. UWAG recommends that EPA address this issue when it revises, as we hope it will, the overall framework and deadlines for permit application and compliance.

EPA Response

EPA believes this comment pertaining to the timing of submission of information has been addressed in the final rule.

RFC: Performance/effectiveness of restoration

Evaluating the Performance of a Restoration Project Is Different from Monitoring Intake Structure Performance or Discharges of Pollutants

If restoration is offered as a means of complying with § 316(b), requirements for monitoring compliance should be flexible. It is not possible in many cases to verify by monitoring that a particular project (a wetland, for example) has a specified impact on the aquatic community. The permit writer should be satisfied so long as the permittee verifies that it has created or restored the number of wetland acres that were agreed to.

As an important first step, the scope and nature of the agreed-to environmental restoration project should be documented in the permit or another binding document. Schedules of implementation and any appropriate monitoring plans also could be documented. Because of the many possible types of restoration measures and the varied ways they may interact with the environment, EPA should avoid attempting to limit in advance the type of monitoring measures or other types of demonstrations that might be used to evaluate restoration projects for § 316(b) purposes. Instead, EPA should make restoration projects subject to some form of evaluation, leaving it to the regulator to decide, based on his best professional judgment, what constitutes an acceptable demonstration of the project's efficacy.

The scope of the evaluation of restoration measures may depend in part on the degree of uncertainty surrounding the project. A restoration projection that involves an experimental technique or is unproven in a certain environmental setting may be subject to more rigorous evaluation than a restoration that is routine, like fish stocking. In any case, however, the scope of the evaluation should be scientifically reasonable and should not impose an unreasonable burden of proof. One possible approach is to agree on the size of the enhancement project in advance, based on an expert evaluation of how much of the CWIS losses the enhancement would replace, and then rely on structural criteria to measure compliance.

Monitoring to demonstrate effectiveness of a habitat enhancement program must not be required to count fish or larvae as replacements. An alternative approach might be that physical environment measurements (such as changes in elevation that enable certain habitats to proliferate or aerial photo imaging over time that demonstrates habitat expansion in conjunction with a specific program) are more acceptable monitoring parameters. Even in these cases, we must caution EPA that if other uncontrolled factors may be impacting the habitat evolution, they should be taken into consideration in the monitoring program.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

EPA believes restoration measures will be well suited for some sites, and not well suited for others. Evaluation and monitoring difficulties are two reasons why restoration measures may not be suitable for a particular site.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

EPA believes the requirements for restoration measures in the final rule contain a significant amount of flexibility.

RFC: Performance/effectiveness of restoration

Proving Fish-for-Fish Replacement Should Not Be Expected

While habitat restoration is a valid and important alternative, and UWAG commends EPA for including a restoration alternative in the proposed rule, we have a number of cautions regarding the application of the HRC approach to validating that a restoration project offsets resource and ecosystem losses. In most cases, proving this offset biologically (that is, demonstrating that an equal or commensurate number of larvae or adult fish of some or similar species are replaced by restored or enhanced habitat) is an unreasonable if not impossible task. In most waterbody situations, particularly estuarine environments, the number and variety of impacts on the waterbody are far too complex to reasonably correlate habitat improvements with long-term and complex species population variations.

For these reasons, we strongly recommend that any true-up mechanisms for demonstrating the success of habitat restoration and its correlation to CWIS effects be confined to physical demonstration achieved by use, for example, of aerial imaging to verify changes in water quality (clarity), habitat quality and quantity, and sedimentation as determined by bathymetric measurements. These type of verifications avoid the much more difficult and variable biological demonstrations of species replacement, which are subject to too many other impacts in most cases to accurately correlate to CWIS-related changes.

In short, UWAG does not believe that reliance on the HRC approach for demonstrating replacement of biological losses is a valid, defensible, or reliable method. However, the Habitat Equivalency Analysis model itself, given adequate availability of species data, may be able to serve some purpose in acting as a "reality check" on general mitigation acreage requirements of the habitat restoration/program.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

EPA believes restoration measures will be well suited for some sites, and not well suited for others. Evaluation, scaling, and monitoring difficulties are some reasons why restoration measures may not be suitable for a particular site.

EPA is not requiring in the final rule any one method for scaling. For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

EPA believes the requirements for restoration measures in the final rule are written with a significant amount of flexibility.

Subject Matter Code 11.08

RFC: Habitat conservation as part of restoration

"Restoration" Should Be Broadly Defined to Allow a Range of Beneficial Activities

Habitat restoration should be clearly and broadly defined to include habitat protection measures. That is, if a habitat will facilitate the propagation of species lost at the CWIS, then protection of such habitat from sedimentation, erosion, and water pollution should be encouraged where there is evidence that expansion of such habitat will accommodate species population increases.

The Habitat Equivalency Analysis (HEA) process is a useful tool for evaluating restoration projects. Application of the HEA in many cases will vividly illustrate the value to an ecosystem of a habitat restoration or enhancement. The overall productivity resulting from the acre that replaces adult equivalent loss may be tens of times that of the simple species adult equivalent loss. Evaluation of the HEA model (such as at Morro Bay, California) can illustrate how the energy transfer, for example from vegetative biomass such as eel grass to fish, consumes less than one percent of the total energy provided by the habitat food base. Thus the vast majority of the system's energy flows into the system, a situation that does not occur when entrainment is simply prevented or when aquaculture simply replaces the eggs or larvae.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority in determining the appropriate level of performance to meet the requirements of the final, see EPA's response to comment 316bEFR.060.026.

RFC: Performance/effectiveness of restoration

Restoration Has Long-Term Benefits

The long-term and broad-ranging benefits of restoration (or habitat conservation) can be significant. Unlike intake technologies, restoration produces benefits beyond the life of the plant.

Allowing restoration of wetlands to satisfy the § 316(b) rule would be consistent with the national policy of preserving, protecting, and enhancing wetlands. The Corps of Engineers recently opened for comment a "Draft Estuary Habitat Restoration Strategy," which has a strategy of restoring one million acres of wetlands nationwide. Allowing voluntary restoration under the § 316(b) rules would be consistent with this national program.

The long-term nature of benefits from restoration projects has implications for how restoration, when it is voluntarily offered, should be counted toward compliance with the proposed rule. If restoration is offered as a means of meeting the numerical performance standards, the analysis of how much reduction is accomplished in impingement mortality and entrainment should take into account that the increase in fish from the restoration project will continue far into the future. Similarly, if restoration is offered as part of a site-specific analysis because intake technologies have failed either the cost-cost or benefit-cost test, deciding what level of effort is "justified by the significantly greater costs" should take into account the fact that the restoration will benefit the aquatic community for years into the future. Indeed, whenever a restoration project is compared to an intake technology to determine whether the restoration project is comparable to the technology, the longer life of the restoration project should be counted.

EPA Response

For a discussion of the ancillary benefits associated with restoration measures, see EPA's response to comment 316bEFR.032.011.

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

RFC: Proposed use of restoration measures

Restoration Options Should be Flexible

In order to maximize the ability of facilities, States, and other stakeholders to achieve the benefits of restoration, flexibility is necessary. To restore or improve fisheries and other aquatic resources that are potentially affected by impingement and entrainment losses often requires taking action on several fronts. Limiting factors for fisheries and other aquatic resources might include low dissolved oxygen due to excessive nutrients, lack of suitable spawning habitat due to high sediment loads, migratory obstructions, etc. Resource managers and other stakeholders on most waterbodies where generating stations are situated are taking actions on multiple fronts to address such issues to increase beneficial use of aquatic resources.

Voluntary restoration projects should be encouraged as much as possible, and that means allowing permittees to undertake a broad range of such activities, so long as they can satisfy the permit writer that they will benefit the aquatic community. For example, projects that are distant from the facility site should be allowed, and also projects that would help species different from the ones impacted by entrainment or impingement. When restoration measures are evaluated to address impingement and/or entrainment losses, the benefit increases when such actions support or complement the overall waterbody restoration or enhancement goals.

For example, gizzard shad and threadfin have been stocked in many southern and midwestern water bodies to provide forage for game fish. These species are commonly impinged and entrained yet are not considered depleted or at risk in most waterbodies, and few resource managers would consider it meaningful to have facilities engage in aquaculture or other actions to increase populations of these species. However, they may consider it of high value for a facility to engage in similar actions to increase populations of recreational species that may not be subject to impingement or entrainment or, if so, only in very small numbers. For example, at PEPCO's Chalk Point Station in 1988, the facility was determined to have the potential for adverse impact to bay anchovies in the Chesapeake Bay due to entrainment. The anchovy is an important forage fish in the Bay and along the Atlantic Coast generally. To address this issue, the Maryland authorities agreed to the use of restoration measures using aquaculture.

However, rather than have the facility raise anchovies, the State asked the facility to raise and stock striped bass, which at the time were on the State's threatened species list. After recovery of the striped bass, the State had the facility raise and stock American shad, another protected species in the Bay. Striped bass were not entrained, and only a small number of juveniles were impinged; American shad were neither impinged nor entrained. But Maryland in this case realized a much greater benefit in advancing its fishery management goals by having the flexibility to select species for restoration other than those affected by impingement or entrainment.

Additionally, instead of direct restoration of habitat by permittees, non-profit foundations or trusts could be established that would provide financial support to environmental restoration projects within a watershed or region. Examples include the Hudson River Foundation (http://www.hudsonriver.org) and the Great Lakes Fishery Trust (http://www.glft.org).

UWAG believes that the key elements for successful use of restoration measures are as follows:

-Actual physical improvements to waterbody and aquatic resources should occur. These physical improvements should be favored over programs that result in indirect benefits to the waterbody (e.g., purely educational programs).

-EPA should not require that facilities, when using restoration measures, “replace” impingement and/or entrainment losses on a quantitative species-by-species basis. Instead, natural resource management agencies, in consultation with the permittee, should have the flexibility to restore depleted commercial or recreational species, or threatened and endangered species, consistent with the overall fisheries or restoration management goals for the waterbody.

-For many waterbodies the loss of wetlands, submerged aquatic vegetation or other suitable spawning areas is a well-documented limiting factor for resident fish species. Restoration of these habitats is clearly of benefit to the waterbody. But it is very difficult and time-consuming, and often technically infeasible, to quantify the principle effects of habitat restoration. UWAG is not opposed to reasonable monitoring and verification for restoration measures, but there should not be a requirement to conduct detailed quantitative studies to relate productivity from habitat restoration on the one hand to impingement or entrainment losses on the other.

EPA Response

EPA believes there is flexibility in the final rule in the use of restoration measures. The final rule allows permitting authorities to make decisions on the feasibility of restoration projects on a site-specific, case-by-case basis.

For a discussion of the role of the permitting authority in determining specific needs for a restoration measures, see EPA’s response to comment 316bEFR.060.026.

For a discussion of the extent to which restoration measures may address state program priorities, see EPA’s response to comment 316bEFR.099.029.

For a discussion of the extent to which restoration measures are voluntary, see EPA’s response to comment 316bEFR.060.022.

Restoration measures must result in production of fish and shellfish, including maintenance of community structure and function, within a facility’s waterbody or watershed. For additional discussion of the appropriate spatial scale for restoration measures, see the preamble to the final rule.

EPA agrees that actual physical improvements to the waterbody or watershed or aquatic resources should occur from a restoration measure.

All restoration measures must meet the requirements of the final rule, including those described in sections 125.94 and 125.95.

Section 316(b) Does Not Authorize Mandatory Restoration

UWAG agrees with EPA that restoration measures should be voluntary. The Clean Water Act gives no statutory authority for requiring restoration.

EPA may believe that restoration measures can be required as part of intake structure "design," according to EPA's own interpretation of that statutory term. EPA also may believe that the courts would defer to this interpretation under the doctrine of Chevron v. NRDC, 467 U.S. 837 (1984). But UWAG believes that is not the case.

1. The Chevron Decision Would Not Justify Mandatory Restoration

The Chevron decision prescribes how courts should review an Agency's interpretation of a statute it is charged with administering. In Chevron, the rule in question defined the term "source," for purposes of new source review under the Clean Air Act, to include an entire facility, rather than each stack or activity within a facility. The U.S. Court of Appeals for the D.C. Circuit found that the statutory language and legislative history did not indicate conclusively what Congress meant by "source" but struck down EPA's rule on the ground that EPA was changing prior policy without documenting the impact of such a change on air quality. The Supreme Court reversed, finding that Congress had not spoken directly to the issue in question and that EPA's rules reflected a permissible construction of the statute.

The Chevron case does not justify mandatory restoration under § 316(b) for the following reasons. First, an interpretation authorizing mandatory restoration would be inconsistent with the plain language of the statute. Section 316(b) gives EPA specific and limited authority to require that the "location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact." Restoration projects are clearly not the design of cooling water intake structures, as the statute requires, nor is any "technology" associated with such requirements reflected in the design of the structure. Rather, the restoration projects that we understand EPA has in mind would involve projects done on and for the benefit of a waterbody or some other environmental medium. They would not involve technologies applied on or to the CWIS.

2. An Intake Structure Is a Structure

Nor can EPA credibly claim that it is free to define "cooling water intake structure" to include attributes of the waterbody that are wholly unrelated to any structure by which cooling water enters a facility. EPA's General Counsel has put forth some guidance on the meaning of "cooling water intake structure."

For example, in General Counsel Opinion No. 41, EPA distinguished CWISs from cooling systems, showing that it recognized that intake structures have limits. It would not be credible to interpret the term “intake structure” to give EPA authority to impose requirements that permittees design restoration projects for the general benefit of a waterbody or other environmental medium. See, e.g., Walton v. Hammons, 192 F.3d 590 (6th Cir. 1999) (agency may not ignore traditional tools of statutory language or resolve any apparent statutory ambiguity).

3. An Agency May Not Create Authority that Congress Has Not Given It

The fact that the CWA does not specifically prohibit EPA from imposing restoration also does not justify EPA’s action. Nothing in the Chevron decision suggests that an agency may create any requirement that it thinks is a good idea and that Congress has not had the foresight to prohibit. Rather, a rule must reflect a permissible construction of the statute under which Congress has granted the agency authority to act. The specific authority Congress has given EPA is to set technological requirements for the location, design, construction, and capacity of cooling water intake structures, as necessary to minimize adverse environmental impact. Even if the specific terms are open to some interpretation, nothing authorizes EPA to go beyond the basic jurisdictional grant – i.e., establishment of technological controls for cooling water intake structures. And, as noted above, there simply is no credible way to stretch the term “cooling water intake structure” to cover a whole waterbody (much less other environmental media, which EPA also has talked about as candidates for “environmental restoration”). See, e.g., Lopez-Flores v. Resolution Trust Corp., 93 F. Supp. 834 (E.D. Mich. 2000) (gap-filling activities may increase depth of the penetration of a statute into the affairs that were intended to be regulated, but they may not expand scope of agency’s authority into the external universe of topics that Congress neglected or purposefully omitted).

EPA Response

For a discussion of the extent to which restoration is voluntary under the final rule, see EPA's response to comment 316bEFR.060.022.

For a discussion of the authority EPA has to include restoration measures in the final rule, see the preamble to the final rule.

RFC: Mandatory restoration approach

Author Name Hunton & Williams

Organization obo Utility Water Act Group

UNDER THE PROPOSED RULE, PERMIT WRITERS WOULD NOT BE AUTHORIZED TO REQUIRE RESTORATION MEASURES TO BE ANALYZED UNLESS THEY WERE VOLUNTEERED BY THE PERMIT APPLICANT

By the terms of the proposed rule itself, restoration measures are to be voluntary. It follows that, when a permit applicant analyzes its alternatives for meeting the numerical performance standards, it need not include restoration as one of the alternatives. If a suitable restoration project is available, however, the permit applicant can at its option include it as a possible means, alone or in combination with intake technologies, of achieving a reduction in impingement mortality and entrainment that is in the required range.

If none of the available intake technologies can achieve the performance standards at the site, the permit applicant will have to show that the cost of achieving them is “significantly greater” either than EPA’s estimated costs or the benefits. A site-specific analysis of alternatives will then be required. Again the permit applicant will be able to offer a restoration project as a way of complying with the rule, but the applicant can not be required to seek out a restoration project.

This is, UWAG believes, what EPA intends. The current proposed rule could be interpreted, however, to suggest that a permittee wishing to seek a site-specific limit could be required to accept a limit based not just on alternative technologies, but also on a restoration requirement (or operating restrictions). See proposed § 125.94(c)(2), (3), 67 Fed. Reg. 17,221 col. 3. To prevent this misinterpretation (which would, in any case, exceed EPA’s authority under the CWA), EPA should refine the language of the proposed rule accordingly. EPA should clarify that voluntary means voluntary and prevents the permit writer from requiring consideration of restoration projects in both the above-described situations.

EPA Response

For a discussion of the extent to which restoration measures are voluntary under the final rule, see EPA's response to comment 316bEFR.060.022.

For a discussion of the consideration of design and construction technologies before choosing restoration measures, see EPA's response to comment 316bEFR.033.005.

Under the final rule, a permit applicant seeking a site-specific limit could be required to accept a limit based on design and construction technologies, operational measures, and/or restoration measures.

For a discussion of EPA's authority to include restoration measures in the final rule, see the preamble to the final rule.

SECTION 316(b) DOES NOT AUTHORIZE EPA TO REQUIRE STATES TO SET ADDITIONAL CWIS LIMITS

In proposed § 125.94(e), EPA says that the Director may establish more stringent requirements if necessary to meet the requirements of other applicable Federal, State, or Tribal law. 67 Fed. Reg. 17,222 col. 1 (April 9, 2002). See also proposed § 125.90(e), 67 Fed. Reg. 17,220 col. 1 (April 9, 2002). This proposal is not required by § 316(b) or any other section of the CWA.

A. EPA Should Not Encourage More Stringent § 316(b) Requirements Under Color of State Law

EPA authorizes States to apply any additional requirements the State deems necessary to implement State law, including State water quality standards (designated uses, criteria and antidegradation policy). This provision is inconsistent with the statute, unnecessary, and bad public policy.

1. Section 510 of the Clean Water Act Merely Preserves State Authority to Set More Stringent Standards Under State Law – It Does Not Create Such Authority

Section 510 of the CWA provides that "except as expressly provided in this chapter" nothing in the CWA displaces the authority of a State to impose more stringent requirements than are required by federal law. We might concede that this gives the states the ability, under State laws or rules adopted wholly independent of the CWA, to impose more stringent requirements. However, we do not believe this gives States the authority to impose more stringent requirements for CWIS – which the CWA regulates only under § 316(b) – under the auspices of State water quality standards adopted by states pursuant to the federal CWA. In other words, § 510 does not preserve a State's ability to interpret requirements adopted pursuant to federal law (i.e., technology-based requirements adopted under § 316(b) and water quality standards adopted by a State to satisfy CWA § 303(d) and approved by EPA) more stringently than EPA has.

Nowhere has EPA adopted any rule saying that limitations on cropping of fish by CWIS (or any other intake or instrumentality, for that matter) are necessary or appropriate parts of State water quality standards (which focus primarily on water quality conditions, not on use of resources). Nowhere has EPA suggested how cropping might factor into the designation of uses or the setting of criteria for parameters necessary to attain those uses. And nowhere has it adopted any rule or offered any guidance suggesting how cropping effects might be factored into the antidegradation policy EPA has established in its water quality standards rules. In fact, one can look through many volumes reflecting years of water quality standards rules, criteria, and guidance without finding any allusion to cropping effects. Thus, it is totally inappropriate for EPA to suggest that States should be allowed to interpret (or re-interpret) such standards to cover cropping, when neither the States nor EPA have ever interpreted them as covering cropping before.

2. More Strict State Requirements Would Create Uncertainty

As a practical matter, the proposal to encourage State requirements is unwise for four reasons. First, it undermines the certainty that EPA says it intended to supply with the rule, both in the long and the short term.

Second, like EPA's position on revisiting § 316(b) at each permit cycle (EPA also invites permit writers to rethink § 316(b) requirements every five years), this provision could leave permittees guessing about what requirements they may have to meet and expose them to massive costs (and potentially inconsistent requirements) both on initial permit issuance and every five years thereafter, which could make many plants uneconomic.

Third, if EPA really means only to satisfy § 510, this provision is totally unnecessary. Section 510 would apply by its terms regardless of whether EPA reduces it to a rule (although EPA's rule, as we have said, goes far beyond § 510), and including such a rule only creates a new problem: does the rule itself now create an independent, federal requirement that CWIS meet water quality standards in some fashion?

Fourth, there is no apparent vehicle by which such requirements could be applied because, other than § 316(b), the Act gives authority to impose limits only on discharges (not intakes). Also, application of standards would infringe on resource management and allocation decisions typically made by other arms of state government. Is EPA eager to see States apply water quality standards for cropping to commercial and recreational fisherman as well? What about intakes for process water that are not even covered by EPA's data?

B. State Water Quality Standards Do Not Justify Additional Intake Requirements

For the reasons described above, water quality standards as we know them are ill-adapted to providing a basis for imposing CWIS requirements and would provide at best an open-ended and arbitrary standard. Most States adopted their standards over 25 years ago, based on little or no real data (either on uses attained or pollutant values needed to attain uses). Standards almost uniformly focus on water quality parameters, usually expressed as acceptable concentrations of specific pollutants. The exception is biological criteria, which an EPRI report (submitted as part of EPRI's comments on the proposed Phase I rule for new facilities) showed were poor predictors of CWIS effects. EPRI 2000. EPA appeared to agree with this view in the rule for new facilities.

Section 316(b) is a narrowly drafted provision, unique in the CWA, that requires the application of certain technologies that qualify as the "best available" and are relevant to specific attributes of a CWIS, where necessary, to minimize AEI.

Furthermore, all limits must be applied through the NPDES permit program under CWA § 402, 33 U.S.C. § 1342. The NPDES permit program applies only to point source discharges – not to intake structures of any kind. While § 402 authorizes permits that require compliance with both §§ 301 and 316 (§ 402(b)(1)(A)), nowhere does it suggest that Congress intended to give EPA or States authority to impose additional limits on intake structures based on water quality. CWISs directly affect aquatic organisms, not water quality. The emphasis that § 402 places on discharges of pollutants, and limits on those discharges – with the sole exception of its one reference to § 316 – shows that this was not Congress' intent. In an analogous context, the United States Court of Appeals for the District of Columbia Circuit agreed, saying that § 402 allows EPA to impose limits on discharges to protect water quality only, not other attributes of the facility. See Natural Resources Defense Council v. EPA, 859 F.2d 156, 169-71 (D.C. Cir. 1988). <FN 55>

Further evidence of this is found in the water quality standards themselves. They consist of designated uses and numeric or narrative “criteria” for pollutants, <FN 56> which reflect State or federal judgments, adopted by rule, about what levels of pollutants will protect the designated uses. <FN 57> See 40 C.F.R. § 131.3(b) (1999) (criteria are elements of State water quality standards, expressed as constituent concentrations, levels, or narrative statements, representing the quality of water that supports a particular use (emphasis added)).

Although we understand that EPA has begun to encourage the States to adopt “biocriteria” that attempt to measure, based on biological indices, the health of a waterbody, EPA has no rule requiring such criteria. Nor should it, since such criteria have not been widely validated for many waterbody types and may not be feasible for some types of waterbody. In short, State water quality standards are not well adapted for precise interpretation with respect to § 316(b)-related effects. EPA should not invite State reinterpretation of water quality standards in this proceeding.

Finally, such a rule is simply unnecessary to achieve an appropriate level of protection. In adopting § 316(b), Congress recognized that it was important to protect aquatic populations and communities from over-cropping but that technological availability and cost also are relevant. This is the same sort of analysis a State can and should make when it sets water quality standards, which Congress said should take into account attainability of designated uses. See CWA § 303(c)(2)(B), 33 U.S.C. § 1333(c)(2)(B) (states shall set standards that include the highest uses whenever attainable, after considering the use and value of waters for various uses, including industrial use). Section 316(b) allows both a better-calibrated, site-specific assessment of whether CWIS effects will cause “adverse” environmental effects and a more accurate assessment of what level of minimization is attainable than a water quality standard ever could.

Footnotes

55 As the NRDC Court stated:

EPA can properly take only those actions authorized by the CWA – allowing, prohibiting, or conditioning the pollutant discharge. And, contrary to EPA’s assumption, the CWA does not empower the agency to regulate point sources themselves; rather, EPA’s jurisdiction under the operative statute is limited to regulating the discharge of pollutants. Thus, . . . the agency is powerless to impose permit conditions unrelated to the discharge itself. . . . EPA may not, . . . under the guise of carrying out its responsibilities under NEPA, transmogrify its obligation to regulate discharges into a mandate to regulate the plants or facilities themselves. To do so would unjustifiably expand the agency’s authority beyond its proper perimeters.
Id. at 169-70.

56 EPA also has said that “antidegradation” provisions are enforceable components of the standards. But under EPA’s water quality standards regulations, those provisions too apply only to water quality and effects on water quality, not to intake effects. See 40 C.F.R. § 131.12 (1999).

57 In other contexts, EPA has suggested that State and federal permit writers should “interpret” their designated uses or narrative criteria on an ad hoc basis, whenever they are concerned about a pollutant for which the State has not adopted a criterion. See 40 C.F.R. § 122.44(d)(1999). While the United States Court of Appeals of the D.C. Circuit upheld this rule in a challenge brought by industry, it also clarified that any ad hoc interpretation proposed in a permit must be justified by an adequate record and remain subject to challenge. See American Paper Institute v. EPA, 996 F.2d 346 (D.C. Cir. 1993). In any case, this rule, which until now has been EPA’s only regulation governing when and how water quality-based limits may be established, speaks to the establishment of limits only on pollutant discharges, not intake structures. EPA may not reinvent its interpretation of the water quality provisions of the statute without a good reason, and it does not have one in this

case.

EPA Response

Today's rule recognizes a State's authority to adopt more stringent requirements. EPA disagrees with the commenter's assertion that today's action encourages states to adopt more stringent 316(b) requirements. Rather, as the commenter correctly notes, EPA is fulfilling its obligation under § 510 of the Clean Water Act to maintain a State's authority to determine for itself if more stringent requirements are appropriate.

RFC: Should EPA include impingement trading?

EPA'S PROPOSED TRADING AND BANKING PROGRAMS ARE GOOD POLICY

EPA has proposed trading and banking programs for § 316(b). UWAG strongly supports trading and banking. They are desirable because they are flexible and market-based and can be watershed-based. They are also consistent with EPA's long-term strategy of emphasizing market incentives and other nontraditional regulatory mechanisms instead of "command-and-control" regulations. See EPA Strategic Plan 2000.

EPA Response

Please see response to comment 316bEFR.034.027 regarding the role of trading in today's final rule.

Spatial scale for entrainment trading

Trading should be allowed among facilities (1) on the same waterbody, (2) in the same watershed, and (3) among all coastal stocks in the oceans. EPA should allow one species to be traded for a different species, if the trade makes sense for the management of fishery resources.

EPA Response

Please see response to comment 316bEFR.077.051 for the discussion on the appropriate spatial scale of trading. EPA expects that it would have difficulty approving programs that do not trade numbers of the same species because EPA does not believe it is possible at this time to quantify with adequate certainty the potential effects on ecosystem effects on ecosystem function, community structure and biodiversity when one species is traded for a different species.

RFC: Potential trading units/ credits

At 67 Fed. Reg. 17,171-72 EPA discusses what units (or credits) might be used for trading. As EPA's discussion shows, several different approaches have their various benefits and limitations. The suitability of any one of these approaches depends on the species of fish, its life history, the lifestage that is of concern, and other site-specific factors. Therefore, EPA should keep the trading system flexible and allow a variety of units to be used. With time, experience may show that some units work better than others, but limiting the types of units at the outset would limit the ability to gain that type of experience.

EPA Response

Please see response to comment 316bEFR.077.052 for the discussion on the appropriate unit for trading.

EPA NEEDS TO CLARIFY WHAT DATA NEED TO BE COLLECTED

A. Permittees Should Be Able to Use Existing Data for the Comprehensive Demonstration Study

EPA's proposal to allow the use of existing data, so long as the data still reflect current conditions, is appropriate and important. Starting fresh with new studies and ignoring already-existing data would be expensive and inefficient.

EPA Response

EPA agrees that existing historical data, as long as it reflects current conditions, should be available for use in completing studies. Please see response to comment 316bEFR.040.001 for details.

Comprehensive demonstration study (7 parts)

Some of the Criteria for the Impingement and Entrainment Characterization Study Should Be Clarified

EPA invites comment on whether the narrative criteria it uses to describe the required impingement mortality and entrainment characterization study <FN 58> "are sufficiently comprehensive and specific to ensure that scientifically valid, representative data are used to support the various approaches for determining best technology available for minimizing adverse environmental impact." <FN 59> 67 Fed. Reg. 17,148 col. 3. EPA further invites comment on whether it should set specific minimum monitoring frequencies or specific requirements for dealing with the uncertainty inherent in biological sampling. Id.

EPA's proposal requires characterizing (a) the biological community and (b) the vicinity of the intake and mentions "community-level" information. It is not clear what "in the vicinity" means or what use community-level information has in applying the rule. EPA should clarify these points.

In general, due to the differences between aquatic biota and the environments they inhabit, specifying sampling frequencies and attempting to deal with uncertainty in some abstract fashion is not effective. The permittee, having evaluated available data and being familiar with the facility's operation, is in the best position to design an appropriate sampling program. The permittee also has a strong interest in reducing – to the degree feasible – the uncertainty of any study results. It is simply impossible to set generic sampling standards that would be equally effective in all locations. Therefore, the rule should provide that the permittee, with review and approval from its permitting authority, should design and implement an impingement mortality and entrainment characterization study and that the resulting report should describe areas of uncertainty.

EPA's criteria for the characterization study are quite rigorous, and EPA should explicitly recognize that the characterization study need not present comprehensive, site-specific data for all the criteria EPA lists. For example, the proposal requires the permittee to conduct enough sampling to define diel variations in species location (due to such factors as climate/weather differences, spawning, feeding and water column migration). Proposed 40 C.F.R. § 125.95(b)(3)(ii). Even a several-year period of sampling may be inadequate to capture and assess the diel movements of numerous species.

For these reasons, EPA should endorse the appropriate use of literature information on species behavior as a surrogate for some portions of the characterization study. For example, it is well documented that some estuarine species (such as herrings, anchovies, and opossum shrimp) generally move into deeper waters during the daylight hours to avoid predators and disperse up into the water column at night to feed.

The permittee ought, therefore, to be able to use available literature to make reasonable assumptions about fish movements when there is no reason to suspect that site-specific conditions interrupt a species' normal behavior. Literature information may also be important in identifying species likely to be "most susceptible" to impingement and entrainment and in estimating likely impingement mortality. In short, the characterization study, while documenting the primary species most susceptible to impingement mortality or entrainment, should rely on a mix of information from various sources, including scientific literature, previous studies of the facility, and, where necessary, newly collected data.

Footnotes

58 As pointed out in other sections of these comments, UWAG strongly recommends that EPA focus on entrainment survival, rather than entrainment, due to the proven, high entrainment survival rates for some species.

59 Apparently, EPA means to refer to § 125.95(b)(3) in this comment request, rather than § 125.95(b)(1).

EPA Response

EPA agrees that the permittee is in the best position to design an appropriate sampling program; because of this, EPA has required a sampling plans to be included when a facility submits a Verification Monitoring Plan. Today's rule also specifies requirements for the Technology Installation and Operation Plans and Restoration Plans, if used. All of the parameters presented in the plans must be reviewed and approved by the Director.

EPA also agrees that existing information pertaining to the species found in the vicinity of a facility's intake is acceptable for use in the Comprehensive Demonstration Study, and will welcome information from a variety of sources so long as they are reflective of the species or conditions at the facility. For EPA's position on using historical data, please see EPA's response to comment 316bEFR.034.005.

Regarding the definition of "in the vicinity" of the facility, EPA disagrees that it should put forth a "one-size-fits-all" definition. The permittee and Director will be best positioned to determine which species are located in the vicinity of, and therefore potentially affected by, the facility's intake.

Finally, the term "community-level" refers to the assemblage of species found at a facility's intake.

Monitoring requirements

Compliance Monitoring Should Be Tailored to the Technology and the Site

Any compliance monitoring requirement in the permit should be tailored to the intake technology selected and the amount of data already collected. Further, once the permittee has completed its compliance monitoring for the initial permit term, it should not be required to repeat the monitoring after every permit renewal.

For innovative, largely untried technologies, the rule should be especially flexible and allow permittees to tailor a reasonable monitoring plan to the technology. For emerging technologies with more experience, more monitoring might be required than for established technologies. For established technologies, the permittee should have to demonstrate only that the technology approved by the permitting agency has been properly installed, operated, and maintained.

EPA proposes that verification sampling be done once a month for impingement and biweekly (every two weeks) for entrainment. This, again, is too inflexible. The sampling schedule should be tailored to the needs of the site.

EPA Response

EPA agrees that compliance monitoring should be tailored to the needs of the site. For this reason, in each of the monitoring plan submittals, the permit applicant must specify monitoring parameters for review and approval by the Director. Please see EPA's response to comment 316bEFR.074.023.

Performance standards

NUMERIC PERFORMANCE STANDARDS CANNOT BE USED AS NUMERIC PERMIT LIMITS

A. Under UWAG's Simpler Alternative, Compliance Monitoring Should Be Based On Technology Operation and Maintenance Requirements

As indicated in Section VI, UWAG's simpler alternative to EPA's performance standards approach involves selecting the most cost-effective technology from EPA's list of recommended technologies, taking into account site-specific factors. Under UWAG's alternative, permit conditions relating to § 316(b) would address only whether the permittee properly operates and maintains the selected and approved technology. Permit conditions, for instance, might require the permittee to inspect the technology regularly and document its inspections. The conditions might also require the permittee to maintain the technology according to the manufacturer's recommendations. In any event, since the UWAG alternative does not use impingement/ entrainment reduction performance standards to address technology selection, it would be infeasible to apply such performance standards as a compliance measurement, because there would be no "baseline" data to measure reductions against. Further, as discussed in Section VI, there is no legal reason why a technology-based regulation under § 316(b) has to have numerical standards. EPA may adopt other, non-numeric permit conditions.

EPA Response

Please see response to comment 316bEFR.307.064 and 316bEFR.311.002. Please see response to comment 316bEFR.029.040. For a discussion of Technology Installation and Operation Plans and their role in compliance with the requirements of today's rule, please see the preamble. In addition, EPA agrees that it is not required under section 316(b) to express today's requirements as numerical standards. EPA's decision today to express the rule's requirements both numerically and non-numerically reflects EPA's attempt to ensure that all facilities within the scope of Phase II would implement what was for them the best technology available for minimizing adverse environmental impact.

Determination of compliance

Author Name Hunton & Williams
Organization obo Utility Water Act Group

If EPA Retains the Performance Standard Approach, Compliance Monitoring Should, At the Most, "Benchmark" Reductions

UWAG firmly believes that its site-specific approach, or its simpler EPA-recommended technology approach (Section VI), are more valid and defensible regulatory options than EPA's performance standards. If EPA nonetheless persists in its conviction that technologies ought to be chosen on the basis of its proposed performance standards, the best solution for compliance monitoring would be to use operation and maintenance permit conditions, as suggested above for the UWAG approach. If, after installation of the chosen technology, there remains a significant degree of uncertainty about how well it is working, the permitting authority would have the option of requiring a reasonable amount of impingement/entrainment monitoring, considering site-specific circumstances, during the permit term. The results of the monitoring would be measured against the performance standards, but the standards would be considered benchmarks or targets, rather than rigid limits. If the technology's performance fell short of the performance standards, the permittee would have the option of demonstrating that the cost of achieving additional incremental controls necessary to meet the target was not warranted by either the cost-cost test or the cost-benefit test.

In any event, and under any regulatory option that EPA may choose, it is important that compliance with any numeric performance standards or targets not be judged during the permit term, but rather in the subsequent permit renewal process. In most cases, it is simply not feasible to evaluate biological monitoring data over the course of a few months and reach any firm conclusion.

EPA appears to acknowledge the need for an approach of this kind in the preamble to its proposal. 67 Fed. Reg. 17,143 col. 3. There, it specifically asks for comment on whether compliance with appropriate operation and maintenance requirements should be used as the gauge for compliance with the permit, so that any shortcomings in technology performance vis-à-vis the performance standards would trigger only evaluation of other possible technology alternatives. UWAG agrees with this concept and suggests that EPA follow the approach outlined above to implement it.

EPA Response

EPA disagrees that monitoring should be conducted only to gather information or should be discontinued if a facility achieves the performance standards. However, EPA has included in today's final rule several alternatives for achieving compliance, including demonstrating compliance with a Technology Installation and Operation Plan in place of numeric performance requirements. For a discussion of how compliance is to be determined, please see , e.g., EPA's response to comment 316bEFR.017.003. For EPA's explanation of EPA's monitoring requirements, please refer to EPA's response to comment 316bEFR.307.027. Also please see the final rule preamble for a discussion of the Technology Installation and Operation Plan.

For an explanation of why EPA did not choose UWAG's recommended approach, please refer to the final rule preamble section VII. E., Major Options Considered for the Final Rule and Why EPA Rejected Them.

Permit applications/implementation schedule

PERMIT REQUIREMENTS MUST ALLOW FOR THE TIME NEEDED TO COLLECT DATA, ANALYZE IT, AND DESIGN, INSTALL, AND TEST INTAKE TECHNOLOGY

Because of the unusual nature of § 316(b), a good case can be made that it should be a one-time only requirement – that is, once "best technology available" is determined for a plant, installing and operating that technology ought to relieve the plant of further § 316(b) obligations for life. The "location, design, construction, and capacity" of the cooling water intake structures are matters of design and construction, not operation, and Congress could not have intended that power plants be in the business of redesigning, demolishing, and reconstructing key components of their physical plant every five or ten years.

Taking into account § 316(b)'s uniqueness in the CWA scheme, the most appropriate way to apply it would be as the National Environmental Policy Act (NEPA) is applied to, for example, a construction permit: a one-time review designed to achieve minimal "adverse environmental impact" at a reasonable cost.

If, on the other hand, EPA holds to its proposal to implement the § 316(b) rule by requirements in NPDES permits (which have to be renewed every five years), then two important questions arise. First, how are new requirements of the rule to be implemented for the first time? Second, what effect is the new rule to have on subsequent permit renewals that must take place every five years over the life of a facility?

A. The Application Process Requires Certain Steps to Be Completed, Some of Them Time-Consuming

A permit application addressing § 316(b) will presumably have to be submitted 180 days before an existing permit expires. The 180 days is the time provided in the current permitting regulations between permit application and expiration of the permit to allow for agency review.

EPA's Information Collection Request (ICR) (DCN:4-0001) raises puzzling questions about EPA's intentions as to the initial implementation schedule. For example, on page 47, the ICR says that 350 of the 539 in-scope facilities are scheduled to have permits issued during the first three-year ICR period (9/2000-8/2004). It adds that:

These facilities [i.e., the 350] will be on an accelerated schedule and thus will receive their permits as scheduled. Since these are existing facilities, it is assumed that they will be able to draw on some existing data. In addition, EPA assumes that these facilities will have reopener clauses included in their permits to allow for the results for the Impingement Mortality and Entrainment Characterization Studies to be submitted after permit issuance and for the permits to be modified based on the results of these studies, if necessary. The remaining 189 facilities will not receive their initial permit renewals until after the ICR approval period, and thus will have the full three years to perform their Impingement Mortality and Entrainment Characterization Studies prior to receiving their initial permit renewals.

Although this passage is not entirely clear, it does recognize the need to consider where a permittee is in the application process when the § 316(b) rule becomes final. For example, a permittee who has already submitted an application for permit renewal when the new rule comes out in the Federal Register should not have to go back and rewrite the application to satisfy the new rule. Likewise, a permittee who is only a few days or weeks before the deadline for application cannot be expected to comply with the new regulation on the old permitting schedule.

Moreover, EPA needs to give some thought to the different amounts of time that will be required to determine what will satisfy the new rule at different sites. Consider a best-case situation, where a facility already has performed a § 316(b) demonstration, where the data are still representative of current conditions in the waterbody, and where no additional construction or modification of the intake structure or installation of screens will be required. Even then, a permittee still might require six months to analyze existing data to demonstrate compliance with the 80-95% impingement mortality reduction and 60-90% entrainment reduction and then to write up a permit application.

A different facility might need far more time. It could easily require two, three, or even more years of biological monitoring to collect the data needed to calculate the impingement mortality and entrainment for the baseline, determine what technology might be required, calculate the impingement mortality and entrainment reduction to be accomplished by the new technology, and write up all this information in a permit application. If part of the solution was to create or improve a wetland, even more time would be needed to find a suitable wetland site and prepare a plan for improving it, let alone for doing the work and monitoring its success.

1. The Best Way to Implement the BTA Requirements Would Be to Impose a Permit Condition Setting Out a Process for Choosing BTA

The best way to implement the § 316(b) rule would be to have the permittee, as part of its permit application package, propose a schedule for developing the data collection plan, getting approval from the Director, collecting and analyzing the data, using the data to assess technologies, and preparing the BTA recommendation. This process, once approved by the permitting agency, would be written into the permit as a permit condition, as would be the physical implementation or installation of the BTA once it was selected.

The permit could require that once the technology was finally selected, it would be installed within a certain amount of time (which time limit would have to be chosen carefully, since at the time the permit was written the choice of technology would not yet be known). Alternatively, the permit could be modified, once the technology was chosen, to require that it be installed and operated. This would allow permits to be issued faster and eliminate most of the timing problems.

2. Time Must Be Built In for Agency Review

In the schedule described above for gathering data and choosing BTA, time must be allowed for the permitting agency (the Director) to review and approve the key steps. For example, the Director will need to approve the data collection program and also, later, the permittee's choice of technology. The § 316(b) rule should make clear that time for agency review must be built into any schedule either prescribed by the rule itself or required by an NPDES permit condition.

3. A “Grandfather” Period Is Needed for Permittees Who Are Very Near the Application Deadline

If EPA does not adopt the above-suggested reasonable approach of prescribing a data collection and analysis schedule in the permit, it will have to be much more careful about thinking through the timing of the § 316(b) requirements in the future. For permittees who have applied already for a permit renewal when the § 316(b) rule becomes final and are thus in the period of agency review of the application, the permittee should not have to redo its application on account of the new rule. In such a case, the succeeding five-year permit term should be the time in which the permittee complies with the new rule.

Similarly, if the new rule becomes final when a permittee is very near the time when his or her renewal application is due (for example, between 18 months and six months before his permit expires), it would be almost as unreasonable to require him to adjust his application process to the new rule. The practical difficulties in preparing a permit application, especially if biological monitoring is needed, suggest that the new rule should not apply, until the succeeding permit term, to anyone who has 18 months or less until his permit expires when the § 316(b) rule becomes final.

4. Time Is Needed to Collect Data and Prepare the Application

Assuming a permittee is more than 18 months away from having his permit expire (that is, more than 12 months away from having to file a renewal application), then it might be reasonable to expect him to complete an application to comply with the new rule during the present permit term. Whether this is possible depends on the permittee’s situation. UWAG has said all along that how § 316(b) applies is site-specific, and that is as true of scheduling as of biology.

a. Collecting Data Will Take Time

If the permitting authority expects to approve a permit requirement for new § 316(b) technology, then it will have to have a good deal of information. Assuming that some change will be required to meet the 80-95% and 60-90% reduction criteria, such as new fine mesh or wedgewire screens, then the applicant will have to provide, and the agency will have to review, several things. First, the permittee may have to collect biological data. In particular, if the facility is subject to the entrainment standard and its present configuration is not a shoreline intake with no impingement or entrainment reduction controls, then the permittee may have to sample the density of entrainable eggs and larvae at the place where such a baseline intake structure would have been placed. It may have to collect these data at certain times of the year when eggs or larvae are present, such as the spawning season, and this monitoring may have to be done for several different species. Then the egg and larvae density data will be used, along with information about the volume or flow of the waterbody and the intake flow, to model the number of eggs and larvae entrained for the baseline, for the existing intake technology, and for any new intake technology that may be required. An analysis will have to be done for impingement as well. <FN 60>

b. Analysis and Preparation of the Permit Application Will Take Time

The permittee then will have to calculate the impingement mortality and entrainment at the plant as it is now configured to determine whether the 80-95% and 60-90% criteria are met by the plant “as is.”

If not, the permittee must explore new technologies, such as installing wedgewire screens, fine mesh screens, or an aquatic filter barrier. The permittee then has to do an analysis to show that one or more new technologies would reduce impingement mortality by 80-95% and (except for lakes and a few other waterbodies) entrainment by 60-90%. This analysis might have to be done for a variety of technologies and combinations of technologies, and the permittee might choose to analyze restoration measures or operating restrictions as well. If the costs are too high, the permittee may opt to do a site-specific cost-cost or a cost-benefit analysis of available technologies. The results then would have to be written into a permit application and the data presented in a format that allowed the permit writer to review them.

c. Preparing the Application Could Require Two Years or More

Depending on the complexities of the site and the amount of data already available, then, preparing an application could take two or more years – let us say at least two years to collect data and half a year to analyze the data and write a permit application. Even this 2½-year period might not be enough to compare alternative intake technologies and design a new set of screens, let alone plan a wetland restoration. For a facility that required all this work before an adequate application could be completed, it would be unreasonable to require a completed application less than 2½ years after the rule became final.

d. EPA Could Allow a Simpler, Interim Application

One solution would be to require a complete application in compliance with the new rule only for permittees whose permits are due to expire more than three years after the rule becomes final (thus allowing 2½ years to prepare the application before it is due). A shorter period could be provided if the application was not required to have the final answer of what BTA to install, but rather a conceptual plan for gathering the biological data and designing the intake technology.

Thus, EPA could require a full-fledged application with proposed technology for permittees whose permits expired more than three years after the rule becomes final and no compliance with the new rule (until the following permit term) for those with only one year or less left to prepare an application for renewal (that is, 18 months or less before permit expiration) when the rule becomes final. EPA could require a more abbreviated, conceptual application (including a plan for data collection and analysis) for those in the middle – those with less than three years before their permit expires (that is, less than 2½ years before the application is due) but more than one year before the application is due. Thus:

Time Before Permit Expiration When § 316(b) Rule Becomes Final

[see hard copy for figure]

If a less ambitious, conceptual application was allowed for people in the middle group, it would have to satisfy the permit writer that the permittee had an adequate plan for collecting data. The permit, when issued, would need to allow a reasonable compliance schedule for collecting the data, designing new screens or procuring an aquatic filter barrier, installing the equipment, and testing it. This compliance schedule should take into account what seasons of the year data might have to be collected in and should provide for doing construction, installation, and testing during planned outages so as to minimize the impact on electric power supply.

e. Despite the Need for a Grandfather Period, EPA Should Allow a Facility to Choose to Comply with the New Rule Early

Notwithstanding the timing requirements outlined above, some facility operators may prefer to meet the requirements of the new § 316(b) rule even though they are already well into the application process when the rule becomes final. EPA should permit such operators to choose to comply with the new rule earlier than required, rather than take advantage of any grandfather period that might be allowed. Although a grandfather period is definitely necessary, the rule should not require anyone to use it.

B. Time Is Needed to Install and Test Equipment

Even a permittee who has time to prepare a complete application by 180 days before his permit expires will need a compliance schedule after the permit is issued, if changes in the intake are needed to satisfy the new rule. He will need this in order to install and test the new screens or filter or fish return system. A compliance schedule should provide for installing the new equipment during a regularly planned outage. If part of the solution was restoring a wetland or building a fish hatchery, of course, more time might be required. The rule should allow for this contingency.

C. It Would Be a Mistake to Make the New Rule Immediately Effective and Rely on Administrative Consent Orders While New Technology Was Being Installed

Because so much time has passed since § 316(b) was originally enacted by Congress, there may be some inclination by EPA to make the technology requirements of the new rule immediately effective. Since this would put some facilities overnight in violation of the law, it probably would violate due process. EPA might try to alleviate the hardship by some stopgap measure such as wholesale resort to administrative consent orders.

However, it would be neither fair nor appropriate to make the requirement for BTA immediately effective and then use administrative consent orders to suspend enforcement until the technology could actually be installed. Nor is it necessary to do this. EPA has the authority to define "compliance" as an approved program or plan for collecting the necessary data and choosing and installing appropriate technology.

Section 316(b) says that "[a]ny standard established pursuant to Section 1311 of this title or 1316 of this title and applicable to a point source shall require that the location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact." 33 U.S.C. § 1326(b). In this sense, § 316(b) is tied to the "standards" of § 301. (Since the present rulemaking is for "existing" facilities, the reference to "standards of performance for new sources" in § 306(b)(1)(B) does not apply.)

Section 301(b) provides that "best practicable control technology" and water quality standards-based limitations should have been achieved by July 1, 1977. 33 U.S.C. § 1311(b)(1)(A). "Best available technology" requirements for toxic pollutants are to have been achieved no later than 1981. § 1311(b)(2)(C), (D). Finally, §§ 301(b)(2)(E) and (F) provide for compliance in no case later than

March 31, 1989. Thus, the requirements of § 301 for "existing" facilities, according to Congress' original intent, are supposed to have been achieved by March 31, 1989.

Nevertheless, this cannot mean that the § 316(b) rule for existing facilities must be effective by that date. The reasons are three:

1. The statute does not say that the § 301 deadlines apply to § 316(b). The statute is (at best) ambiguous on the deadline for § 316(b), and EPA is entitled to interpret it in a reasonable way.

2. It is impossible to have immediate compliance with a rule that will require in many cases biological studies, analysis, design, and construction. Congress could not have intended that existing facilities comply with a complex new § 316(b) rule instantaneously.

3. It would be a denial of due process of law to require immediate compliance with a new rule that requires expensive and time-consuming construction.

Section § 316(b) is separate and distinct from § 301 and does not itself contain a deadline. It is hardly necessary to point out here that "best technology" under § 316(b) is different and distinct from, for example, "BAT" under § 301. The § 301 standards apply to the discharge of pollutants; § 316(b) regulates features of intake structures. All § 301 says is that § 301 standards "shall require" that § 316(b) be met; it does not say when.

Moreover, § 316(b) clearly requires, at least in some cases, significant construction. It is not possible to comply with regulations that require construction instantly upon promulgation of the regulations. It would be irrational to suppose that Congress intended instantaneous compliance, especially since in other sections of the Act Congress painstakingly laid out schedules for phasing in new requirements.

Finally, it would violate due process to require instant compliance with a new rule that requires extensive analysis and construction. The Due Process Clause of the Constitution requires that regulated entities have reasonable notice of legal requirements to which they will be subject. There can be no reasonable notice when a new requirement is made to apply instantly.

The notion of throwing many facilities into noncompliance and solving the problem by consent orders is a very poor one. Consent orders may carry the stigma of breaking the law and may not prevent citizen suits by third parties. EPA would do better simply to write a reasonable compliance schedule into the rule and provide for compliance schedules in NPDES permits.

D. Reasonable Compliance Schedules Are Necessary to Avoid Disruption of the Permitting Process

The above scheduling concerns are important because of fairness to permittees, but they are important also for practicality. If EPA were to make the new § 316(b) rule immediately applicable, it would lead to more, rather than less, delay in the NPDES permitting process. For one thing, the available consultants who can help with biological monitoring and design of intake technology would undoubtedly be overworked and would have to put many permittees on waiting lists. Moreover, negotiations over consent orders might well bog down the permit process in some States. Undoubtedly the backlog of unprocessed NPDES permit applications would grow worse. Reasonable compliance schedules are a matter of administrative necessity as well as of fairness to permittees.

Footnotes

60 There is a current shortage of trained larval taxonomists, especially those capable of identifying freshwater larvae. UWAG believes there may be only 12-15 freshwater larval experts nationwide. Therefore, if many facilities need to perform studies requiring larval identification within a short period of years, there will be an extreme shortage of experts capable of performing this work.

Permit applications/implementation schedule

The Time Needed for Compliance Monitoring Differs from Site to Site

Since § 316(b) is different from either the water quality-based requirements of § 303 and § 301(b)(1)(C) or the technology-based requirements of §§ 301 and 306 and since EPA's performance standards are based on certain specific intake technologies that EPA has found to be effective (wedgewire screens etc.), the most appropriate way to ensure compliance would be to require the permittee to install one of the selected technologies and then monitor simply to be sure that it was being maintained and operated correctly.

As EPA has constructed the rule, facilities may need to do impingement/entrainment compliance monitoring, but only as specified by their permitting authority. Proposed 40 C.F.R. § 125.96. This flexibility make sense, since many facilities have been thoroughly studied and their regulators have adequate data already about the performance of impingement/ entrainment reduction equipment. Yet EPA also would require facilities subject to the rule to design and submit a two-year plan for compliance monitoring. Proposed 40 C.F.R. § 125.95(b)(7). This provision may, for all practical purposes, remove the flexibility provided in § 125.96, because regulators may simply require that the submitted two-year plan be carried out, without considering whether such a plan is necessary in light of existing data or adequate to access accurately the efficacy of the installed technologies.

To take another example, on larger river systems like the Mississippi River and Illinois River, it may take as many as 10 years to effectively demonstrate that new technology has achieved reductions consistent with EPA's performance standards. This may indicate a need to perform source water sampling after the monitoring phase. Such monitoring is costly and subject to seasonal river variations that may have to go on for years until such time as an improvement in impingement or entrainment can be demonstrated. In Midwest river systems that are subject to river flooding in the spring and summer, flooding may coincide with typical fish spawning periods. At such times environmental conditions would have more impact on entrainment than intake technology would. It would be difficult to compare a reduction in entrainment or impingement numbers and take credit for it when environmental conditions, not newly installed technology, would be determinative.

But a period of two years as a minimum is needlessly inflexible. At some facilities, much less than two years of monitoring will be required. This would be the case, for example, if a plant had collected copious data already and if no change to the plant was required by the new rule. On the other hand, two to five years of monitoring might be required at some estuarine sites where fish populations vary widely from year to year.

If biological monitoring is required, UWAG recommends that, after a verification monitoring period, the data should be analyzed to determine whether the newly installed technology is indeed achieving 80-95% reduction in impingement mortality and 60-90% reduction in entrainment. As long as the data showed performance within these ranges, the technology should be deemed to comply with the rule. For example, if the entrainment reduction technology was predicted to reduce entrainment by 85% but in fact achieved only 80%, that should be sufficient.

Assuming the data showed performance within the ranges, then no further biological monitoring should be required. Instead, the permittee should be required thereafter simply to monitor and document that it continued to operate and maintain the technology.

If the initial monitoring showed that the technology was not achieving reductions with the performance standards, on the other hand, then there seems to be no fair alternative but to provide for a period of additional study to determine what went wrong and what should be done to fix it, including the replacement of the technology with something different, if necessary and if the cost is not excessive.

EPA Response

Today's final rule requires that monitoring be conducted in accordance with the verification monitoring plan (125.95(b)(7), the Technology Installation and Operation Plan (125.95(b)(4)(ii)), if selected, and, if applicable, the Restoration Plan required at 125.95(b)(5). The Director may consider additional monitoring requirements as well. Specific study parameters may be proposed by the applicant for review and approval by the Director. For a discussion of EPA's reasons for choosing a two-year minimum monitoring period, see the preamble and other comment responses in this record.

Permit applications/implementation schedule

Permit Terms Should Use Appropriate Averaging Times

As already noted, the best solution to the compliance issue would be to require in the NPDES permit that the appropriately selected intake technology be installed and then maintained and operated properly. The alternative of requiring a permittee to prove periodically that he is entraining or impinging a specified percentage of fish would be highly variable, very expensive, technically unsound, and unfair.

Suppose, however, that EPA retains its numeric performance standards and that a permittee has chosen a technology (wedgewire screen, fine mesh screen, or aquatic filter barrier) that it predicts will reduce entrainment (compared to the baseline) by 75%, thus meeting the entrainment performance standard. How should the permit requirement be written to implement its commitment to install and operate this technology?

Because of the variability of biological systems and the lack of control that a permittee has over fish and shellfish in the water, it would be unfair to write a permit term requiring the permittee to reduce entrainment by 75% or, for that matter, to achieve any fixed numerical limit on the biomass or number of organisms entrained. Any performance within the specified ranges of 80-95% and 60-95% should count as compliance.

Over what period of time should the percentage reductions be calculated? As suggested above, the permittee would be required to monitor for a period of time, which would be two years or less for most plants and possibly up to 5 years for some estuarian plants. The averaging time for determining compliance should be the period of monitoring, usually two to five years. Thus, if a plant were required to monitor for two years after installation of new technology and calculated that the technology reduced entrainment by 50% the first year and 70% the second year, for a two-year average of 60%, then it should be considered in compliance with § 316(b). Because of the natural fluctuation of aquatic populations, a short averaging time would be unfair.

But a longer averaging time can be unfair as well. For example, if the plant has monitored for two years and discovered only at the end of that time that it has not achieved the 60-90% reduction in entrainment, then it might, in theory, face two years' worth of penalties for "noncompliance." For the same reasons as cited above (the natural variability of aquatic populations and the lack of control of the permittee), failure to meet the performance standards after several years of monitoring should not be considered a "violation." It should be a signal that additional study is needed, with a suitable compliance schedule for improving performance.

The above recommendation means that, once the permittee has demonstrated that his technology performed within the performance standard ranges, he would have only to maintain and operate the same technology for the life of the plant and would not have to make repeated demonstrations. This is a fair proposal, given that § 316(b) is a construction-type requirement, that fish populations are highly variable and subject to many stresses besides cooling water intakes, and that the permittee has limited control over what animals approach its intake.

EPA Response

Today's final rule requires that monitoring be conducted in accordance with the verification monitoring plan (125.95(b)(7), the Technology Installation and Operation Plan (125.95(b)(4)(ii)), if selected, and, if applicable, the Restoration Plan required at 125.95(b)(5). The Director may consider additional monitoring requirements as well. Specific study parameters may be proposed by the applicant for review and approval by the Director.

In meeting performance standards, any percentage within the rule specified range (80%-95% for impingement mortality, 60%-90% for entrainment), would be deemed in compliance. For a discussion of how compliance with today's rule will be determined, please see the preamble to the final rule.

Implementation

The Permit Should Allow the § 316(b) Technology to Be Bypassed if Necessary for Plant Operation

The permit should have a provision, analogous to EPA's "upset" and "bypass" provisions in the NPDES permit regulations, to allow an intake technology to be bypassed, if necessary, for plant operation. For example, if the screens are fouled so as to jeopardize plant operation, the permittee should be allowed to bypass them until they can be cleared. Such exceptional bypasses should be allowed only for short periods of time, until the emergency has passed and the permittee has had time to restore the intake technology to proper operation. A bypass provision also could be useful in the event that an emergency situation beyond the control of the plant operator (such as terrorist threats or actions to destroy dams) arose.

EPA Response

For a discussion of compliance, see response to comment 316bEFR.063.005.

Permit applications/implementation schedule

THERE IS NO NEED TO RE-DO THE § 316(b) ANALYSIS EVERY FIVE YEARS

EPA's proposed rule suggests a "comprehensive reevaluation" of the § 316(b) demonstration every time a permit is renewed. This is unnecessary. Once a successful § 316(b) demonstration is made, maintaining and operating the technology for the life of the plant should be enough. At a minimum, there should be no reconsideration for at least ten years, absent evidence that conditions have so changed that the aquatic community is threatened.

Another way to put it is that, after a successful demonstration of compliance with EPA's performance standards, at each later permit renewal the permit writer should accept the initial demonstration, unless there have been significant changes in plant operations or material adverse changes to the aquatic populations. This has been EPA's position, as reflected in guidance issued by EPA's Office of General Counsel to the regions over 20 years ago (Cooper 1982). Conservation of scarce administrative resources (which EPA claims is essential) and practicality weigh in favor of retaining that policy.

EPA Response

EPA agrees that a Comprehensive Demonstration Study may not need to be conducted each time a permit is renewed. As such, under 125.95(a)(3) of today's final rule, EPA offers an opportunity for reduced Comprehensive Demonstration Study requirements at each permit renewal cycle. Under this provision, the facility may receive reduced information collection requirements if conditions (such as biological, chemical, or physical) at the cooling water intake structure and waterbody remain substantially unchanged since the last permit issuance. The facility must request the reduced information requirements at least one year prior to the expiration of the existing permit and provide justification for each information requirement in 122.21(r) and 125.95 that they believe has not changed.

RFC: Application to "unique" facilities

EPA MAY NOT APPLY § 316(b) TO FACILITIES SUBJECT ONLY TO PERMITS FOR STORM WATER

EPA proposes to apply § 316(b) to existing facilities covered by NPDES permits (whether general or individual) applicable solely to storm water. UWAG believes that EPA lacks authority to do this, because such facilities are not subject to effluent limitations under §§ 301 and 306, which is a threshold requirement for applying § 316(b). Also, EPA's proposal to cover these facilities vastly increases the number of permits covered and raises numerous administrative issues that will serve only to increase burdens on State and federal permit writers – the opposite of EPA's avowed intention.

EPA's proposal also raises complex and troubling legal issues – for instance, does EPA have authority, as it claims, to issue to a general permittee a separate permit containing only intake limits? Section 402 of the CWA suggests it does not. If EPA were to take the position that it could require storm water permittees to obtain individual storm water/CWIS permits, would it not have to amend the storm water rules and the storm water general permits, estimate and justify the additional reporting and recordkeeping burden, and obtain OMB approval? If EPA were to attempt to include CWIS conditions in general permits, would it not need to prepare burden estimates, obtain OMB approval, and develop special mechanisms to ensure that such conditions apply only to relevant facilities?

All of these factors weigh against EPA's proposal to apply the § 316(b) rule to storm-water-only permittees with cooling water intake structures.

EPA Response

Regarding EPA's authority to address facilities permitted for storm water, see response to 316bEFR.035.001. With regard to the other issues raised, the commenter does not explain why EPA lacks authority to issue to a general permittee a separate permit containing only intake limits, other than to state, "Section 402 of the CWA suggests it [EPA] does not [have such authority]." CWA section 402 provides authority to issue NPDES permits to any facility that discharges any pollutant from a point source to waters of the U.S. By definition, any general permittee meets these requirements. In addition, section 316(b) requirements apply to any standard established pursuant to CWA sections 301 or 306, including standards applicable to the discharge of pollutants in storm water discharges. How such permits are administered concerns program implementation, rather than Agency authority. Implementation of this rule will comply with all relevant NPDES program regulations.

Similarly, the comment does not explain the commenter's other two concerns, but poses them as questions. In general, EPA notes that the existing general permit regulations (40 CFR 122.28) provide that individual permits can be required in certain circumstances. In addition, this Phase II final rule has been developed and promulgated according to applicable rulemaking requirements and includes appropriate provisions for its implementation. Finally, Directors will continue to follow applicable rulemaking and permit issuance requirements in pursuing any of the alternatives discussed.

Comprehensive demonstration study (7 parts)

EPA HAS NOT ADEQUATELY ASSESSED THE COSTS OF THE RULE

A. EPA Has Not Adequately Defined the Scope or Extent of the Impingement Mortality and Entrainment Characterization Study

In the proposed rule, EPA indicates that applicants are to conduct an Impingement Mortality and Entrainment Characterization Study (I&E Study) (see proposed § 125.95 b(3)). However, the only guidance provided is that the study should be "based on the collection of a sufficient number of years of data to characterize annual, seasonal, and diel variation in impingement and entrainment." 67 Fed. Reg. 17,222 col. 3.

The ICR bases its cost estimate on a three-year monitoring program, but EPA nowhere indicates whether a three-year program is the minimum EPA expects, the maximum applicants should plan for, or a mean period of time. In fact, there is no guidance whatever regarding the effort to be expended over the three-year program (assuming that is the duration EPA wants). Since this is the largest single cost identified by EPA (over $300,000 in Exhibit 35, 67 Fed. Reg. 17,209), EPA should make clear what it expects so that industry and the public can determine whether what is requested is reasonable. However, given the lack of details, we cannot comment either on the reasonableness or the cost of implementing the I&E Study.

Also, UWAG does not understand why there is such a large discrepancy in laboratory costs between the I&E Study and Verification (O&M) Monitoring. EPA estimates that lab costs (i.e., for enumerating and identifying larval samples) for the I&E Study will cost $117,000 in freshwater and $197,730 in marine water (ICR, Exhibit A.11). This is apparently in addition to the $300,000+ for the basic I&E Study referred to above. EPA estimates that the lab cost associated with verification monitoring will be only $7,800 in freshwater and $10,140 in marine waters. Even if these costs are doubled to account for a two-year verification monitoring period, there is still a fivefold difference in annual lab costs ($7,800 per year for verification monitoring vs. $39,000 per year for the I&E Study). Without details on study duration, sampling frequency, etc., UWAG cannot even speculate on why these annual lab costs are so different. UWAG's contractor tried repeatedly to obtain answers to these questions, but was unable to obtain the needed information.

EPA Response

EPA made available additional information regarding the Impingement Mortality and Entrainment Characterization Study at the time it published the NODA. For additional information see Updated Information Collection Costs for the 316(b) Phase II Notice of Data Availability, January 31, 2002 and Information Collection Request for the final rule.

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 9.06

Burden to facilities (general)

A Two-Year Verification Monitoring Program Will Cost Permittees More Than EPA Has Estimated

The proposed rule requires compliance monitoring, but does not specify minimum sampling frequencies or durations. However, in its Information Collection Request for the Rule (ICR) (DCN:4-0001), EPA developed costs for verification monitoring that apparently are based on the following level of effort:

-Duration – 2 years

-Impingement – samples collected at least once per month over a 24-hour period

-Entrainment – Samples collected at least biweekly over a 24-hour period during the primary period of reproduction, larval recruitment, and peak abundance.

To collect these samples, EPA estimated that annual costs (in 2001 dollars) would be as follows:

	Freshwater	Marine
Impingement	$16,985	$21,623
Entrainment	$37,369	$46,044
TOTAL	$54,354	$67,667

ICR, Table 8.

A review of these estimates shows clearly that EPA made several mistakes. EPA correctly assumes that much of the monitoring will be conducted by contractors hired by the facilities. According to information presented on page 54 of the ICR, the total markup on contract employees will be 2.2 to 2.3 times their actual salaries. Based on the utility industry's experience, markups of 2.5 to 3.0 on contract labor of this kind would be more realistic.

EPA assumes that consultants will collect and process the samples, but facility personnel will prepare all reports. Over the years, the utility industry has cut back greatly on the number of biologists it employs. Thus very few facilities have staff with the expertise (or time available) to prepare the required reports. As a result, most reports will be written by consultants at higher rates.

In Appendix A to the ICR, EPA developed cost estimates for activities required by the proposed rule. In all the tables, EPA has transposed the labor rates for statistician (shown as only $36 per hour) and biological technician (shown as $57 per hour). Thus, all estimates that include hours for one or both of these categories are wrong.

EPA correctly assumes that impingement sampling would usually be performed by contract labor. However, EPA incorrectly assumes that all sample processing will be done onsite and that no travel costs are associated with the contract labor. UWAG agrees that most specimens in a given impingement sample will be processed onsite. However, impingement samples are dominated by small species (minnows, silversides, etc.) and juveniles of larger species. In freshwater, numerous minnows, suckers (especially redhorse), and other taxonomically difficult species (e.g., hybrid Morone) are often present. Such specimens would need to be returned to the contract lab for proper identification.

Parallel taxonomic problems exist in marine waters. In the industry's experience, few samples can be processed entirely in the field. Samples that must be returned to the lab need to be preserved, labeled, and examined under microscopes, all of which will add to the cost estimates developed by EPA.

EPA has assigned "other direct cost" (ODC) amounts of only $500 and $650 for verification impingement monitoring in freshwater and marine systems, respectively (ICR, Table 8). EPA apparently assumes not only that all the sample processing will be done onsite, but that no travel costs will be associated with getting to the site. To the contrary, for the level of effort suggested by EPA (monthly impingement collections), technicians will not be stationed onsite. Instead, they will make monthly trips to the facility. Contrary to what EPA may be assuming, there is not a biological contractor working at or even nearby every facility. Based on the industry's experience, reputable, experienced contractors may be 100-300 miles or more away. If we conservatively assume that the contractor is an average of 150 miles from the facility, then there would be on average six hours' travel associated with each monthly collection.

For entrainment samples, EPA has already assumed that specimen identification will take place offsite. However, it does not appear that the labor and travel costs associated with the biweekly visits to the site were incorporated into EPA's estimates. Including these necessary costs will add substantially to the estimates EPA developed.

UWAG developed its own estimate for a two-year impingement verification program that EPA has estimated to cost only $16,985 (ICR, Table 8). We used the same hourly rates used by EPA (even though we believe higher labor mark-ups are appropriate), but added in labor and travel costs associated with getting to and from the site for a contractor located 150 miles away and also included the costs of identifying some specimens in the contractor's lab. Our estimate for two years of monthly impingement monitoring is $38,724, exclusive of preparing a report (which the facility could prepare but is not likely to). Thus, we estimate that at freshwater sites verification impingement monitoring will cost more than double EPA's estimate. Since EPA made the same erroneous assumption regarding marine sites, the cost of impingement monitoring at marine sites should also at least double compared to EPA's estimate.

Furthermore, UWAG believes these costs likely represent the low end of the spectrum. The proposed rule would require the permittee to prepare a plan for at least two years of verification monitoring, so it is likely that two years of monitoring will be the norm. It is also possible that, regardless of the duration, the frequency of sampling might need to be increased.

UWAG agrees with EPA that less frequent monitoring might be appropriate, depending on the technology chosen (67 Fed. Reg. 17,149 col. 1). For example, a Gunderboom barrier should essentially eliminate the impingement of juvenile and adult fish. Unfortunately, some facilities will not be able to take advantage of this technology due to site-specific constraints. Many plants may have to monitor impingement more frequently than once a month to ensure that they are not deemed to be in noncompliance as a result of variability in impingement rates or episodic events that can greatly skew catch estimates when the sample size (i.e., number of collections) is low. In such cases, the costing errors made by EPA would be accentuated, because more sample collections would be needed.

EPA Response

In the Phase 2 NODA ICR, EPA corrected the transposition mistakes, revised costs, and clarified monitoring assumptions. EPA believes that the resulting revised costs provide a reasonable estimate of monitoring costs that may be incurred, however some facilities may have higher or lower costs depending on site specific issues.

As stated in 125.96, monitoring must be conducted in accordance with the verification monitoring plan, the Technology Installation and Operation Plan, as appropriate, and the Restoration Plan, if relevant. The Director may set additional monitoring requirements. EPA believes that two years of monitoring is a reasonable period of monitoring to assess if a facility's design and construction technologies, operational measures, and/or restoration measures are satisfying the performance requirements promulgated under today's final rule.

Other regulatory requirements

The State of the Record Makes it Impossible to Follow EPA's Reasoning on Many Aspects of its Benefit-Cost Analysis

It is virtually impossible to assess EPA's analysis of costs and benefits, because nowhere has EPA clearly explained its reasoning. Although it has summarized the benefit-cost analysis in the preamble to the proposed rule and included underlying technical documents and a large number of worksheets in the record, the method EPA used to determine costs and benefits is so poorly articulated that a reader cannot follow it. For example, many of the background documents in the record are merely pages of spreadsheet formulas that EPA's contractors apparently used to calculate their numbers.

Generating many pages of calculations and tables of numbers is not enough to satisfy the Administrative Procedure Act or due process of law. EPA is required to provide enough explanation of its reasoning to enable reviewers to identify the strengths and weaknesses in the analysis.

UWAG acknowledges that EPA has provided several opportunities to question its consultants by telephone. But allowing the regulated community to develop an understanding of the agency's rationale laboriously by question-and-answer does not satisfy the Administrative Procedure Act or due process of law.

EPA Response

EPA provided adequate notice of the final rule and its bases and therefore, EPA has complied with the Administrative Procedure Act's requirements and due process requirements.

EPA published the proposed rule on April 9, 2002, and made the supporting records and technical development documents available to the public. EPA published the NODA on March 19, 2003, along with support documents to update the data, information, and rulemaking process for the public consideration. In addition, as described in detail in section III of the preamble to the final rule, EPA has conducted extensive public outreach throughout this rulemaking and the Phase I rulemaking that preceded it, including holding or participating in stakeholder meetings, forums, workshops, and technical symposiums. Further, in a concerted effort to respond to a questions concerning the data and analyses that EPA developed as part of the Phase II proposal, EPA held a number of conference calls with multiple stakeholders to clarify issues and generally provide additional information. To supplement these verbal discussions, EPA drafted three supporting documents: one that explained the methodology EPA used to calculate entrainment rates; and two others that provided specific examples of how EPA applied this methodology to calculate benefits for the proposed rule. In addition, EPA prepared written responses to all questions submitted by the stakeholders involved in the initial conference calls. Thus, EPA has made substantial efforts to make information available, be responsive to inquiries, and to generally provide reasonable notice regarding this rulemaking. EPA notes that given the complex technical issues addressed in this rule, and the variety of comments and information developed and received, final rule development has been very dynamic. For example, much of the information presented in the NODA was generated based on comments on the proposal. Throughout this process and to the extent consistent with the defined schedule under the consent decree, EPA has provided reasonable notice of, and access to, available information and how the Agency anticipated using such information, particularly with respect to the core aspects of the rule, including the scope of the rule, the basic options proposed and considered, and the performance standards. EPA notes that the Agency received a significant number of substantive comments (i.e., estimated in excess of 3000 distinct comments) in response to the public notice provided in the proposal and NODA.

With regard to EPA's peer review of its assessment of entrainment survival data, EPA notes that EPA initial findings were fully described and discussed in the proposal and NODA. The peer review process was sought to gain an additional level of review of these data. EPA also notes that the final rule allows for consideration of an entrainment survival rate other than zero based on a study approved by the Director where a facility is seeking a site-specific determination of BTA.

EPA provided adequate notice of the methodologies it used to assess cost and benefits in the proposal, the NODA, and supporting documents.

Mkt-level impacts/Reliability/EO 13211: Energy Effects

EPA Should Reconsider the Impact of the Rule on Energy Supply

In Chapter B6 of the Phase II EBA, EPA concludes that the proposed rule is a “significant regulatory action” but not a “significant regulatory action”:

This proposed rule does not qualify as a “significant energy action” as defined in Executive Order 13211 because it is not likely to have a significant adverse effect on the supply, distribution, or use of energy. The proposed rule does not contain any compliance requirements that would directly reduce the installed capacity or the electricity production of U.S. electric power generators.

Phase II EBA, Chapter B6, B6-7.

EPA should reconsider this conclusion. Based on our current understanding of the proposed rule, UWAG believes it will have a significant adverse effect on the supply of energy. Some generators would be forced to cease operations while others would suffer the consequences of higher generation costs. A valid economic analysis should be performed and a Statement of Energy Effects be furnished as required by Executive Order 13211.

EPA’s analysis is not sufficient to show that there will be no significant adverse effect on energy supply. UWAG therefore asks EPA to revisit this issue and justify its conclusion that the proposed rule is a significant regulatory action but not a significant energy action.

EPA Response

EPA did re-evaluate the conclusion that the rule is not a significant energy action in the light of re-estimated costs of compliance for the final rule. EPA reached the same conclusion as at proposal: while the final rule is considered a “significant regulatory action” it is not considered a “significant energy action.” Executive Order 13211 states criteria that a regulation must meet to be considered a “significant energy action.” As documented in Chapter B6 of the Economics and Benefits Analysis for the Final Section 316(b) Phase II Existing Facilities Rule (DCN 6-0002), the final Phase II rule meets none of these criteria. Therefore, a statement of energy effects is not required for this final rule.

Burden (facility information collection)

EPA'S ICR LACKS PRACTICAL UTILITY AND DOES NOT JUSTIFY THE BURDENS OF THE RULE

As noted in the introduction to these comments, UWAG intends these comments to address both the proposed rule and the proposed information collection request (ICR) that accompanies the rule (ICR No. 2060.01, DCN:4-0001). UWAG finds that the ICR lacks practical utility because EPA has not provided significant supporting materials to explain how it arrived at its conclusions. Also, in some instances EPA has underestimated the costs of complying with the ICR.

The ICR would permit EPA to require facilities subject to the rule to provide the following types of information:

-source water physical data, which shows the physical configuration of all source waterbodies used by the facility, and identifies and characterizes the source water body's hydrological and geomorphological features;

-cooling water intake structure data;

-cooling water system data, which characterizes the operation of the cooling water system;

-information for the comprehensive demonstration study, including:

---historical information;

---source water body flow information;

---impingement mortality and entrainment characterization study information, which would provide information to support the development of the calculation baseline and characterize current impingement/entrainment;

---preparation of the design and construction technology plan;

---information to support any proposed restoration measures;

-preparation of the verification monitoring plan; and

-data requirements for a site-specific technology determination, such as preparation of a comprehensive cost evaluation study; valuation of the monetized benefits of reducing entrainment and impingement; and development of a site-specific technology plan.

ICR, pp.2-4. There are at least two problems with the ICR: (1) EPA has not provided enough information to verify its cost estimates but has underestimated at least the costs of the impingement mortality and entrainment characterization study and all other activities requiring statisticians or biological technicians, and (2) the ICR continues to overstate the environmental impact of power stations.

A. EPA Has Not Provided Supporting Information

EPA priced out the burdens for the facility in gathering and analyzing the required data. UWAG, despite its best efforts and numerous requests to EPA, has been unable to obtain information necessary to understand some of EPA's price estimates. For example, despite several requests, EPA was unable to provide a general scope of work for the impingement mortality and entrainment characterization study.

1. EPA Does Not Provide Important Details Like the Number of Samples Required and the Sampling Methods Used

The ICR says that EPA assumed the sampling for the study would take place over a three-year period, but it does not indicate: (1) the number of samples for both impingement and entrainment, (2) the timing of sampling events, or (3) the sampling methods used for estimation purposes. EPA assumes that a contract laboratory will perform taxonomic classification and data tabulation on the samples and that the total for these laboratory services over the entire three-year period will be $117,000 for facilities located in freshwater rivers/streams or lakes/reservoirs and $199,230 for facilities located in the Great Lakes, estuaries, and tidal rivers. ICR, p. 55. These numbers, however, cannot be evaluated without knowing the numbers and types of samples (i.e., either impingement or entrainment samples) being analyzed. UWAG's consultant contacted EPA on more than four occasions <FN 61> on this issue, and EPA was not able to supply any sort of scope of work for the impingement mortality and entrainment study or any details about how the cost-of-sampling numbers were generated, until August 5, just two days before the filing deadline. UWAG reserves the right to comment on the new information EPA supplied at a later date.

In short, information critical to EPA's calculations is not available in the ICR, the proposal, the record, or from direct and repeated inquiry from the Agency. If EPA cannot explain the scope of the study it is costing out, then it is clear the ICR is flawed and cannot be used to justify the burdens EPA would impose.

2. EPA Has Mixed Up the Hourly Rates of Statisticians and Biological Technicians

In addition to lacking critical information and analysis, the ICR obviously underestimates the costs of the impingement mortality and entrainment characterization study and all other activities involving either a statistician or a biological technician. As noted in Section XIX above, EPA transposed the labor figures for statisticians and biological technicians when putting together the summary tables of costs. On page 54 the ICR states that the average hourly pay of statisticians and biological technicians is $57 and $35 per hour, respectively. But in the Appendix A tables detailing the costs of the study, EPA transposed these hourly rates, and therefore the estimates provided are invalid. This error occurs in Exhibits A.1.g, A.1.h, A.1.i, most of the tables in Exhibit A.2., and Exhibit A.9 (Costs for the ICR Approval Period Year by Year for Facilities).

Therefore, even if EPA properly estimated the number of facilities affected by the rule and otherwise made sound basic assumptions, the ICR is flawed and should be redone.

Footnotes

61 Personal Communications of Greg Seegert, EA Engineering, Science and Technology, to Dana Thomas (early June), Lynne Tudor (early June), Deborah Nagle (June 10), and Deborah Nagle, Blaine Snyder and others (June 20).

EPA Response

EPA has a practical utility for the data collection requirements in the final rule. (See the preamble of today's final rule.) In general, the information requested will facilitate evaluation of potential impacts to the source waterbodies and their associated aquatic communities and to demonstrate that facilities have implemented the appropriate technologies to minimize adverse environmental impacts from Cooling Water Intake Structures. EPA also expects permit writers to use the information to identify species at risk or other potential concerns that might necessitate the specification of additional permit limits or special conditions. In addition, EPA believes the information is similar in scope and detail to that collected under other NPDES programs, including previous 316(b) efforts.

With respect to providing supporting information for the ICR, EPA made available additional information at the time it published the NODA. (see “Updated Information Collection Costs for the 316(b) Phase II Notice of Data Availability, January 31, 2002). The document summarized the general derivation of information collection, study, and monitoring activity costs associated with the Phase II rule. Labor categories, labor rates, monitoring components, and associated costs are outlined and additional cost details were presented in summary tables to facilitate ease of review and understanding.

EPA agrees the hourly rates of statisticians and biological technicians are incorrect in the proposed ICR. The labor figures were inadvertently transposed when EPA put together the summary tables of costs. EPA has recalculated the ICR cost to rectify this error. The following corrections and revisions were made since proposal: 1) EPA corrected the hourly rates for the statistician and biological technician labor categories, which were inadvertently transposed at proposal; 2) EPA increased the burdens associated with impingement and entrainment monitoring associated with the Impingement Monitoring and Entrainment Characterization Study; and 3) EPA revised the pilot study costs to assume that only facilities which are projected to install new technologies in order to comply with the rule will perform pilot studies; EPA further assumed that the costs of these pilot studies would be proportional to the projected capital costs for installing these new technologies. (see “Information Collection Request for Cooling Water Intake Structures Phase II Existing Facility Final Rule”)

Burden (facility information collection)

The ICR Repeats Errors About Potential Impacts

The ICR perpetuates inaccuracies about the alleged adverse impacts caused by power plants. ICR, pp. 6-9. For example, the ICR, like the New Facilities Rule ICR, continues to cite the loss of one million fish in three weeks at the D.C. Cook Nuclear Plant as evidence of unacceptable impact. As UWAG explained in response to the New Facilities Rule, the great majority of the fish impinged at Cook were alewives, a non-native species introduced into the Great Lakes by the opening of the St. Lawrence Seaway. In the context of the Great Lakes ecosystem, one million alewives impinged in three weeks is not evidence of adverse impact.

1. Alewives in the Great Lakes Were Abundant and Undesirable

Originally alewives were an undesirable species in the Great Lakes. When they entered the Great Lakes, there were no natural predators to control their numbers, and the alewife population grew until there were too many for the lake ecosystem to support. In the early 1960s and 1970s, billions of alewives died each spring and washed up on the shores of Lake Michigan. When the Cook Nuclear Plant impinged the one million alewives in three weeks, the alewife population had been reduced by introduction of predatory species, but it was still the most abundant species in the lake. One positive result of the reduced alewife population was an increase in yellow perch, a highly prized game fish.

2. EPA Relies on Information from Before Brunswick Added Fish Protection Equipment

The ICR likewise makes several misleading statements about Progress Energy's Brunswick Nuclear Plant, located near Southport, North Carolina. The ICR asserts that "specific losses associated with individual steam electric generating facilities include 3 billion to 4 billion larvae and post larvae per year" (ICR, p. 7). The ICR also alleges that "a modeling study of the impact of entrainment mortality on the population of representative fish species in the Cape Fear estuarine system predicted a 15 to 35 percent reduction in the species population" (id.). In support of both statements, EPA cites Brunswick Station's "Historical Summary and Review of Section 316(b) Issues" prepared by EPA Region IV (September 19, 1979).

This information, which dates from the early stages of Brunswick operation, is out of date. The original facility owner took steps many years ago to address the alleged impacts. Although no adverse environmental impact would have occurred at the Brunswick facility even without mitigation, the owner installed mitigation measures in the 1980s. These include a diversion fence at the mouth of the intake canal (installed in 1982), fine mesh screens (1983 and 1987), and a fish return system. Studies conducted since the installation of these mitigation measures indicate that they have significantly reduced entrainment. Reductions in entrainment of total organisms as a result of the combination of voluntary flow minimization and fine-mesh screens ranged up to approximately 90 percent, depending on species and life stage. (See CP&L 1985.) Thus, EPA has used extremely outdated information to characterize impacts from the Brunswick Station, even though UWAG had in the past informed EPA that its information was misleading and inaccurate.

3. EPA Ignores San Onofre's Attempt to Correct the Record

Similarly, EPA continues to use inaccurate information about the San Onofre Generating Station. First, the ICR claims that "the operation of cooling water intake structures resulted in a 60 percent (80 hectare) reduction in the area covered by moderate to high density kelp" (ICR, p. 8). But the kelp bed impacts are discharge issues, not intake issues, and are not related to entrainment and impingement. See Appendix I to UWAG's 2000 Phase I Comments for further information about the kelp bed impacts.

Also, EPA makes several misleading statements about alleged fish impacts attributed to the San Onofre Generating Station. Southern California Edison, in a letter dated January 7, 2002 to Tracy Mehan (DCN:4-022A), the Assistant Administrator for Water, strongly objected to EPA's mischaracterization of San Onofre's impacts, and yet the ICR perpetuates these errors. For example, the ICR notes that "within 3 kilometers of SONGS, the density of queenfish and white croaker decreased 34 to 63 percent in shallow water samples and 50 to 70 percent in deep water samples." ICR, p. 9. As pointed out in the January 7, 2002 letter, this is incomplete and misleading. In fact, the data show density increases for these species of 80 and over 100 percent in the same vicinity as the supposed decreases, but nearer to the ocean bottom, indicating not fish loss, but simply local fish movement. <FN 62>

For further discussion of the misleading statements regarding environmental impacts in the ICR, see Appendix I to UWAG's comments on the New Facilities Rule.

Footnotes

62 EPA largely corrected these misleading assertions in the preamble to the proposed rule, but they continue to appear in the ICR.

EPA Response

The examples cited by EPA in the Information Collection Request (ICR) were intended to illustrate that the numbers of organisms impinged and entrained by a facility can be substantial. EPA believes that it has used the best data available.

With respect to the commenter's concerns about nuisance species, EPA agrees that they are an environmental problem. Cooling water intake structures, however, do not discriminate as to the organisms they impinge and entrain.

EPA acknowledges that historical data from selected facilities may not reflect current impingement and entrainment rates at certain facilities, particularly if technologies and other operational measures for reducing impingement and entrainment rates at the facility have been implemented since the original study. With respect to the comments that no adverse environmental impact would have occurred at Brunswick Nuclear Plant even without mitigation, EPA disagrees: the statement is conclusary as to what constitutes adverse environmental impact and is unsupported by any data. Historical studies like those documented at Brunswick provide only a partial picture of the severity of environmental impact associated with cooling water intake structures.

In response to comments about inaccuracies related to facility-specific impacts caused by impingement and entrainment at San Onofre Nuclear Generating Station (SONGS), EPA provides the following clarification. Specifically, the ICR for the proposed rule described entrainment losses at SONGS. EPA received updated information from SONGS facility scientists that clarified actual entrainment losses in normal (non-El Nino) years and described trends in shallow-water and deepwater fish species affected by entrainment. In addition, prior to publication of the proposed rule, EPA concluded that kelp bed losses in proximity to the SONGS intake were attributable to turbidity increases caused by cooling water discharges, not cooling water withdrawals. The updated information for SONGS was placed in the preamble to the proposal (see 67 FR 17138-17139), but was inadvertently omitted from the ICR. EPA has corrected the final ICR to reflect the changes described above.

Comment period

UWAG RESERVES THE RIGHT TO COMMENT ON NEW DATA AND INFORMATION

In addition to the analyses of EPA's benefits analysis undertaken by UWAG and EPRI experts, many of the companies whose facilities are the subject of the EPA case studies on which EPA's benefits assessments tests have undertaken detailed analyses of the Agency's studies and conclusions. For UWAG and the individual member companies, the process of obtaining and deciphering what EPA did has been extraordinarily difficult and complex. In many cases, the data on which EPA relied were confidential business information and, thus, unavailable. In many other cases, EPA's explanation of what it did, presentation of information it used, and description of results were incomplete and confusing.

As UWAG said in its May 13, 2002 letter requesting an extension of the comment period (Bailey 2002), these issues, as well as the amount of material involved, made it nearly impossible to meet EPA's original July 8 comment deadline. In its May 14, 2002, letter to Tom Wall, UWAG counsel further identified the problems UWAG had encountered with the record (Bulleit 2002a). EPA agreed to extend the comment period to August 7 (67 Fed. Reg. 41,668 (June 19, 2002)) and to engage in a series of discussions with UWAG and individual companies to address the industry's questions about what data EPA used to estimate benefits and where in the record that information could be found. As a result of those discussions, UWAG submitted written questions to which EPA supplied some written answers (Potter 2002; Bulleit 2002b; Wall 2002a; Wall 2002b; Wall 2002c).

UWAG appreciates EPA's willingness to engage in those discussions. Although EPA's answers were in some respects cryptic or non-responsive, some were quite helpful. See Appendix 16. However, UWAG and the affected companies did not receive them until July 2, 2002 (almost three months into the comment period). Therefore, UWAG and the affected companies requested a further 14-day extension, to August 21, 2002, to submit comments on all issues relating to EPA's benefits estimates (Bulleit 2002c). Although EPA was unwilling to reopen the comment period officially, the Agency agreed, in a letter dated July 12, 2002, to include in the record comments on benefits estimate topics from UWAG and to make its best efforts to consider those comments (Grubbs 2002).

UWAG and its members have made every attempt to develop complete comments, including comments on EPA's benefits estimates, for submission on August 7. We are supplying much of that material today. Despite those enormous efforts, some companies have not completed their evaluations, and UWAG as a whole has not had an opportunity to review many such reports. Therefore, UWAG endorses in these comments the case study evaluations that we understand will be submitted by American Electric Power Service Corporation (on behalf of itself, Cinergy, First Energy, Ohio Valley Electric Corporation, Tennessee Valley Authority, Vectren, Buckeye Power, and Alcoa), Consumers Energy Company, Entergy, Conectiv, Mirant Corporation, PG&E National Energy Group, and PSEG. We reserve the right to review reports that we understand are under development by other companies, and to submit by August 21, 2002, new or amended comments endorsing those reports and, as appropriate, incorporating the results into our analysis.

EPA Response

EPA accepted and considered all comments. EPA considered those that were submitted after the official close of the comment period to the extent it was able. Those comments were included in the public rulemaking record.

Organization obo Utility Water Act Group

Subject Matter Code 1.01

Comment period

PROBLEMS WITH THE RECORD HAMPERED UWAG'S ABILITY TO COMMENT

Despite its best efforts, UWAG encountered several problems with the rulemaking record which hampered the development of these comments. Our greatest problem was simply understanding, in the face of the 57,000+ pages in the record, how EPA conducted critical portions of its analyses. For example, it took direct inquiries to EPA before we were able to locate within the record EPA's list of 539 in-scope facilities. While the list was in the record, it was not clearly labeled in the index, and was inserted as part of a larger document. By the time EPA identified the list, several weeks of the comment period had elapsed.

As explained in the preceding section, we also had great difficulty understanding many aspects of the Case Study Analysis and the Economic and Benefits Analysis. Although the CSA is 1,074 pages long, UWAG's experts had difficulty understanding how EPA reached some of its ultimate conclusions, <FN 63> because it was not clear how tables presented in the CSA related to each other. The same was true of the Phase II EBA. This confusion resulted in a series of conference calls between UWAG experts and representatives and EPA experts and representatives regarding the CSA. Despite the lengthy conference calls, and despite UWAG's submission of questions to EPA in advance of the conference calls, EPA was unable, in many instances, to provide answers to the questions posed. Appendix 16 lists (1) questions about the Case Study Analysis and Phase II EBA that UWAG posed to EPA, (2) provides UWAG's reaction, and (3) where necessary formerly requests some additional response.

Footnotes

63 Other members of the public, including the Riverkeeper, Inc., also had trouble understanding the CSA. The Riverkeeper submitted numerous questions to EPA regarding the CSA.

EPA Response

EPA has made substantial efforts to help explain the complex issues involved with 316(b), and done a great amount of public outreach, including responding to comments, creating a publicly available record and hosting conference calls. EPA notes that no specific questions were identified by the commenter.

Option: UWAG's recommended approach

UWAG's Proposed Decision Principles for Applying 316(b) to Existing Facilities

Overview

UWAG believes that any rule implementing 316(b) should be written to achieve both its goals of protecting the environment and of providing the flexiblity to do so cost-effectively. To that end, UWAG is recommending an approach for 316(b) decisionmaking that has the following components:

1. A definition of Adverse Environmental Impact (AEI)

2. Use of Representative Indicator Species (RIS) for AEI assessment. (In the past, "RIS" has traditionally stood for Representative "Important" Species. We have chosen a different term for reasons given below.)

3. Making 316(b) decisions consistent with, but not duplicative of, other regulatory programs such as the Endangered Species Act.

4. Use of a de minimis criterion to exempt small cooling water users that pose no appreciable risk of causing AEI because only a small amount of water (in a relative and absolute sense) is withdrawn from a waterbody, at a location that does not require special protection.

5. Determination of Adverse Environmental Impact or its absence using any of three methods either alone or in combination:

a. Use of previously conducted 316(b) demonstrations that are still relevant for the present conditions of the facility, waterbody, and RIS

b. Use of ecological risk assessment by means of:

i. Demonstration of "no risk" (ie, no appreciable risk) of AEI using very specific conservatively protective decision criteria or

ii. Assessment of risk using a structured AEI decisionmaking process consistent with EPA's Ecological Risk Assessment Guidelines

6. A "maximize net benefits" approach for selecting Best Technology Available (BTA)

7. At the option of the permittee, recognition of voluntary enhancements (for example, fish stocking or habitat improvements)

8. Providing data or information with NPDES permit renewals if new information shows that the previous 316(b) demonstration is no longer scientifically valid

Each of these components is discussed below in terms of what it contributes to a sound approach to 316(b) decisionmaking that is environmentally protective, scientifically based, and socially responsible.

Not every component of this proposal will be relevant to every existing facility. For example, a facility might decide not to apply the conservative criteria (step 5.b.i above) at all and instead go directly to a more detailed risk assessment (step 5.b.ii).

II. Terms and Principles

A. Defining AEI

UWAG believes that defining AEI is critical to the 316(b) rulemaking in order to provide the basis for 316(b) decisionmaking. A defintion of AEI sets the benchmark for the BTA determination.

UWAG has worked to develop a definition of AEI that is both implementable and based on sound science. The following definition was submitted to EPA as part of UWAG's comments on EPA's proposed 316(b) rule for new facilities:

Adverse environmental impact is a reduction in one or more representative indicator species (RIS) that (1) creates an unacceptable risk to a population's ability to sustain itself, to support reasonably anticipated commercial or recreational harvests, or to perform its normal ecological function and (2) is attributable to operation of the cooling water intake structure.

This defintion is scientifically sound and environmentally protective because it focuses on protecting populations of species that are subject to impingement and /or entrainment by CWISs and because it requires that the level of population be adequate to ensure protection of ecosystem integrity (community structure and function). The definition is socially sound because it is consistent with universally accepted and applied principles both of natural resource management and of ecological risk assessment. Fisheries management science provides goals and tools (field and analytical methods) that are used to monitor the fishery resource. Risk assessment provides the tools and process for determining when the risk of AEI is acceptable.

By defining AEI in terms of "unacceptable risk", this approach recognizes that there is no "bright line" test, based on engineering or science, that can make the AEI decision. Whether AEI is occurring or will occur at an existing facility is a question of risk, not certainty, and combines science with value judgments that society must make about the value of different resources. But that mixture of scientific and social judgments does not preclude a rational process. The approach to AEI decisionmaking presented in this paper allows the AEI decision to be made without a "bright line" test by using three approaches.

First, under the approach proposed in this paper, the facility can make use of previous 316(b) studies. If the 316(b) decisionmaking process has been engaged in the past, then decisions have already been made about the appropriate level of risk that is "acceptable" or "unacceptable" on a particular waterbody. The decisionmaking approach presented here allows maximum use of the technical, scientific, and decisionmaking resources that have already been expended, but with the possibility of "fine-tuning" past decisions if conditions have changed.

Second, the facility can use ecological risk assessment. One approach is to demonstrate that there is no risk of AEI by using very conservative criteria that are below the level of harm that would create an unacceptable risk to populations, communities, or the fishery. Such criteria are proposed in Attachment A, and additional biocriteria are undergoing peer review.

A second risk assessment approach is to demonstrate no risk of AEI using EPA's Ecological Risk Assessment Guidelines. The risk assessment approach offers not so much a test for AEI as a process by which the facility can work with regulators and stakeholders to determine what level of risk is tolerable. This approach recognizes that risk tolerance is a social decision based on tradeoffs. Using the risk assessment guidelines allows the decisionmaker (a state regulator in most cases) to balance, for example, the risk to the fishery of open-cycle cooling against the risks presented by cooling towers, such as energy penalties, visibility impairment, noise, land use, increased solid waste, and air emissions.

In short, the decisionmaking process presented here is not, and need not be, based on "bright line" tests. Instead, it is based on either very conservative risk criteria or a site-specific assessment (taking into account information already gathered and decisions made in past studies) to determine the appropriate level of risk.

B. Representative Indicator Species

UWAG believes that the use of Representative Indicator Species (RIS) for 316(b) decisionmaking is important to provide a focus for biological investigations, thereby ensuring that the permitting process is not unduly complex and is manageable for permit writers. Use of this concept was proposed in EPA's 1977 draft 316(b) guidance, Guidance for Evaluating the Adverse Impact of Cooling Water Intake Structures on the Aquatic Environment: Section 316(b), and has also been used in 316(a) demonstrations and in many state programs as well. EPA's 1977 draft guidance document used the term "Critical Aquatic Organisms" (CAO) rather than RIS.

UWAG uses the term RIS, instead of "Critical Aquatic Organisms" or other terms that have been used in various state regulatory programs, to avoid any confusion associated with the history of these terms and to avoid the implication that some species are unimportant. This choice would allow EPA flexibility to tailor the concept for the current rulemaking. Although EPA used six criteria for CAO selection in the 1977 guidance document, all of the selection criteria are captured in the following four categories:

-Commercial and recreational importance;

-Federal or state threatened or endangered or specially designated species;

-Importance in local ecological community structure and function; and

-Species and life stage vulnerability.

In evaluating AEI under 316(b), the issues of specially designated species and areas designated for special protection must be considered. Examples include federal or state threatened and endangered or otherwise specially protected species, marine sanctuaries, and jurisdictional wetlands. Considering the risk of impacts to such legally protected species and areas is a necessary part of the AEI determination. However, because there are already legal mechanisms in place to protect such species and areas, the existing legal framework should be used in order to avoid duplication of the existing programs and conflict between them and 316(b). UWAG's recommended approach to 316(b) would complement rather than duplicate other federal, state, and local regulatory programs, and this Decision Principles document assumes such assessment has taken or will take place.

The approach taken here to 316(b) decisions is compatible with the companion provision 316(a), which addresses the effects of heated effluent. If a facility has performed a 316(a) demonstration for its thermal discharge, the information collected for that demonstration may be useful for addressing the 316(b) entrainment and impingement issues as well. Section 316(a) also has a population and community focus (the statutory standard is "the protection and propagation of a balanced, indigenous population of shellfish, fish, and wildlife"), which is compatible with the definition of "adverse environmental impact" proposed here. Many of the scientific methods that are used to assess the impact of a thermal discharge on an aquatic population can also be used to assess other impacts, such as entrainment and impingement.

D. De Minimis Criteria

UWAG also continues to endorse setting a scientifically supportable threshold exemption for de minimis intake flows. EPRI is conducting (and will be reporting) research to address the relationship between flow withdrawal and AEI. (As with other aspects of this proposed decisionmaking process, the de minimis criterion would be applied in conjunction with regulatory programs for protected species or areas.)

III. Determining Adverse Environmental Impact

One of the key issues in developing an implementable 316(b) regulatory program is crafting a workable approach for determining when there is AEI. Lack of clarity for permit writers as to the specific endpoints or process is a concern that EPA has expressed. To address this concern, three options are proposed here for making the AEI determination. They are (1) the use of a previously conducted 3 16(b) demonstration or demonstrations as appropriate and (2) the use of ecological risk assessment, by means of (2a) a demonstration of no risk of AEI using conservatively protective decision criteria or (2b) the use of a structured AEI decisionmaking process consistent with EPA's Ecological Risk Assessment Guidelines.

Previous 316(b) studies and decisionmaking endpoints established prior to the current study can often serve as the basis for the AEI decision (in some cases augmented, as necessary, with current studies to address any newly identified issues). The use of previously conducted 316(b) demonstrations recognizes that many states have already developed 316(b) regulatory programs with significant information-gathering requirements, which in many cases have already identified the level of CWIS impacts. It is recognized, however, that previous studies must meet certain standards if they are to be used in current or future 316(b) decisions.

The second approach, based on ecological risk assessment, involves either a demonstration of no risk, based on explicit AEI decisionmaking criteria that have conservative thresholds (with the thresholds so low that, for all practical purposes, the risk of AEI is eliminated) or a structured AEI decisionmaking process using the EPA Ecological Risk Assessment Guidelines (based on establishing a clear process in which the facility works with permit writers, resource managers, other technical experts, as appropriate, and stakeholders to decide what constitutes an unacceptable risk of AEI in the waterbody).

A facility should be free to pursue an AEI determination using any of these options (use of previous 316(b) demonstration, demonstration based on conservative criteria, or structured process consistent with the EPA Ecological Risk Guidelines), either independently or in any combination. For example, if a facility has a previously approved demonstration that is scientifically sound and that remains current from a waterbody biological perspective, as well as in terms of the facility location, design, construction and capacity, then that demonstration could serve as the basis for an AEI determination. However, if the demonstration did not focus on a species that is currently an issue in the waterbody, the facility might use the no-appreciable-risk criteria, either alone or in combination with a structured AEI decisionmaking process consistent with EPA Risk Assessment Guidelines, to make an AEI determination. Another example might be the use of a demonstration of no risk using the percent population reduction criterion to address AEI for some RIS, but to use the structured AEI decisionmaking process based on the EPA Risk Assessment Guidelines to make the final determination for other RIS.

A. Use of a Previously Conducted 316(b) Demonstration

UWAG believes that previously conducted 316(b) demonstrations should be considered in making AEI determinations to the degree they reflect current biological conditions in the waterbody and the current CWIS location, design, construction, and capacity. Previous 3 16(b) demonstrations may need updating, in some cases, to reflect current conditions. If 316(a) studies have been conducted, they may also be relevant to the evaluation of CWIS effects on the RIS, since 316(a) requires assessment of indigenous populations. Specific issues to be considered include:

1. Are the RIS still the appropriate ones? — This question recognizes that the RIS in a waterbody may change as a result of changes in habitat, long-term population fluctuations or fisheries management policies and goals. This may require collecting additional data or information to evaluate one or more RIS.

2. Were the data collection and analytical tools adequate? — This question recognizes that both fluid dynamics engineering and fisheries science have generated new methods, analytical tools, and knowledge of hydrodynamics and fisheries. In particular, there have been significant advances in fisheries assessment, modeling, and risk analysis. Previously collected data may need to be reviewed, if the permitting agency has information that circumstances have changed, to verify that the data were adequate and that the methods used were sufficiently robust to support conclusions regarding AEI.

3. Were waterbody biological conditions at the time of the study reflective of current biological conditions? — This question recognizes that there may have been significant changes in the waterbody, such as improvement or degradation in water quality, changes in physical habitat such as an increase in or loss of vegetation or occurrence of an exotic or invasive species that could alter the risk of AEI in the waterbody.

4. Has the CWIS been altered in terms of facility location, design, construction and capacity from that at the time the previous demonstration was conducted? — If a CWIS was altered in terms of its technology to address AEI, was the alteration successful? If the CWIS or its operation were altered for some other reason, could the change reasonably be expected to result in an increased risk of AEL?

The above list is not exhaustive; other significant changes (for example, a climate change that has affected reproduction of marine species) should be considered if there is reason to believe they have made the previous 316(b) demonstration inadequate.

B. Use of Ecological Risk Assessment

1. Demonstrating No Risk of AEI Using Conservatively Protective Decision Criteria

Another approach is a demonstration of no risk of AEI using explicit conservative criteria. The criteria should be set at a level that, if not exceeded, would result in no risk of AEI in the waterbody on which the facility is located.

UWAG recognizes that there will always be some level of background risk to RIS, with or without a CWIS. “No risk” in this proposal means no appreciable risk. Because the decision criteria are set well below levels that would result in AEI, these criteria would not be appropriate for use as performance standards. Thus, although meeting the criteria shows that there is no risk of AEI, the converse is not true: exceeding them does not mean that AEI exists. Rather, additional criteria are required to make an AEI decision. Any additional information can be gathered and criteria considered in the structured decisionmaking process described below.

The use of clear, specific criteria allows the permit writer for the facility to determine readily if the facility’s CWIS meets one or more of the “no risk” criteria. There are physical criteria based on CWIS location, on facility design, and on the proportion of the source waterbody used and biological criteria based on the percentage of the population lost due to impingement and/or entrainment and on no significant downward trend in population abundance. Other biocriteria are undergoing peer review.

Each of these criteria is applied independently; passing a single criterion can serve as the basis for a successful demonstration of no risk of AEI for a facility. However, if population-based biological criteria are used, they must be independently applied to each RIS species, and each species must meet the criteria for the facility to demonstrate no risk of AEI. (RIS not meeting the no-risk criteria can be addressed either by the structured AEI decisionmaking process or by implementing the BTA assessment process.)

The following specific conservative criteria are proposed:

A. Physical Criteria

(1) Locational Criterion - A CWIS does not create a risk of AEI if it withdraws water from a zone of a waterbody that does not support aquatic life due to anoxia or other reasons.

(2) Design Criterion - An existing CWIS does not create a risk of AEI if it uses wet closed-cycle

cooling or technologies that achieve a level of protection reasonably consistent with that achieved by wet closed-cycle cooling.

(3) Proportion of Flow or Volume Criteria - On freshwater rivers, lakes (other than the Great Lakes), and reservoirs, a CWIS does not create a risk of AEI if it withdraws no more than 5% of the source waterbody or the "biological zone of influence," as defined below in Attachment A.

b. Biological Criteria

(1) Percent Population Loss Criteria - On freshwater rivers, lakes (other than the Great Lakes), and reservoirs, a CWIS does not create a risk of AEI if it causes a combined loss from entrainment and impingement of no more than 1% (for harvested species) or 5% (for nonharvested species) of a RIS population.

(2) No Significant Downward Trend Criterion - On freshwater rivers, lakes (other than the Great Lakes), and reservoirs, a CWIS creates no risk of AEI if adequate data show no statistically significant downward trend in the population abundance of RIS.

(3) Other - Other biological criteria are undergoing peer review.

Most of these criteria have limitations on their use, such as being limited to certain waterbody types or for only impingeable or entrainable organisms. This is important, because some facilities may use the criteria not to make the risk-of-AEI decision for all RIS, but more narrowly, to help focus studies during the structured AEI decisionmaking process. This focusing can be accomplished by using the criteria to help select or eliminate from concern one or more RIS species or to limit AEI risk assessment studies to address only impingeable or only entrainable organisms. The benefit of eliminating entrainable organisms from concern would be that subsequent analysis could focus entirely on conducting population studies of impingeable organisms (species) or on determining what CWIS technology would minimize any AEI from impingement. (Note that in this example, even though the entrainment level is below the threshold, the combined effect of impingement and entrainment for a given RIS must be considered in the assessment of potential impingement AEI.)

These criteria are not intended to replace federal or state programs for threatened or endangered or otherwise protected species or to affect areas designated for special protection. The criteria apply only to the 316(b) decision.

UWAG believes additional conservative no-risk criteria can be developed and provides the above examples to demonstrate that such criteria with clear decisionmaking endpoints are feasible.

These criteria are explained in more detail in Attachment A.

2. Structured AEI Decisionmaking Process Consistent with EPA Ecological Risk Assessment Guidelines

Under the second option, the "structured decisionmaking process," the facility would use a structured process, based on EPA's 1998 Ecological Risk Assessment Guidelines, to make an AEI determination. Key steps in this process are as follows:

1. Stakeholders will be involved in identifying issues of concern caused by the cooling water intake structure relative to the RIS. Previous 316 studies, results of demonstrations using the "no AEI" criteria, information on the design and operation of the facility, waterbody fisheries management data and plans, and other relevant waterbody information may be used to focus the effort to identify RIS at risk for AEI due to the CWIS.

2. The permit writer, with input from the facility, will then determine what data collection and assessment studies are necessary to address the RIS of concern. Decisions regarding the assessment scope will include identification of RIS; study design, sampling methods, locations and durations; and analytical methods and/or models to be employed.

3. The facility and regulators will also identify explicit measurement endpoints and criteria for assessing AEI before any studies are conducted. If the studies demonstrate that predetermined endpoints are not exceeded, the proposed intake structure will be considered not to cause AEI. If not, the facility will proceed to identify alternative options for BTA or to identify enhancements that will eliminate AEI.

UWAG believes this structured process addresses many of the concerns raised regarding site specific 316(b) decisionmaking. It explicitly includes participation by all stakeholders, including state natural resource managers, to identify issues of concern. It then allows resource managers and the facility to determine the nature of studies necessary to address issues of concern and set predetermined endpoints and criteria for decisionmaking. It is anticipated that EPA staff who are working on the 316(b) rulemaking would work with EPA Headquarters risk assessment staff to develop this approach for application to 316(b) decisions.

If it is determined, using one of the above approaches, that there is no AEI, then the existing intake structure satisfies 316(b). If it is determined that there is an appreciable risk of AEI, however, then a facility moves on to evaluate alternative technologies using the "maximize net benefit" approach and/or may offer environmental enhancements in place of or in combination with BTA, as explained in sections IV and V below.

IV. Maximizing Net Benefits for BTA Selection

If the above steps fail to demonstrate that the existing cooling water intake structure is not causing AEI, then the permittee must proceed to the next step of determining the "best technology available" (BTA). The permittee does this by, first, identifying and listing all intake structure technologies that are reasonably "available" for the site in question.

Each of these BTA candidates must then be evaluated to determine its net costs and benefits at the site. The analysis should be as complete as possible in terms of identifying and quantifying net costs and benefits. The "benefits" of an intake structure technology typically include the fish and other aquatic organisms expected to be saved by the candidate technology, compared to the existing technology, and economic benefits to recreational and commercial fisheries, as well as any other benefits that can be identified The costs of each technology include the capital costs of constructing it; the operating and maintenance costs of using it each year, including the energy penalties associated with its use; adverse environmental effects such as evaporative loss, salt drift, visible plumes, noise, or land that must be devoted to cooling towers; and, for those technologies that will lower the generating output of the facility, the cost of replacement power and the environmental effects of increased air pollution and waste generation from generating that replacement power.

For each candidate technology, the total costs should then be subtracted from the total benefits to determine the net benefit of each technology. Ideally, the available technologies should be rank-ordered by cost-effectiveness and the ones whose marginal costs exceed their marginal benefits should be discarded. The technology with the greatest net benefit (the “maximum net benefit”) is the “best” technology for the site.

In short, the steps of the BTA determination are these:

1. Identify 316(b) BTA alternatives

2. Develop estimates of the costs and benefits of the alternatives

3. Organize the alternatives by increasing cost

4. Calculate the marginal costs and marginal benefits (relative to the next least expensive) of each of the alternatives

5. Identify the best alternative, i.e., the alternative with the highest net benefit (benefits minus costs)

The calculation of costs and benefits for a candidate technology need not be elaborate. For over twenty years the federal government has, under a variety of environmental programs, undertaken to assign dollar values to environmental amenities and impacts. This is done, for example, in preparing environmental impact assessments under the National Environmental Policy Act, in calculating the “benefit” of violating the environmental laws using EPA’s BEN model, in calculating natural resource damages under CERCLA, and in a variety of other contexts. While UWAG does not necessarily endorse any of these approaches per Se, UWAG does believe that cost-benefit analyses adequate for § 316(b) purposes can be done with existing techniques for a reasonable amount of time and effort. In particular, a “tiered” approach can be developed in which simplified methods can be used for cases in which the facts are simple or the costs low and more elaborate methods used for more complicated cases.

V. Enhancements

UWAG believes that voluntary use of enhancements can play a beneficial role in the 316(b) regulatory process. UWAG considers enhancements to be actions taken to address AEI other than changes to the location, design, construction or capacity of the CWIS. This concept is increasingly being employed by EPA and the states to address environmental issues and has been demonstrated to be an effective method of addressing 316(b) issues in a number of instances. The concept of enhancements is being used in Maryland, for example, as part of the nutrient TMDL program. In this Maryland program, trades can be made to achieve nutrient reductions between different sources, so long as specific criteria are met.

If it is determined that a facility’s CWIS may potentially cause AEI, this means that a risk of impairment exists for one or more species that would create an unacceptable risk to a population's ability to sustain itself, or to commercial or recreational harvests, or to ecological integrity within the waterbody. If a facility proposes an enhancement within the waterbody that will remove AEI or achieve a substantial benefit to the resource, then the goal of 3 16(b) of minimizing AEI to the waterbody is achieved. UWAG believes that voluntary enhancements should be considered instead of, or in combination with, changes to the CWIS, so long as the criteria of(l) directly addressing the AEI in the waterbody and (2) removing AEI or achieving a net benefit are achieved.

Types of enhancements that might be considered include stocking fish to replace impaired RIS, creating or restoring spawning or nursery habitat for RIS, raising the dissolved oxygen in anoxic areas to expand carrying capacity of the RIS in a waterbody, or removing obstructions to migratory species. In essence, focusing in this manner on what would help the fish, rather than narrowly on what can be done to modify the CWIS, might have the triple benefit of achieving a greater benefit to the RIS, doing so at less cost, and creating an environmental benefit in perpetuity (not just for the life of the CWIS). Any current enhancements implemented by existing facilities to address AEI directly should be considered in final AEI decisionmaking.

If NPDES permits include conditions based on enhancements, objectives should be established before implementation, and appropriate monitoring and/or reporting obligations should be included in the permit to confirm that enhancement requirements and/or objectives have been achieved.

VI. Periodic BTA Review

UWAG recognizes that, over time, changes may occur in the waterbody or the facility design, or operations may change, so as to potentially alter a CWIS BTA determination. Therefore a facility may need to provide information to confirm a previous BTA determination at the time of NPDES renewal (taking appropriate credit for previous CWIS investments that continue to have beneficial effects). A reassessment may be advisable at permit renewal if the permitting agency has information suggesting that:

-The RIS selected in the past are no longer the relevant ones for the waterbody,
-The previous 316(b) decision was based on inadequate data collection or analytical methods,
-There have been changes in the waterbody that could alter the AEI determination, or
-There have been changes in facility operation or the CWIS that could alter the AEI determination.

The amount and nature of additional data and/or information will vary on a site-specific basis.

Attachment A

Conservative Decision Criteria for Determining No Risk of AEI

I. Physical Criteria

A. Locational Criterion

The locational criterion applies to any waterbody type and to both entrainable and impingeable organisms. A facility will not be considered to pose an AEI risk if it:

withdraws water from a zone of a waterbody that does not support aquatic life due to anoxia or other reasons.

Many waterbodies have deep-water zones coincident with stratification that cannot support RIS due to anoxia/hypoxia, lack of habitat, poor habitat, or water quality conditions. In some deep parts of the Chesapeake Bay, for example, dissolved oxygen can be as low as 1 - 1.5 ppm (Dauer et al. 2000; Malone et al. 1988; Malone 1992). These zones are often the hypolimnia or bathypelagic zones of lakes, reservoirs, and estuaries (Anderson and Taylor 2001; Ritter and Montagna 1999; Brietburg 1994; Coutant 1990; Oliver and Hudson 1987). Impingeable nektonic or meroplantonic organisms will generally avoid these areas (Knights et al. 1995; Das and Stickle 1994; Brietburg 1994; Coutant 1990; Kramer 1987), and entrainable life stages of an RIS drifting through such areas would not be expected to survive in these zones (USEPA 2000; USEPA 1986). Thus there is no appreciable risk of AEI from impingement and/or entrainment by a CWIS located in such areas.

If such areas are uninhabitable only for certain time periods, certain RIS, or certain impingeable or entrainable life stages, then the locational criterion and the “no risk” decision also apply only to those time periods, RIS, and impingeable or entrainable life stages. Use of other criteria, or the structured risk assessment approach described in UWAG’s proposed “316(b) Decision Principles for Existing Facilities,” may be used for time periods, species, or life stages not covered by the locational criterion.

To account for the possibility that an area of the waterbody may be anoxic (or otherwise unable to support life) only part of the time, these conditions should be present at least 95% of the time for nonharvested RIS and 99% of the time for harvested ones in order to satisfy the locational criterion. This is consistent with the protection level embodied in other biological criteria. As for longer-term fluctuations in conditions such as dissolved oxygen, such conditions can be reviewed at the five-year permit renewal if there is new information showing they have changed significantly.

B. Design Criterion

The proposed “design” criterion applies to any facility in any waterbody type. An existing facility is not considered to pose a risk of AEI if it:

uses wet closed-cycle cooling or technologies or other measures□that achieve a level of protection reasonably consistent with that achieved by wet closed-cycle cooling.

“Reasonably consistent with” wet closed-cycle cooling means in the range of protection that would be provided by a wet cooling tower at the same site. UWAG believes that existing facilities using closed-cycle cooling do not pose any appreciable risk of causing AEI and should be considered to comply with 316(b). The Nuclear Regulatory Commission has concluded that for facilities with cooling towers, environmental effects related to impingement and entrainment are not detectable or are so minor that they will neither destabilize nor noticeably alter any important attribute of the resource (see USNRC 1996; CFR 2001).

Wet closed-cycle cooling or reasonably consistent protection will be insufficient only if there are specific local circumstances such as impacts to threatened and endangered or otherwise protected species or areas designated for special protection. (The NPDES permitting agency and/or fishery and wildlife management agency would be aware of such circumstances.) Permit writers and natural resource agencies, who would normally review the draft permit, can be expected to identify any such special circumstances and impose requirements under existing laws such as state or federal endangered species acts.

C. Entrainment Criterion Based on Proportion of Source Waterbody Flow or Volume Used

This criterion, which amounts to 5% of flow or volume, is available only to facilities located on freshwater rivers, lakes (other than the Great Lakes), or reservoirs and applies only to entrainable life stages. It is listed as a “physical” criterion because its focus is a calculation of the facility’s cooling water use as a percentage of the source waterbody flow or volume. Because it may not be appropriate for many RIS to consider the entire source waterbody in making this decision, determining the appropriate flow for a river or volume for a lake or reservoir is of critical importance.

The appropriate flow or volume for RIS assessment is identified as the “biological zone of influence.” Discussed in more detail below, this is the zone that is occupied by an RIS. In contrast, the portion of the source waterbody hydraulically affected by the CWIS withdrawal of water is identified as the “hydraulic zone of influence.” For an RIS to be considered to be at risk of AEI, the biological zone of influence and the hydraulic zone of influence must overlap. In essence, the hydraulic zone of influence serves as the numerator, while the biological zone of influence serves as the denominator for these criteria.

The criterion applies only to smaller fresh waterbodies because, in larger waterbodies, identifying the biological zone of influence is more complex, and due to the size/complexity of these waterbodies, the criterion might not meet the test of being universally conservatively protective and explicitly quantitative, which forms the basis of these criteria. The concept of the biological zone of influence in general and its application in these criteria are discussed below.

The biological zone of influence as used in this proposed decisionmaking process applies only to freshwater rivers, reservoirs, and lakes. For any RIS, the biological zone of influence is defined as the zone (cross-sectional for rivers and volumetric and geographic for lakes and reservoirs) within a waterbody that is occupied by an RIS. The biological zone of influence is expected to vary for different species, and so the RIS with the most limiting biological zone of influence will determine whether a facility meets the criteria. If only one RIS exceeds the criterion, the value of the criterion is to focus the analysis on that species (the one that may be at risk), so that the more detailed risk assessment process can be applied to that species.

The biological zone of influence has the following components:

(1) Facilities must be able to define the biological zone of influence using new or existing data or information sufficient to determine the distribution patterns of vulnerable RIS.

(2) For smaller fresh waterbodies (rivers, reservoirs, and lakes other than the Great Lakes):

(a) In freshwater rivers the biological zone of influence for RIS entrainable life stages is the portion of the cross-sectional flow of the river occupied by the RIS where the river flows past the CWIS. If an RIS is found primarily along the shoreline, the biological zone of influence is the sum of the flow along the shorelines on both sides of the river. (This is a conservative definition of the biological zone of influence, to be used only for these conservative entrainment criteria and not for more detailed ecological risk assessments.)

(b) In smaller freshwater lakes and reservoirs, and in controlled-flow rivers that have lake-like characteristics, the biological zone of influence is the volumetric area occupied by the RIS during the time when the RIS is vulnerable to entrainment. Each RIS will be evaluated for three distribution patterns:

(i) Pattern 1 — The RIS has a relatively well-mixed distribution throughout the waterbody in which the CWIS is located. With this pattern, the entire waterbody is the biological zone of influence.

(ii) Pattern 2 — The RJS is essentially limited to a subarea of the waterbody. In this case the smaller subarea within the waterbody is the biological zone of influence. (But note: If the hydraulic zone of influence of the CWIS is not located in the limited volumetric area occupied by the RIS, it can be assumed that there will be no risk of AEI for the RIS.)

(iii) Pattern 3 — The RIS is limited to two or more areas within the waterbody (e.g., for entrainable life stages there may be multiple spawning and nursery areas associated with some habitat or water quality condition). In this case, the biological zone of influence is the sum of those areas within the waterbody unless one of the subareas in which the CWIS is located supports a distinct subpopulation, in which case the biological zone of influence is limited to the area occupied by that subpopulation. (Note: If the hydraulic zone of influence of the CWIS is not located in the subarea(s) occupied by the RIS, it can be assumed that there is no risk of AEI for the RIS.)

A CWIS presents no appreciable risk of AEI by entrainment if it withdraws no more than 5% of the source waterbody or the appropriate biological zone of influence, whichever is smaller. The specific criteria for waterbody types are the following:

1. Rivers — No more than 5% of the 90% exceedance flow of the biological zone of influence, measured during the period when entrainable life stages of RIS are present. (The “90% exceedance flow” is the flow that is exceeded 90% of the time, that is, the 10th percentile flow and would be determined based on the available period of record for the current hydrological flow conditions.)

2. Lakes — No more than 5% of the volume of the biological zone of influence during the period when entrainable life stages of RIS are present.

Reservoirs and large rivers with controlled flow may have either riverine or lake-like characteristics. In such waters there may be several types of spawners (migratory, nest building, broadcast, vegetation, etc.), and suitable habitat may be disproportionately distributed (up-versus downstream of the plant). For such waters the more appropriate of the above two criteria must be determined and applied.

Facilities employing these criteria may consider entrainment survival data to the extent such data are available and appropriate for the flow circumstance at hand. Also, if a facility has made quantifiable environmental enhancements related to the production of entrainable life stages, these enhancements may likewise be taken into account.

II. Biological Criteria

This section describes biological criteria based on percent of population loss and no significant downward trend. Other biocriteria are undergoing peer review.

A. Biological Criteria Based on Percent of Population Loss

The criteria based on the percent of population lost apply to both impingeable and entrainable organisms. The application of these criteria is limited to facilities located on freshwater rivers, reservoirs, and lakes other than the Great Lakes.

A facility design will be considered to create no appreciable risk of AEI if the CWIS causes the combined loss, from entrainment and impingement, of:

1. No more than 1% of the population of any harvested RIS AND
2. No more than 5% of the population of any nonharvested RIS,with fractional losses summed over life stages for the entire lake, reservoir, or river reach included in the evaluation.

There are two options for making this determination. One option is to compute a conditional mortality rate (EPRI 1999; Vaughn 1988; Boreman and Goodyear 1988; Boreman et al. 1981) for the combined effects of entrainment and impingement. Conditional mortality rate estimates of loss to adult populations are conservative because they do not include compensation (Barnthouse 2000; Boreman and Goodyear 1988; Vaughn 1988).

Another option, for sites where the population of a harvested species is unknown, is to express the loss as an equivalent number (EPRI 1999; Boreman 1997) at some life stage and compare that to a sustainable harvest for the same life stage. If the loss is less than 1% of the sustainable harvest, then the percent loss to the overall population must be even smaller. If the loss is much less than 1% of the harvest, it may not even be necessary to make the equivalent adult conversion; natural mortality experienced by juvenile fish subsequent to impingement might be ignored (see, e.g., Matty et al. 1999). The same cohort (a group of fish spawned during a defined time period, usually one year) may be impinged or harvested in more than one year, so that care would be required to take all harvest and impingement losses into account and to ensure that comparable values were compared.

The rationale for limiting these 1% / 5% criteria to fresh waterbodies other than the Great Lakes is the greater complexity of identifying the biological zone of influence for an RIS in larger waterbodies and the difficulty of identifying explicit protective conservative criteria with universal applicability.

The 1% / 5% population loss criteria are based in part on recognition that these percentages are small relative to the inter-annual population fluctuations typical of fish populations and also small relative to the compensatory responses typical of many species. Under commonly used modeling methods, if compensation is excluded, any increase in mortality leads to extinction (Ginzburg et al 1990; Rose and Cowan 2000; Rose et al. in press). (Thus, if there were no compensation, even a 1% increase in mortality could be deemed too high. And, since compensation decreases with decreasing stock size, a

1% loss could in fact be too high for a population on the verge of collapse.) Rose et al. (in press) provide a comprehensive review of compensation, including its importance, associated controversy, and needed research. Also, a meta-analysis by Myers et al.(1999) shows that fish species have substantial compensatory reserve. Compensation is recognized as a factor that reduces the actual population decrease associated with a given conditional mortality rate, particularly when the population is at or above some equilibrium level (Rose et al. in press; Rose and Cowan 2000; Van Winkle 2000). It is not included in the computation of percent loss for the purposes of these “no risk” criteria but could be included more formally in a subsequent risk analysis, if required and if there were data to support its use for a particular application.

The topic of how much loss a fish population can tolerate has been addressed by a number of researchers. Fishery managers consider removal of 70 to 80 percent of an unfished stock’s biomass (Spawning Stock Biomass or SSB) and 65 to 80 percent of a stock’s reproductive potential (Spawning Stock Biomass per Recruit or SSBPR) to be safe, given the compensatory reserve inherent in most fish stocks. The National Marine Fisheries Service (NMFS 1996) recently reviewed overfishing definitions proposed by regional fisheries management councils for 117 fish stocks. For most of these stocks, overfishing was defined in terms of SSBPR, with the overfishing definitions ranging between 65% and 80% reduction in SSBPR.

While the compensatory ability of specific species will vary, UWAG believes that the criteria of 1% for harvested species and 5% for non-harvested species are so far below levels at which stocks are typically managed for harvest — are so conservative, in other words — that they would ensure no appreciable risk of AEI. The 1% value for harvested species is lower than the 5% for non-harvested species because there is existing fishery management exploitation of these species. For the smaller waterbodies to which these criteria apply, in almost all cases harvesting will be limited to recreational, rather than commercial, harvest. However, there may be instances in which these criteria would not be sufficiently conservative at a particular site (due to overexploitation as a result of commercial or recreational fishing, resulting in a fishery management recovery plan, or the presence of threatened or endangered species).

Facilities employing these criteria should include impingement and/or entrainment survival data to the extent such information is available. If a facility has made environmental enhancements, such as aquaculture or habitat creation for a specific RIS, the quantifiable benefit of these enhancements should be considered.

B. Biological Criterion Based on No Significant Downward Trend

The following criterion applies to both entrainable and impingeable life stages but is limited to freshwater rivers, reservoirs, and lakes other than the Great Lakes:

A CWIS will be considered not to create an appreciable risk of AEI if there are adequate data collected over a representative period of years (representative in terms of meteorology, hydrology, biology, and plant operations), including pre-operational data, showing no statistically significant (95% confidence interval) downward trend in the population abundance of MS.

The adequacy and robustness of the data and the use of the data for meaningful trend analysis in this context are achieved, ideally, by publication in a peer-reviewed journal. However, acceptance for use in a source waterbody by appropriate fishery and wildlife managers and water quality regulators, based on sample size and design adequacy, would be sufficient.

C. Other Biological Criteria

Other biological criteria are undergoing peer review.

Attachment B

Proposed 316(b) Decision Principles for Existing Facilities

[see hard copy for diagram]

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Applicability to facilities subject to NPDES permit

Is my Facility Covered if it is a Point Source Discharger Subject to an NPDES Permit?

-EPA invites comment on the approach of drafting an individual NPDES permit containing requirements for cooling water intake structures when a facility's only NPDES permit is a general permit for storm water discharge.

17,129, col. 2

Section XXI: EPA lacks authority to apply § 316(b) to existing facilities covered by an NPDES permit only for storm water because such facilities are not subject to effluent limitations under § 301 and§ 306.

-Alternatively, EPA invites comment on the approach of adding requirements applicable to cooling water intake structures into general permits.

17,129, col. 2

See preceding comment.

EPA Response

RFC: Cooling water withdrawal thresholds of 25%

Who Is Covered Under the Thresholds Included in This Proposed Rule?

EPA requests comment on the thresholds included in the proposal, which focus the rule on facilities that 1) withdraw cooling water from waters of the U.S. and use at least 25% of the water withdrawn for cooling purposes and 2) have at least one cooling water intake structure with a design intake capacity of 50 MGD or more.

17,130, col. 1

Section VII: Rarely used emergency service water should not count toward the 50 MGD threshold.

Also, (1) facilities whose operators agree to limit actual intake flows to less than 50 MGD should be excluded from Phase II, and (2) EPA should rethink the 25% threshold and, at any rate, should revise the calculation to ensure the test is not reapplied each month, but instead only once when the permit is issued.

EPA Response

The final rule does not explicitly exclude emergency cooling water and emergency service water intakes from consideration in determining which facilities are in-scope. Although EPA does not have detailed data on emergency cooling water and emergency intakes, based on other available data EPA does not believe that including consideration of emergency intakes within this rule significantly alters the scope of the rule. EPA estimates that 84 percent of in-scope facilities have an average flow that equals or exceeds 50 MGD. Since such facilities would by necessity require a design intake flow that also equals or exceeds 50 MGD, and given that the average flow data represent normal operation and, therefore, are not significantly affected by emergency cooling water use, EPA believes that relatively few facilities are potentially affected by this issue. EPA notes that under § 125.94(f), if compliance with Part 125, Subpart J results in a conflict with a safety requirement established by the Nuclear Regulatory Commission, the Director must determine best technology available for minimizing adverse environmental impact on a site-specific basis such that it would not result in a conflict with the Commission's safety requirement.

Costs

Repowering of Steam Electric Power Generating Facilities (Utility and Nonutility)

In order to determine compliance costs, EPA will consider the results of its repowering research and any comments provided on this subject for the final rule. EPA requests comment on all repowering activities and the above summary of its repowering research. Of particular interest is information from facilities that have enacted repowering changes and the degree to whichthese changes have changed their design intake flow.

17,134, col. 1

Because EPA did not (perhaps due to CBI restrictions) provide full data for the facilities it considered in either its original cost analysis or its repowering analysis, UWAG was unable to develop comments on this point.

EPA Response

The Agency provided its repowering analysis at 66 FR 17134. There the Agency explained that it analyzed a proprietary database (NewGEN) for information on plants that planned to undertake repowering activities. The Agency outlined the data sources it utilized and provided all of the summary data on the subject. Other commenters were able to provide critiques of EPA's approach or respond to EPA's direct request for information from facilities enacting repowering changes. EPA notes that the commenter represents a vast majority of facilities within the scope of the rule, and yet did not respond to EPA's direct request for more information on facilities enacting repowering changes. In addition, the commenter did not respond to or provide general comments on the conclusions of EPA's repowering research. The Agency notes that other commenters without access to the NewGEN database were able to provide detailed comments in response to EPA's analysis summarized in the preamble to the proposal.

Option: UWAG's recommended approach

How Will Requirements Reflecting Best Technology Available for Minimizing Adverse Environmental Impact be Established for My Phase II Existing Facility?

-EPA invites comment on all aspects of this proposed regulatory framework as well as the alternative regulatory approaches discussed later in this section.

17,140, cols.1 -2

All UWAG comments are relevant here.

-EPA seeks comment on its proposal to allow three different methods to establish the best technology available for minimizing adverse environmental impacts. The three methods include 1) a facility would demonstrate that the existing design meets minimum performance standards; 2) a facility would select a design and demonstrate it meets minimum performance standards; or 3) a facility would prove that costs are significantly greater than EPA's estimates or site-specific benefits and would qualify for site-specific determination of best available technology.

17,142 col. 1

Executive Summary; Sections II, III, VI, XII: Although UWAG believes that a site-specific approach would be superior to a technology-based approach, we also believe that many aspects of EPA's proposal have merit. In particular, its inclusion of a cost-benefit test for setting site-specific alternative limits and its recognition of the efficacy of CWIS technologies (not cooling systems retrofits involving closed-cycle cooling) are important. UWAG recommends in these comments a number of ways in which this approach could be improved.
.

EPA Response

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Performance standards

Author Name Hunton & Williams

Organization obo Utility Water Act Group

How Could a Phase II Existing Facility Use Newly Selected Design and Construction Technologies, Operational Measures, and/or Restoration Measures to Establish Best Technology Available for Minimizing Adverse Environmental Impact?

In the event that a design was not achieving compliance, EPA solicits comment on whether the proposed regulation should specify that proper design, installation, operation and maintenance would satisfy the terms of the permit until the permit is reissued pursuant to a revised Design and Construction Technology Plan. If EPA were to adopt this approach, EPA would specify in the regulations that the Director should require as a permit condition the proper design, installation, operation and maintenance of design and construction technologies and operational measures rather than compliance with performance standards.

17,143, col. 3

Sections VI, XVIII: UWAG believes strongly that any NPDES permit provisions should not specify a rigid numeric performance standard for compliance assessment. Rather, as EPA suggests, performance standards, if adopted at all, should be used to select technology and the permit should specify that that technology must be properly operated and maintained.

UWAG’s comments suggest a simplified approach to choosing among EPA’s recommended technologies. That recommended approach also addresses this issue.

EPA Response

Please see response to comment 316bEFR.029.040. For a discussion of Technology Installation and Operation Plans and their role in compliance with the requirements of today's rule, please see the preamble.

RFC: Appropriateness of "significantly greater"

Site-Specific Determination of Best Technology Available

EPA invites comment on whether a "significantly greater" cost test is appropriate for evaluating requests for alternative requirements by Phase II existing facilities.

17,146, col. 1

Section XII B 5: According to EPA, the "significantly greater" cost test is not as stringent as the "wholly disproportionate" test. That does not make it a rational test, however, because it could still result in costs greater than benefits. EPA should adopt a benefit-cost standard that maximizes net benefits.

EPA Response

See responses to 316bEFR.006.003, 018.009 and 045.012.

Subject Matter Code 10.09

RFC: Does today's proposal allow for 'backsliding'

Site-Specific Determination of Best Technology Available

-EPA invites comment on whether the standards proposed today might allow for backsliding by facilities that have technologies or operational measures in place that are more effective than in today's proposal.

17,146, col. 2

EPA need not be concerned about "backsliding" (that is, abandoning a more effective technology in favor of one less effective, as a result of a relaxation of the rules) for three reasons. First, EPA's proposal is very stringent. Second, Phase II facilities are highly unlikely to abandon a significant investment in an existing CWIS technology, assuming that it is operating effectively, whether or not the rules change. Third, the CWA includes, and EPA has promulgated as part of the NPDES rules, anti-backsliding provisions. To the extent those rules apply to situations of this kind, there is no reason to duplicate them in this rulemaking. To the extent they do not, EPA would have no authority to impose them.

-EPA invites comment on approaches EPA might adopt to ensure that backsliding from more effective technologies does not occur.

17,146, col. 2

Such provisions are unnecessary for the reasons explained above.

EPA Response

RFC: Proposed use of restoration measures

What is the Role of Restoration Under Today's Preferred Option?

EPA invites comment on all aspects of using restoration measures in lieu of or in combination with reductions in impingement mortality and entrainment.

17,146, col. 3

Section XIII: UWAG supports the use of restoration on a voluntary basis, in lieu of or with CWIS technologies, where CWIS technologies otherwise would be needed to minimize AEI. UWAG also encourages flexibility in defining appropriate restoration projects, nature and extent of the project, species benefited, and extent and nature of information required to predict and verify project results. Such flexibility allows society to benefit from historical and ongoing experience with restoration efforts.

EPA Response

For a discussion of the extent to which restoration measures are voluntary, see EPA's response to comment 316bEFR.060.022.

The final rule allows permitting authorities the flexibility to make decisions on the feasibility of restoration measures on a site-specific, case-by-case basis. All restoration measures must meet the requirements of the final rule, including those described in sections 125.94 and 125.95.

Comment ID 316bEFR.041.209

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 11.02

RFC: Restoration measures as supplement only?

What is the Role of Restoration Under Today's Preferred Option?

EPA specifically invites comment on whether restoration measures should be allowed only as a supplement to technologies or operational measures.

17,146, col. 3

Section XIII.A: Restoration should be allowed in lieu of technology measures, not merely as a supplement. Nothing in the CWA requires that restoration serve only as a supplement, nor would such a result reflect good public policy. The basis for restoration -- that is, avoidance of AEI in the first place -- applies whether restoration occurs in lieu of or supplementary to technology. In both cases, the goal of § 316(b) is met, because AEI is avoided or minimized.

EPA Response

Facilities may use restoration measures under the final rule either in lieu of or in combination with technologies that reduce impingement mortality and entrainment. All restoration measures must satisfy the requirements in the final rule, including those described in sections 125.94 and 125.95.

For a discussion of EPA's authority for including restoration measures as a compliance option in the final rule, the preamble to the final rule.

RFC: Appropriate spatial scale for restoration

What is the Role of Restoration Under Today's Preferred Option?

EPA also seeks comment on the most appropriate spatial scale under which restoration efforts should be allowed should restoration measures be limited to the waterbody at which a facility's intakes are sited, or should they be implemented on a broader scale, such as at the watershed or State boundary level.

17,146, col.3

Section XIII G: The spatial scale of restoration measures should be flexible to allow maximum short- and long-term environmental benefits. In light of the wide variety of situations in which restoration might be used and techniques that might be applied, it would be difficult for EPA to craft a uniform set of limitations that would not unduly constrain innovation in this area.

EPA Response

For a discussion of the appropriate scale on which to conduct restoration measures, see EPA's response to comment 316bEFR.212.001.

Comment ID 316bEFR.041.212

Author Name Hunton & Williams
Organization obo Utility Water Act Group

Subject Matter Code 11.04
RFC: Consultation with wildlife agencies

What is the Role of Restoration Under Today's Preferred Option?

EPA invites comment on the nature and extent of consultations with Federal, State, and Tribal fish and wildlife management agencies that would be appropriate in order to achieve the objectives of section 316(b) of the CWA, in cases where restoration is proposed.

17,146, col. 3

As a general matter, the nature of the information EPA suggests would be produced and considered where consultation is required is typical of current experience, with three caveats. First, formal consultations under the federal Endangered Species Act and other relevant federal statutes are not required where the state is the permit issuer. Second, any type of consultation should focus on species that are likely to be affected by the intake -- not all species that are likely to be anywhere in the vicinity but for which there is no evidence of contact or effect. For the same reason, it is not necessary or appropriate for EPA to require that consultations result in identification of all stressors to the waterbody, as EPA suggests it might. Third, it must be clear that the final decision remains with the permit writer and must be made consistent with § 316(b). Section 316(b) does not necessarily displace other applicable laws, which remain in full force, but neither do those laws expand EPA's or the permit writers' authority under § 316(b).

EPA Response

For a discussion of the role of authorities other than the permitting authority, see EPA's response to comment 316bEFR.320.007.

Comment ID 316bEFR.041.213

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 11.05

RFC: Info. to include in a restoration plan

What is the Role of Restoration Under Today's Preferred Option?

-EPA seeks comment on the type of information that would be appropriate to include in a written request for consultation on proposed restoration projects submitted to the State, Tribal, and Federal agencies responsible for management of aquatic resources within the waterbody at which the cooling water intake is sited.

17,146, col. 317,147, col. 1

The information EPA proposes to request for restoration measures generally appears reasonable. EPA should recognize, however, that the nature of and need for design and engineering calculations, drawings, and maps will vary based on the nature of the restoration project proposed.

-EPA invites comment on whether the following information proposed to be included in a request for consultation is appropriate and adequate or if it should be augmented or streamlined.
--- proposed restoration measures
--- summary of benefits
--- implementation and maintenance plan
--- summary of past or voluntary consultation with Federal, State, or Tribal fish and wildlife agencies
--- design and engineering calculations, drawings, and maps.

17,147, col. 1

See preceding comment.

-EPA invites comment on what specific, additional information should be included in a facility's restoration plan and/or which of the proposed information requirements are unnecessary.

17,147, col. 1

Section XIII: See preceding comment.

EPA Response

EPA believes the requirements in the final rule provide permit applicants and permitting authorities with the flexibility to perform an assessment of a restoration measure that is commensurate with the restoration measure's level of complexity.

Comment ID 316bEFR.041.214

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 11.06

RFC: Performance/effectiveness of restoration

What is the Role of Restoration Under Today's Preferred Option?

EPA invites comment on how to measure "substantially similar performance" of restoration measures and methods that can be used to reduce the uncertainty of restoration activities undertaken as part of today's preferred option.

17,147, col. 2

Section XIII C: EPA should emphasize the scientifically sound design of restoration projects in the first instance. Any demonstration should then focus on whether or not the physical structures or other attributes that were designed have been put in place as proposed. EPA should not require unduly burdensome "species replacement"-type demonstrations.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 11.06

RFC: Performance/effectiveness of restoration

What is the Role of Restoration Under Today's Preferred Option?

-EPA seeks comment on how it may measure the success or failure of restoration activities given the high degree of uncertainty associated with many areas of this developing science and that many of these activities do not produce measurable results for many months or years after they are implemented. For these reasons, EPA requests comment on whether to require that a facility using restoration measures restore more fish and shellfish than the number subjected to impingement mortality or entrainment.

17, 147, cols 2-3

Section XIII C: Physical demonstrations should be used including aerial imaging to verify changes in water quality (clarity), habitat quality and quantity, and sedimentation as determined by bathymetric measurements.

EPA should not require that restoration programs address uncertainty by increasing the scale of the project or otherwise assigning an inflated restoration/loss ratio. Rather, EPA should promote restoration projects, and the broader, typically longer-term benefits they yield, by giving permit writers broad flexibility to decide exactly how much restoration is enough. This will vary, depending on the amount of uncertainty, the extent and value of the impingement or entrainment losses to be offset, the nature of the proposed restoration project and experience with projects of that kind, and many other site-specific factors. Rigid requirements for a high degree of precision will increase demonstration costs unnecessarily and divert resources that otherwise could be used to enhance the project itself. While experimental projects should be subject to more rigorous evaluation, EPA should not impose unreasonable burdens of proof.

-EPA requests comment on establishing margins of safety for restoration measures (particularly for activities associated with outcomes having a high degree of uncertainty) and identifying the appropriate authority for establishing safety measures.

17,147 col. 3

See the preceding comment

-EPA also seeks comment on an appropriate basis for establishing safety margins (e.g., based exclusively on project uncertainty, relative functional value or rareness of the system being restored, or a combination of these) to ensure that restoration measures achieve performance comparable to intake technologies.

17,147, col. 3 - 17,148, col. 1

See the preceding comment

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

RFC: Consideration of additional env. Benefits

What is the Role of Restoration Under Today's Preferred Option?

EPA requests comment on whether and how additional environmental benefits provided by restoration measures should be considered in determining appropriate fish and shellfish rates for restoration projects.

17,148, col. 1

Section XIII: UWAG’s comments describe very generally the need to account for non-aquatic life benefits of restoration as well as benefits that extend beyond the life of the plant. In general, UWAG believes that there is no single method of accounting for these factors and that flexibility will be required. That they must be considered is evident from the terms of § 316(b) itself, which refers to “environmental impacts,” not to aquatic organism impacts alone.

EPA Response

Any restoration measure must meet all the requirements described in the final rule.

For a discussion of the ancillary benefits associated with restoration measures, see EPA's response to comment 316bEFR.032.011.

Comment ID 316bEFR.041.217

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 11.08

RFC: Habitat conservation as part of restoration

What is the Role of Restoration Under Today's Preferred Option?

EPA seeks comment on whether habitat conservation would be an appropriate component of a facility's restoration efforts.

17,148, col. 2

Section XIII E: Habitat conservation should be considered a restoration technique. In many cases, important habitat might be lost if private resources are not found to ensure its conservation. As a matter of public policy, it makes more sense to allow permittees to put resources into conservation rather than forcing them to wait until habitat is lost and then replace it. Habitat conservation yields tangible and immediate benefits and should play an important role in restoration.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority in determining the appropriate level of performance to meet the requirements of the final, see EPA's response to comment 316bEFR.060.026.

Comment ID 316bEFR.041.218

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 11.06

RFC: Performance/effectiveness of restoration

What is the Role of Restoration Under Today's Preferred Option?

EPA invites comment on the role of restoration in addressing the impact of cooling water intake structures. EPA invites commenters to suggest alternative approaches to ensuring that restoration efforts are successful.

17,148, col. 3

See preceding comments.

Flexibility is the key to encouraging restoration and ensuring successful programs. There is no surer way to stifle innovation in this regard than to impose too many constraints on permit writers. Instead, EPA should set reasonable goals and appropriate, flexible standards for demonstration (such as a “reasonable amount of relevant and scientifically credible data supports the proposal”) and allow the public comment process to ensure full airing of any issues.

Also, as UWAG has noted, in many instances natural resource managers find greater benefit overall from projects that focus on benefits to a waterbody’s living resources different from those impinged or entrained.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

EPA believes restoration measures will be well suited for some sites, and not well suited for others. Evaluation and monitoring difficulties are two reasons why restoration measures may not be suitable for a particular site.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

EPA believes the requirements for restoration measures in the final rule are written with a significant amount of flexibility.

For a discussion of the role of ancillary benefits in restoration measures, see EPA's response to comment 316bEFR.032.011.

RFC: Monitoring frequencies

What are the Minimum Elements of an Impingement Mortality and Entrainment Characterization Study?

-EPA invites comment on whether it should set specific, minimum monitoring frequencies and/or whether it should specify requirements for ensuring appropriate consideration of uncertainty in the impingement mortality and entrainment estimates.

17,148, col. 3

Sections VI, XVII, XVIII: EPA should not set inflexible minimum or maximum monitoring requirements, either as to monitoring intervals or total duration. Rather, any monitoring should be tailored to the site, considering the amount and reliability of existing data, the nature of the species of interest, and the type of technology or other alternative used to satisfy § 316(b). Permittees should have the initial responsibility for developing and supporting an appropriate monitoring plan. EPA could provide guidance on factors that weigh in favor of different monitoring frameworks.

The simpler approach UWAG recommends avoids the need for such monitoring in most cases, and focuses on evaluation of proper operation of the selected technology.

What Should be the Minimum Frequencies for Impingement and Entrainment Compliance Monitoring?

-EPA invites comment on including minimum sampling frequencies and durations as follows: for at least two years following the initial permit issuance, impingement samples must be collected at least once per month over a 24 hour period and entrainment samples must be collected at least biweekly over a 24 hour period during the primary period of reproduction, larval recruitment, and peak abundance.

17,149, col. 1

Section XVII: See preceding comment.

-EPA invites comment on whether more frequent sampling would be appropriate to accurately assess diel, seasonal, and annual variation in impingement and entrainment losses.

17,149, col. 1

Section XVII: See preceding comment.

-EPA also invites comment on whether less frequent compliance biological monitoring would be appropriate (perhaps depending on the technologies selected and implemented by a facility).

17,149, col. 1

Section XVII: See preceding comment.

RFC: Entrainment vs. entrainment mortality

How is Entrainment Mortality and Survival Considered in Determining Compliance With the Proposed Rule?

EPA invites comment on regulatory approaches that would allow Phase II existing facilities to incorporate estimates of entrainment mortality and survival when determining compliance with the applicable performance standards proposed in § 125.94(b) of today's proposed rule. EPA invites commenters to submit any studies that document entrainment survival rates for the technologies used as the basis for today's performance standards and for other technologies,

17,149, col. 2

Sections V, VIII E: UWAG believes that EPA should allow for consideration of entrainment survival, where scientifically sound studies show it occurs. That entrainment survival occurs for some species and life stages at some plants is proven fact, and ignoring it would be bad science and bad policy.

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards. Please see response to comment 316bEFR.002.015 regarding the inclusion of entrainment survival estimates in site-specific benefit analysis.

Benefit Estimation Methodology

What Should be the Appropriate Methodology for Benefits Assessment?

EPA invites comment on which of these methodologies (environmental and economic analyses) or any other, is the most appropriate for determining a fair estimate of the benefits that would occur should the Phase II existing facility implement technology to comply with the applicable performance standards. In addition, EPA invites comment on whether narrative benefits assessments should supplement these methodologies to properly account for those benefits which cannot be quantified and monetized.

17,149, col. 2

Section V and Appendices 9 and 13: RUMs and, in appropriate cases, benefit transfer methods are best, but must be carefully and appropriately applied. EPA's Habitat Replacement Cost (HRC) and Societal Revealed Preference (SRP) methods are not benefits estimation methods at all, but instead estimate costs. Use of those methods is wholly invalid.

As for narrative benefits assessments to capture non-monetized benefits, such assessments could be used, albeit with great care. In particular, any narratives should be based on appropriate economic assessment principles. Also, if EPA includes monetized estimates for nonuse values, the narrative should explain the relationship between the nonmonetized and monetized assessment of non-use benefits. Conceptually, such an approach would be better than EPA's wholly illegitimate HRC and SRP methods, and less resource intensive than Contingent Valuation (CV) methods. But narrative assessments are necessarily somewhat subjective and cannot be treated on the same level as more objective economic methods and data. And, most important, before any method is used to try to capture non-use benefits, there must be at least some legitimate linkage between the regulations and the hypothesized effects and values.

EPA Response

EPA agrees that RUMs and benefit transfer are the best available methods for valuing recreational use benefits. The Agency believes that it has carefully applied these methods to evaluate benefits to recreational anglers for the final 316(b) regulation. For detail on recreational fishing benefits analysis, see Chapter A11, Estimating Benefits with a Random Utility Model, and Chapter 4, RUM Analysis, in Parts B through H in the Regional Case Study report (DCN # 6-0003). See responses to comments #316bEFR.041.452, #316bEFR306.320, and #316bEFR337.010 for additional details regarding EPA's RUM analysis.

The HRC method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see comment # 316bEFR.005.035.

The SRP method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For

EPA's response to comments on the SRP method, please see comment # 316bEFR.005.006.

The Agency disagrees that qualitative assessments are more subjective and cannot be treated on the same level as other economic methods and data. EPA's Guidelines for Preparing Economic Analyses (DCN #6-1931) recommend that benefits be considered from a qualitative perspective when developing monetized estimates is not feasible. The Agency believes that it adequately considered the benefits of the environmental protections at issue in the final 316(b) rule and carefully developed a qualitative assessment of ecological benefits stemming from the final 316(b) regulation.

Valuing Forage Species (incl non-use and non-landed)

Quantified and Monetized Baseline Impingement and Entrainment Losses

EPA invites comment on including its approach for estimating nonuse or passive values. It estimates nonuse impacts at 50% of the value of recreational use impact.

17,149, col. 3

Section V D: This is a wholly unfounded assumption on which EPA should not rely for any purpose. If EPA were sure that appreciable non-use benefits existed for the forage effects in question, it could attempt to capture those by doing careful, unbiased CV studies (although the reliability of such studies is the subject of debate among many economists). But EPA has no basis for believing that such non-use values really exist in this context, much less that they are 50% of use values. Even if it does not revise its own benefit estimates, EPA cannot legitimately endorse or require this approach for future benefit estimates.

UWAG also notes that EPA's unfounded and highly conservative approach addressing any uncertainty regarding the existence and value of non-use benefits contrasts markedly with its approach to accounting for uncertainty with regard to entrainment survival. There, even in cases for which some data exists to show that survival occurs, EPA has chosen to assume that none occurs. As to non-use values, even in the absence of any evidence that non-use values exist for the types of forage fish losses at issue here, EPA has assumed that such values are 50% of its already inflated use values.

EPA Response

For EPA's response to comments on the use of the 50% rule-of-thumb to estimate non-use benefits, please refer to EPA's response to comment #316bEFR.005.034.

Please also refer to EPA's response to comments on the HRC methods (316bEFR.005.035) and the SRP methods (316bEFR.005.006); the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003); and to EPA's Guidelines for Preparing Economic Analyses (EPA 240-R-00-003).

Please see response to comment #316bEFR306.105 for additional discussion of the potential use of stated preference (e.g. CV or CVM) approaches to address the nonuse valuation issue.

Please see response to comment #316bEFR306.306.506 for additional discussion of issues related to entrainment survival.

RFC: Entrainment vs. entrainment mortality

Should Estimates of Entrainment Mortality and Survival be Included in Benefits Assessments?

-EPA requests comment on whether it is appropriate to allow consideration of entrainment mortality and survival in benefit estimates, and if so, should EPA set minimum data quality objectives and standards for a study of entrainment mortality and survival used to support a site-specific determination of best technology available for minimizing adverse environmental impact. EPA may decide to specify such data quality objectives and standards either in the final rule language or through guidance.

17,150, col. 2

Section VIII E: Yes, EPA should consider entrainment survival and net it out of any loss estimates it derives for purposes of assessing regulatory options. Equally important, EPA should ensure appropriate consideration of such survival during future benefit estimates (assuming the Agency does not amend the performance standard for entrainment so that it applies only to entrainment mortality).

-EPA could provide guidance on appropriate survival studies, but it should not set inflexible criteria that would preclude use of otherwise legitimate data. Alternatively, EPA could look to a knowledgeable scientific or technical association to develop such guidelines.

17,150, col. 3

See EPRI comments on this issue.

-EPA invites comment on its preliminary review of the data quality of entrainment survival studies provided in Chapter D7. EPA also requests that commenters submit additional entrainment survival or mortality studies for review.

17,150, col. 3.

See EPRI comments on this issue.

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards. Please see response to comment 316bEFR.002.015 regarding the inclusion of entrainment survival estimates in site-specific benefit analysis. Please see the response to comment 316bEFR.306.506 for the discussion regarding EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule.

Subject Matter Code 13.0

More Stringent Requirements

When Could the Director Impose More Stringent Requirements?

-EPA requests comment on specifying that more stringent requirements would be appropriate when compliance with the applicable requirements in § 125.94(b) and (c) would (1) result in unacceptable effects on migratory and/or sport or commercial species of concern to the Director; and (2) not adequately address cumulative impacts caused by multiple intakes or multiple stressors within the waterbody of concern.

17,151, col. 1

Section XV: No such additional limits are justified. Indeed, as UWAG's comments show, even the ambitious standards EPA proposes probably are well in excess of what is justified by the need to minimize AEI by protecting aquatic populations. Moreover, if EPA is convinced that § 316(b) merits a consistent, technology-based approach, any additional requirements such as it describes would undermine such consistency. Last, UWAG does not believe that § 316(b) authorizes EPA to require power plants to remediate the consequences of "multiple stressors" as this language suggests. While effects of a CWIS in light of other sources of cropping are relevant, § 316(b) does not make that CWIS responsible for cutting losses to zero where its effects are de minimis.

-EPA requests comment on whether any explicit regulatory provision for more stringent requirements is needed in light of section 510, which does not apply when EPA is the permitting authority.

17,151, col. 1

Section XV: An explicit regulatory provision applying CWA §510 is unnecessary, because the statute applies of its own force, as states are well aware. Adding such a provision also would serve only to create confusion and muddy the distinction between state and federal requirements. Also, serious constitutional issues are raised if EPA is suggesting that EPA should be able to impose requirements more stringent than federal law in jurisdictions where it is the NPDES permitting authority.

EPA Response

Please see response to comments 316bEFR.002.016 and 316bEFR.041.113.

With respect to the last portion of this comment, EPA observes that, as the permitting authority, it must not only impose permit requirements that satisfy the applicable section 316(b) regulations but also include requirements consistent with the conditions in a certification made by a state under section 401 of the Clean Water Act.

Comment ID 316bEFR.041.226

RFC: Appropriateness of "significantly greater"

When Could the Director Impose More Stringent Requirements?

EPA requests comment on whether recovery of aquatic communities in such waterbodies designated for propagation of fish and shellfish might be delayed by use of the significantly greater cost-to-benefit test proposed today.

17,151, col. 2

Such a result is unlikely because in most cases cropping by the CWIS is not the proximate cause of any non-attainment and thus will have little or no effect on achievement of fishable/swimmable uses. Experience over the years with numerous waterbodies which, once impaired by pollutants, are now supporting such uses despite the de minimis cropping of burgeoning populations by existing CWIS, bears this out.

EPA Response

The comment generally supports the rule. However, EPA notes that impingement and entrainment can affect achievement of some designated uses (e.g., "fishable").

More Stringent Requirements

When Could the Director Impose More Stringent Requirements?

EPA requests comment on a regulatory alternative that would explicitly allow the Director to require more stringent technologies or measures where not doing so would delay recovery of an aquatic species or community that fish and wildlife agencies are taking active measures to restore, such as imposing significant harvesting restrictions.

17,151, col. 2

The CWA only allows EPA to impose requirements on CWIS location, design, construction and capacity reflecting “BTA.” Those requirements must be selected by reference not just to impingement and entrainment, but to minimize adverse environmental impact in light of technology practicability, costs and overall benefits.

Equally important, such a provision is unneeded, since (1) what EPA already proposes would require appreciable loss reductions, whether necessary or not (unless the benefits do not justify the costs) and (2) there is no evidence that CWIS-related losses are likely to be a determining factor in cases where harvest restrictions need to be imposed due to fishing pressure or other factors.

EPA Response

Please see response to comment 316bEFR.002.016.

RFC: 5% threshold and supporting documents

Discussion of the 5% Flow Threshold in Freshwater Rivers

-If a facility withdraws more than 5% of the mean annual flow of a freshwater river or stream, the facility would be required to reduce entrainment by 60- 90%. EPA invites comment on the use of the 5% threshold and its supporting documents in the NODA for New Facility Rule (66 FR 28863).

17,151, cols.2-3

Section VII A: UWAG believes that this requirement is arbitrary and unfounded. EPA should not impose across the-board entrainment control requirements for freshwater facilities withdrawing a given percentage of the instream flow.

If it retains this provision, however, EPA should give permittees who have or wish to collect the necessary data the opportunity to show that the mean flow criterion should be applied only during a portion of the year when entrainable-sized organisms are relatively abundant.

-EPA also requests comment on the following alternative withdrawal thresholds for triggering the requirement for entrainment controls: (1) 5% of the mean flow measured during the spawning season (to be determined by the average of flows during the spawning season, but remaining applicable to non-spawning time periods); (2) 10% or 15% of the mean annual or spawning season flow; (3) 25% of the 7Q10; and (4) a species-specific flow threshold that would use minimum flow requirements of a representative species to determine allowable withdrawals from the water body.

17,151, cols. 2-3

See preceding comment.

Subject Matter Code 15.01

RFC: State or Tribal alts. achieve comparable perf.

State or Tribal Alternative Requirements that Achieve Comparable Environmental Performance to the Regulatory Standards Within a Watershed

EPA requests comment on its proposal to include an alternative where an authorized State or Tribe may choose to demonstrate to the Administrator that it has adopted alternative regulatory requirements that will result in environmental performance within a watershed that is comparable to the reductions in impingement mortality and entrainment otherwise achievable under § 125.94.

17,151, col. 3

Section II B: UWAG agrees. EPA should encourage successful state programs. EPA's rule requires some refinement, however, so that good programs will not fall short just because they have not in the past met what EPA now envisions as the appropriate procedural or paperwork requirements, or do not ensure numerically equivalent loss reductions across the board.

EPA Response

Today's final rule maintains the prerogative of a permitted State to demonstrate to the Administrator it has adopted alternative requirements that will result in reductions in impingement mortality and entrainment within a watershed comparable to those that would be achieved under § 125.94. This alternative recognizes the successful achievements of many states in regulating environmental impacts associated with cooling water intakes.

Comment ID 316bEFR.041.230

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 15.01.01

Definition and geographic scale of a watershed

State or Tribal Alternative Requirements that Achieve Comparable Environmental Performance to the Regulatory Standards Within a Watershed

-EPA also requests comment on the appropriate definition of watershed.

17,151, col. 3

No one-size-fits-all definition is necessary or appropriate, especially given the widely different waterbody types that predominate in different states and regions. EPA either should defer to an existing state definition or give states the flexibility to craft their own with public input.

-EPA invites comment on use of the USGS eight-digit hydrologic unit (generally about the size of a county) as the maximum geographic scale at which an authorized State or Tribe could establish alternative regulatory requirements.

17,152, col. 1

See preceding comment.

EPA Response

In the proposal, EPA requested comment on the appropriate definition for watershed with regard to achieving comparable environmental performance through alternative regulatory requirements in a State (125.90(c)). In today's final rule, EPA has deferred the decision on the appropriate definition of watershed to the permit director; however, EPA will review the State's alternative regulatory requirements. EPA believes that allowing a State to use an existing definition will allow the State greater flexibility in their NPDES permitting process which is sometimes done on a watershed basis. With regard to watersheds that cross political boundaries of a Tribe or State, the permit directors involved should consult each other.

RFC: States to demonstrate comparable env. perf.?

State or Tribal Alternative Requirements that Achieve Comparable Environmental Performance to the Regulatory Standards Within a Watershed

EPA requests comment on whether it should instead allow States to demonstrate comparable environmental performance at the State level, thus allowing States the flexibility to focus protection on priority watersheds.

17,152, col. 2

Section II B: UWAG Agrees. EPA should give the states maximum flexibility and allow them to set their own priorities.

EPA Response

EPA believes today's final rule allows ample flexibility with section 316(b) determinations. In addition to five means with which to comply with the applicable performance standards, the rule allows States and Tribes to demonstrate alternative regulatory requirements (§ 125.90(c)) that will result in environmental performance within a watershed that is comparable to the reductions of impingement mortality and entrainment in the performance standards. Additionally, § 125.90(d) states that nothing in today's rule precludes a State or Interstate Agency from adopting or enforcing any requirement that is not less stringent than those required by Federal law.

Subject Matter Code 10.08

RFC: "Significantly greater" for eval. alt. req.

Comprehensive Cost Evaluation Study

EPA invites comment on whether it should establish minimum standards for a Comprehensive Cost Evaluation Study and on whether such standards should be established by regulation or as guidance only.

17,153, col. 1

See Section XII E: In general, UWAG believes that establishing inflexible minimum standards in this regard is unnecessary and will serve only to increase burdens on the permit writers and the regulated community. While some guidance to provide greater clarity might be helpful, any such guidance should be developed with substantial input from engineers and other experts with substantial experience developing estimates for and implementing actual projects (not vendors, who may not know, and are not responsible for, the final costs).

EPA Response

The final rule includes provisions that allow a site-specific determination of BTA in certain circumstances. To support this approach, the rule also includes requirements for existing facilities to submit information needed by the permit writer to determine whether the facility meets the requirements for a site-specific determination of BTA and what requirements represent BTA for that facility. These requirements, which include the requirements for the comprehensive cost evaluation study, are generally specified in 125.95(b)(6) and consist of the minimum criteria necessary to ensure that sufficient and appropriate information will be available for making permitting decisions. EPA has tailored these provisions so they only apply where necessary and appropriate. All of these provisions have developed based on the information and data available to the Agency during development of the rule.

Comment ID 316bEFR.041.234

Subject Matter Code 10.1

General: cost tests

Cost Benefit Test

EPA requests comment on the cost benefit provision in §124.95.

17,153, col. 2

Sections V and XII and Appendix 13: UWAG strongly endorses inclusion of an appropriate benefit-cost test. Any such test must be economically and socially rational, however. UWAG does not believe the "significantly greater costs than benefits" test is rational, and the wholly disproportionate test would be even less so. We advocate a provision requiring the maximization of net benefits.

EPA Response

For a discussion of "maximization of net benefits" see response to comment 316b.EFR.005.020.

Comment ID 316bEFR.041.236

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 21.08

Burden on permitting agencies (general)

Cost Benefit Test

EPA requests comment on the burden estimates in docket items 2-034A and 2-034B. For example, EPA estimates 650 person hours per permit and 25,000 in contract dollars.

17,153, col. 2

UWAG is not in a position to provide information on state permit review costs. We note, however, that the limited cost data provided reflect decisions made in the absence of any EPA rules or final guidance. One would expect that costs incurred after rules and guidance are in place would be lower (perhaps much lower)

EPA Response

EPA hopes that this will be the case, but recognizes that this is speculation.

Comment ID 316bEFR.041.237

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 10.06.01

RFC: Incorp. costs/benefits without burden on Dir.

Cost Benefit Test

EPA invites comments on ways to incorporate site-specific consideration of costs and benefits without undue burden on the Director. In particular, EPA invites comment on decision factors and criteria for weighing and balancing these factors that could be included in a regulation or guidance that would streamline the workload for evaluating site-specific applications and minimize the potential for legal challenges.

17,153, col.2

See Sections V, XlI and Appendix 13: Using a "maximize net benefits" test would be clearer and reduce disputes because it allows for straightforward comparison of alternatives, without having to make subjective (and, we submit, irrational and counterproductive) decisions about whether a cost is or isn't "significantly' greater or "wholly" disproportionate. Other steps that would avoid disputes and streamline decisionmaking include: (1) authorizing use of only well-accepted and documented economic methods for estimating benefits, such as those set forth in EPA's own Guidelines for Preparing Economic Analyses (EPA 240-R-00-003, Sept. 2000) (2) avoiding unfounded multipliers and other factors, and (3) focusing on use values except where there is solid evidence that non-use values exist and would be affected.

See also comment above on guidance for cost estimates.

EPA Response

EPA has considered the suggestions provided by the commenter. See discussion regarding site-specific compliance alternative in the preamble to the final rule for additional information.

Comment ID 316bEFR.041.238

Subject Matter Code 16.01

RFC: Regulating limited capacity facilities

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Capacity Utilization

EPA invites comment on its proposed approach to regulating Phase II existing facilities with limited capacity utilization. EPA specifically invites comment on the above alternative thresholds (20% and 25% capacity utilization) for using capacity utilization to establish performance standard that address impingement mortality but not entrainment.

17,154, col. 1

Section VII: UWAG agrees that the alternative factors EPA identifies would be fairer than the 15% factor it has proposed, and would be more consistent with the way power companies (and, perhaps DOE) classify peaking plants. According to EPA's analysis of the issue in Ch. 2 of the TDD (which would benefit from substantial clarification), UWAG believes the incremental difference in protection associated with using a 20% or 25% capacity utilization rate would be insignificant.

Whatever rate EPA sets, it should (1) clarify how the rate should be calculated for facilities (vs. units) and (2) allow a facility whose rates in the past have not fallen below the annual threshold to (a) commit to maintaining its capacity utilization rate below the threshold in the future, and/or (b) show that its period(s) of operation do not overlap with the times that entrainable species are vulnerable.

EPA Response

The Agency has analyzed for the final rule the incremental protection potentially afforded with a 15 percent utilization rate as compared to the hypothetical 20 and 25 percent factors (see DCN XXXX). The Agency found that in considering a 20 percent factor for utilization rate threshold that the entrainment reduction potential of the rule decreased by 5 percent on a national level. With the 25 percent factor for utilization rate threshold, the entrainment reduction potential of the rule decreased by 8 percent on a national level. Considering the additional concern that the Agency has with extending the threshold to average periods of operation approaching an entire seasonal operation period (i.e., those likely covering peak spawning and migration periods) the 20 and 25 percent thresholds are not acceptable. Additionally, see comments 316b.EFR.038.024, 316b.EFR.330.032, 316b.EFR.002.028 for a sampling of comments that object to raising the threshold on the grounds of increased entrainment potential.

EPA has clarified the basis for calculating the utilization rate threshold (i.e., facility vs. units), see the definition of capacity utilization rate in the final rule. EPA has allowed facilities to commit to maintaining capacity rates below the threshold in the future. Also, the Agency has allowed for facilities to incorporate into their entrainment reduction calculations the effect of flow reductions through strategic operation that does not overlap with times that entrainable species are vulnerable. Hence, the commenter's requests on these matters have been met.

Subject Matter Code 17.02

Option: Reduce capacity comm. with closed-cycle

Other Technology-Based Options Under Consideration

EPA invites comment on the alternative regulations requiring closed-cycle cooling for all existing Phase II plants, along with additional technologies where needed to address concerns about T&E species, migratory species, and the like.

17,154, col. 2

Section IV: UWAG believes that requiring retrofitting of close-cycle cooling is both unauthorized by the statute and wholly unjustified on environmental or economic grounds. The other concerns EPA raises are best addressed by a site-specific approach or, in the case of T&E species, by the specialized state and federal laws already designed to protect those species.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

Comment ID 316bEFR.041.240

Author Name Hunton & Williams

Sample site-specific rule (p.17159-61)

Sample Site-Specific Rule

-EPA also invites comment on site-specific approaches for determining the best technology available for minimizing adverse environmental impact at existing facilities,

17,159, col. 1

As noted above, and in Section III of our comments, UWAG endorses site-specific processes for § 316 decisionmaking. We prefer either the option we have crafted, or that offered by PSEG (although we do not endorse the wholly disproportionate cost test which PSEG's approach mentions). The other alternative site-specific approaches described by EPA in its preamble have some merit, but have some problems that make them technically and practically inferior to either of these two processes.

-EPA invites comment on the framework included in the sample rule on 17,159, 17,160, 17,161 as an appropriate approach for implementing section 316(b) as an alternative to today's proposed requirements.

17,161, col. 2

See preceding comment.

-EPA also invites comments on the following site-specific approaches for implementing section 316(b) on a site-specific basis within the general framework set forth in the Sample Rule.

1) alternative based on EPA's 1977 Draft Guidance
2) UWAG alternative
3) PSEG alternative

17,161, col. 2

Sections III A, B, and C: UWAG prefers either the UWAG or PSEG approach (but does not endorse the "wholly disproportionate" cost-benefit test).

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment

316bEFR.338.002 for more information.

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

Subject Matter Code 18.01.03

RFC: EPA 1977 definition of "AEI"?

Questions for Commenton the Determination of Adverse Environmental Impact

(b) Should the final rule adopt the 1977 Draft Guidance approach to defining adverse environmental impact as any entrainment or impingement damage caused by a cooling water intake structure?

17,164, col. 2

Section III B: UWAG believes that, in framing its question, EPA has taken out of context one statement from a much larger EPA guidance document and used it inappropriately for purposes of characterizing the 1977 Draft Guidance.

In any case, UWAG recommends the following definition of AEI: "a reduction in one or more representative indicator species that (1) creates an unacceptable risk to the population's ability to sustain itself, to support reasonably anticipated commercial or recreational harvests, or to perform its normal ecological function and (2) is attributable to the operation of the cooling water intake structure."

UWAG believes that the 1977 Guidance (including the paragraph from which EPA lifted one short sentence) supports this definition.

EPA Response

EPA rejects UWAG's definition of adverse environmental impact because it seeks to limit the scope to large changes at the population level only. This definition is too broad and could allow too much damage to a population before controls on cooling water intake structures would be put in place as the best technology available. EPA believes the 1977 guidance contemplated recognition of adverse environmental impact on both the individual and population levels. Please see the response to comment 316bEFR.075.012.

Comment ID 316bEFR.041.244

Subject Matter Code 18.01

RFC: Definition of "adverse environmental impact"

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Questions for Commenton the Determination of Adverse Environmental Impact

-(c) Should the final rule state that any impingement and entrainment is an adverse environmental impact and focus site-specific assessment on whether that impact is minimized by technologies already in place or potential changes in technology? Alternatively, should the final rule define adverse environmental impact in terms of population-level or community-level effects?

17,164, col. 2

Section III B: EPA should not state that any impingement and entrainment is an adverse environmental impact. As discussed above, this is not the position EPA has taken in the past (either in the 1977 Draft Guidance or elsewhere), nor would it make any sense from a biological, economic, or public policy point of view.

UWAG believes that AEI occurs when the loss of fish or other organisms causes declines at the population level sufficient to affect the types of factors identified in our comment above.

-(d) Should EPA adopt an approach that makes more explicit use of threshold determinations of whether adverse environmental impact is occurring? If so, should EPA adopt any or all of the conservative decision criteria suggested by UWAG in a final rule?

17,164, col. 2

Section III B: UWAG supports its own approach. We stress, however, that the highly conservative decision criteria set forth in our approach were explicitly designed as screening criteria only, and were not intended for use as definitive criteria for determining that AEI will occur.

-(e) Should the structured risk assessment decision process that UWAG recommends for determining adverse environmental impact be adopted?

17,164, col. 2

Section III B: UWAG strongly supports the process it has proposed. As we have shown that process is useful for evaluating the risk of AEI, and the data collection and interpretation framework it provides also would be useful for evaluating benefits of various approaches for minimizing AEI where it occurs.

EPA Response

Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define "adverse environmental impact" in today's final rule. For these same reasons, EPA has rejected the approaches proposed by UWAG.

RFC: Use of previous demonstration studies

Questions for Comment on Using Previous Demonstration Studies

EPA invites public comment on whether a final rule should permit the use of a previous section 316(b) demonstration for determining whether there is adverse environmental impact and the best technology available for minimizing adverse environmental impact. If such a provision is included in the final rule, what criteria or conditions should be included to ensure that the previously conducted demonstration is an adequate basis for section 316(b) decisions?

17,165, col. 1

Section II A: This question could arise in two circumstances. The first involves using past § 316(b) demonstrations in lieu of the new technology-based assessments EPA has proposed. UWAG believes that, where a successful § 316(b) demonstration has been done, its conclusions should be accepted if its studies were scientifically sound and conditions have not changed. Making those judgments might require (1) a reasoned explanation by the permittee of the methods and data used and why it is reliable, and (2) some comparison of current conditions with the most important conditions under which the study was done.

The second involves using past § 316(b) demonstrations to provide, in whole or in part, data for the application of EPA's proposed technology-based approach. Again, UWAG believes strongly that such data should be usable, so long as they are scientifically sound and relevant to the conditions at the site.

EPA Response

EPA has disallowed the use of historical determinations of BTA in today's final rule; however, existing data that is reflective of current conditions may be used to support the required studies. Please see response to comment 316bEFR.040.001 for details.

Comment ID 316bEFR.041.246

RFC: Cost: benefit ratio for site-specific BTA?

Processes Structured on Incremental Cost-Benefit Assessment

EPA solicits comment on whether an evaluation of the cost-effectiveness (i.e., the incremental cost to benefit ratio) of cooling water intake structure technologies and any operational and/or restoration measures offered by the owner or operator of a facility is an appropriate component of the analysis that would be undertaken in a site-specific approach to determining best technology available for minimizing adverse environmental impact.

17,165, col. 3

Section XII: If by this question EPA is asking whether or not UWAG believes a cost-effectiveness test should be used when selecting among recommended technologies or other options, we agree strongly that it should. Where the performance of different technologies is relatively close, but one is less expensive, then all other things being equal the permittee should be allowed to use the less expensive technology. Similarly, where one technology produces a somewhat greater increment of reduction than the next most effective, but a reasonable person would, absent special circumstances, view that increment as trivial in comparison to the incremental cost, then the permittee should be allowed to choose the next most effective technology.

If, on the other hand, EPA's question goes to whether a cost-effectiveness test would serve as an appropriate means of comparing costs and benefits, that is another matter. As we have said, UWAG believes that any § 316(b) rule should include a cost-benefit provision. But a cost effectiveness test cannot be used for this purpose. But, UWAG would not support use of a cost-effectiveness ratio (or any ratio, for that matter) for making benefit/cost assessments, or framing a benefit/cost standard, because that is not what such a test is for.

A cost-effectiveness test (which seeks the least expensive way of achieving a given outcome or closely related outcomes) differs fundamentally from a cost-benefit analysis, which compares the costs of different options to the economic benefits they produce, based on the value individuals place on different goods and services as reflected by their willingness to pay.

If EPA is asking whether UWAG supports inclusion of an appropriate cost-benefit test for purposes of selecting BTA, we do for the reasons discussed in our comments. UWAG urges EPA to adopt a test that maximizes net benefits. We note that, if EPA uses the maximum net benefit criterion, it will, by definition, include the most cost-effective alternative.

RFC: Cost: benefit ratio for site-specific BTA?

Questions for Comment on a Process for Determining the Best Technology Available for Minimizing Adverse Environmental Impact and the Role of Costs and Benefits

EPA invites public comment on the standard that would be included in any site-specific final rule for determining best technology available for minimizing adverse environmental impact, including the appropriate role for a consideration of costs and benefits.

17,166 col. 2

Sections III, XII: UWAG believes the rules should first ask the permittee to assess whether or not AEI is occurring or is likely to occur. If the answer is yes, the rules should require the permittee to identify feasible CWIS technologies and select as BTA that technology or technologies that maximize net benefits. Voluntary restoration also should be an option for avoiding AEI.

EPA Response

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020. EPA disagrees with this commenter that the plain language of section 316(b) provides for any threshold test that would require no technology unless an impact is determined to occur on an ecosystem, community, or population level and be attributable to a particular cooling water intake structure. Also, please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define adverse environmental impact in today's final rule.

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

Questions for Comment on a Process for Determining the Best Technology Available for Minimizing Adverse Environmental Impact and the Role of Costs and Benefits

EPA also invites comment on whether a test based on the concept that benefits should justify costs would be more appropriate, as is used in various other legal and regulatory contexts (see, e.g., Safe Drinking Water Act Section 1412(b)(6)(A) and Executive Order 12866, Section 1(b)(6)).

17,166, col. 2

Section XII: A test based on the concept that benefits should justify costs is closer to the "maximize net benefits" test UWAG favors and, therefore, as a practical matter is better than either of the other two. Still, the maximize net benefits test would be clearer and more consistent with core economic precepts.

EPA Response

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020. See also the preamble to the final rule.

Comment ID 316bEFR.041.251

RFC: Proposed use of restoration measures

Use of Voluntary Restoration Measures or Enhancements

EPA invites public comment on whether a final site-specific rule should permit voluntary restoration or enhancement measures to be taken into account in determining compliance with section 316(b) and, if so, what criteria should be included for evaluating the effectiveness of such measures.

17,166, col. 3

Section XIII: A number of states have used restoration successfully to avoid adverse impacts that might be caused by impingement or entrainment. As we've said above, allowing restoration, in lieu of or in addition to technology requirements, is good environmental and social policy. Measures of effectiveness need to be tailored to the project and should not be unrealistic or unduly burdensome.

EPA Response

Facilities may use restoration measures under the final rule either in lieu of or in combination with technologies that reduce impingement mortality and entrainment.

Permitting authorities have the flexibility under the final rule to make decisions on the necessary attributes of a restoration measure on a case-by-case, site-specific basis. All restoration measures must satisfy the requirements of the final rule, including those described under sections 125.94 and 125.95. Restoration measures may not be feasible for all sites.

Organization obo Utility Water Act Group

Subject Matter Code 21.08

Burden on permitting agencies (general)

Implementation Burden Under Any Site-Specific Approach

EPA seeks additional information and data on the resources necessary and available for the review of section 316(b) determinations in existing facilities' permit renewals

17,167, col. 3

This question appears to be directed at states. We note, however, that past resource demands associated with § 316(b) decisions made in the absence of a rule are not good predictors of the resources needed to implement this rule.

EPA Response

EPA disagrees. Burden information on historical 316(b) determinations may be qualitatively useful to gauge approximate resource needs for aspects of today's final rule.

Comment ID 316bEFR.041.255

Subject Matter Code 21.07

Alternative site-specific requirements

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Implementation Burden Under Any Site-Specific Approach

-EPA invites comment on whether the resource requirements of the site-specific approach also have served as a disincentive to a comprehensive revisiting of section 316(b) permit conditions during each renewal (typically every 5 years), despite advances in technologies for reducing impingement mortality and entrainment.

17,167, col. 3

Again, this question appears directed primarily to states. That said, UWAG members' experience suggests that permit writers do not have widespread concerns about past § 316(b) decisions, even though the spotlight on use attainment has intensified greatly over the past ten years. Equally important, many states have proven that they are not shy about requesting new data or making new determinations in cases where they have a concern or even a suspicion that an issue might exist.

Last, state decisions not to endlessly revisit § 316(b) decisions absent a good reason are consistent with existing EPA policy. See Section XX.

-EPA seeks comment on the above discussion of the resource implications of implementing the requirements of section 316(b) on a case-by-case basis

17,167, col. 3

Section III C: Again, this appears directed to the states. Nevertheless, UWAG emphasizes that resource implications should not drive how the rule is structured. It should be based on the sound science and good public policy.

-EPA invites comment on how the workload of a site-specific approach could be streamlined so as to provide for the benefits of a site-specific approach (e.g., application of technologies specifically tailored to site-specific conditions) while recognizing the resource constraints faced by so many permitting agencies.

17,167, col. 3

See preceding comments.

EPA Response

EPA disagrees that a large percentage of facilities will opt for a site-specific determination of BTA. Please refer to the response to comment 316bEFR.202.002 for more information.

Subject Matter Code 21.02

Director's role in determining requirements

How Would the Director Determine the Appropriate Cooling Water Intake Structure Requirements? What Are the Respective Federal, State, and Tribal Roles?

-EPA is interested in ways to decrease application review time and make this process both efficient and effective.

17,179 col. 3

Sections II, IV: UWAG offers simpler alternatives that conserve regulatory resources.

-EPA invites comment on such "functionally equivalent" programs. In particular, EPA invites comment on the proposed alternative and on decision criteria EPA should consider in determining whether a State program is functionally equivalent. If EPA adopts such an approach, it would also need to specify the process through which an existing State program is evaluated and whether such process can occur under the existing State program regulations or whether additional regulations to provide the evaluation criteria are needed.

17,180 col. 2

Section II B p. 11: Successful state programs should continue even if they do not conform to EPA's numeric performance standards. So long as a state has complied with state law in developing and implementing its § 316(b) program, it should be eligible for consideration as an alternative regulatory program that is functionally equivalent.

EPA Response

EPA disagrees that State programs should continue even if they do not conform to the performance standards set forth by today's final rule. It is possible that existing State programs are less stringent than the requirements set by today's final rule. While States have the authority to require more stringent standards, they are not authorized to set downward-departing standards. Nonetheless, if a State demonstrates that its regulatory program will result in reductions in impingement mortality and entrainment comparable to the standards at § 125.94, EPA will to approve the program. Furthermore, EPA has provided State permitting Directors with a great deal of authority over program implementation, including establishing how compliance will be determined at a facility (please see EPA's responses to comments 316bEFR.307.007 and 316bEFR.063.005). EPA believes that setting national performance standards for the reduction of impingement mortality and entrainment, whether alone or with restoration measures, will fulfill the Agency's obligation to minimize adverse environmental impact caused by cooling water intake structures.

Executive Orders (except EO 13211)

Executive Order 13132: Federalism

In the spirit of this Executive Order and consistent with EPA policy to promote communications between EPA and State and local governments, EPA specifically solicits comment on this proposed rule from State and local officials.

17,216, cols. 2-3

Not Applicable.

EPA Response

EPA has followed Executive Order 13132 regarding federalism and concluded that this rule does not have federalism implications.

FACTORS AFFECTING THE POTENTIAL FOR ADVERSE ENVIRONMENTAL IMPACT FROM COOLING WATER WITHDRAWALS

By
Edward P. Taft, Alden Research Laboratory, Inc.
William P. Dey, Applied Science Associates, Inc.
Lawrence W. Barnthouse, Ph.D., LWB Environmental Services, Inc.

PREPARED FOR UTILITY WATER GROUP

November 2001

EXECUTIVE SUMMARY

This report describes the primary factors influencing cooling water intake structure ("CWIS") entrainment and impingement of aquatic organisms at power plants. The report is intended to serve as basic technical background for rules under development to implement CWIS controls pursuant to § 316(b) of the Clean Water Act.

In describing the primary entrainment/impingement factors, the report illustrates the interrelationships among the factors (e.g., between organism swimming ability and behavioral cues in the area of the intake). The report also illustrates the advantages, in many circumstances, of site-specific evaluation, whether that evaluation is based on existing and readily available data reasonably transferable from other sites or on actual site-specific studies.

The report is organized around two broad categories of entrainment/impingement factors: (1) those that influence organism involvement with a CWIS, and (2) those that influence organism mortality due to entrainment or impingement. For entrainment, the primary biological factors affecting organism involvement with the CWIS include: (1) location of spawning and/or nursery areas in relation to the CWIS; (2) seasonal occurrence of species, including occurrence in relation to seasonal changes in power plant operation; (3) vertical distribution and movements of species; (4) cross-sectional distribution of species; (5) swimming ability of species and life stages; (6) growth rates and factors affecting growth; (7) species-specific morphometry; and (8) far-field hydrologic/hydraulic conditions that determine the probability that organisms will be transported into the zone of an intake's hydraulic influence.

As to entrainment mortality, the factors include: (1) organism sensitivity to physical stresses of entrainment; (2) organism sensitivity to thermal stresses; (3) acclimation temperature; (4) salinity of the source waterbody; (5) losses due to biofouling predation; (6) transit time through the cooling water system; and (7) losses due to biofouling treatment. The report notes that existing entrainment survival studies demonstrate that species exhibit a wide range of survival rates.

Factors affecting involvement of aquatic species with the intake resulting in impingement include: (1) location of the intake relative to areas of fish concentration; (2) species seasonal occurrence and non-random vertical and cross-sectional distributions; (3) species swimming ability; (4) species exposure to physiological stresses; (5) intake design features; (6) water quality; and (7) velocity and related hydraulic phenomena.

Impingement mortality factors include: (1) species sensitivity to physical stresses; (2) fish behavior (both in avoiding the intake or when encountering the intake); (3) intake screen type and operation; and (4) the deployment of other fish protection technologies, such as barrier nets.

The extent to which one or more of the factors described in this report may be conclusive as to whether adverse environmental impact is likely to occur at any site will vary according to the individual site and the species and life stages potentially involved with the intake. In some cases, evaluation of one or just a few factors may be conclusive. In other cases, a multitude of factors may warrant consideration.

Section 4 of the report discusses factors that affect an aquatic population's response to losses due to entrainment and/or impingement, including the potential for natural mechanisms to compensate for such losses. The section considers losses of individual organisms in a population context and explains why such losses of early life stage organisms often are not significant in terms of species sustainability or abundance.

In Section 5, we discuss factors such as the recreational or commercial value of some fish stocks and how such factors figure into society's perspective on the relative worth of species and individual organisms. In addition to engineering and biological factors, the risk manager should also examine the ways in which society values the potentially affected resource. Only through an integrated perspective that considers pertinent factors in light of existing research and the specifics of the site can the manager reach an appropriate decision regarding the potential for adverse environmental impact.

1. INTRODUCTION

In 1995, EPA entered into a consent decree that requires it to propose and take final action on regulations implementing § 316(b) of the Clean Water Act. <FN 2> Cronin v. Browner. 93 Civ. 0314 (AGS) (S.D.N.Y.). Section 3 16(b) provides that:

any standard established pursuant to section 1311 [effluent limitations] of this title or section 1316 [new source performance standards] of this title and applicable to a point source shall require that the location, design, construction and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact.

Under the consent decree (as amended), EPA released proposed § 316(b) rules for new facilities on August 10, 2000 (65 Fed. Reg. 49,060), and must propose rules governing existing larger-flow utility and non-utility power producing facilities by February 28, 2002.

Despite the absence of formal § 316(b) rules, EPA and the delegated states have regulated CWISs on a case-by-case basis at both new and existing facilities for many years. The purpose of this report is to organize and summarize the information gleaned from existing § 316(b) demonstrations, peer-reviewed literature and other sources for use by EPA, states, and other industries and organizations in working together to develop technically sound § 316(b) rules.

This report focuses on the primary factors (based on location, biology, and engineering) affecting entrainment and impingement, and how those factors interrelate with each other. In addition to the factors affecting impingement and entrainment discussed in this report, there are many other factors which could, considering site-specific conditions, be significant in determining AEI. This report is not intended to include every possible factor related to impingement and entrainment. At any individual site, it is possible that a factor other than those discussed in this report will be the primary factor for assessing AEI. Also, it is possible that the factors described in this report will be significant for the site in question, but that their interaction will differ from that reported here. However, the factors described in the report should be applicable in the majority of situations.

Report Organization

This report is divided into four major sections. The first two sections discuss factors affecting entrainment and impingement. Each of these sections is further divided into discussions of factors affecting potential organism involvement with the CWIS, and factors affecting the potential for mortality as a result of that involvement. The third section discusses factors (such as life history of the affected species, mean generation time, etc.) affecting population-level responses to entrainment and impingement. The fourth section briefly describes factors that may affect how society values fishery resources potentially impacted by CWIS operations.

2. FACTORS THAT AFFECT ENTRAINMENT LOSS

Organisms small enough to pass through the screens deployed at intakes for steam electric power plants may be entrained along with the cooling water flow, pass through the cooling water intake structure ("CWIS"), and enter other parts of the cooling water system. Entrainable organisms typically include smaller planktonic species and the early life stages of fish and larger invertebrates. The magnitude of entrainment loss of any species is a function of the involvement of the species with the intake (number or fraction entrained) and the subsequent mortality of those organisms as they pass through the cooling water system (entrainment mortality). This section discusses the primary factors influencing both entrainment involvement and entrainment mortality.

2.1 FACTORS THAT AFFECT INVOLVEMENT

Involvement refers to the actual entrainment of organisms through the cooling water system of a power plant along with the cooling water flow. Susceptibility to entrainment is affected by two processes. First, the organisms must be in the area of the source waterbody from which cooling water is withdrawn. Second, the organisms must be transported into the intake along with the cooling water flow. A variety of biological and CWIS factors affect these two processes, as discussed below.

2.1.1 Biological

This section discusses biological factors that affect potential involvement of aquatic populations with entrainment. These factors largely revolve around species and/or life stage considerations that can alter the susceptibility of potentially affected organisms to cooling water withdrawals.

Location of Spawning and/or Nursery Areas

One factor affecting potential involvement is the location of the intake in relation to primary spawning and/or nursery areas for species potentially entrained. As an initial screening step, the general presumption is that the closer a species' principal spawning and/or nursery areas are to the point of water withdrawal, the greater the likelihood that a larger proportion of that population will be entrained, all other factors being constant. Conversely, the greater the distance between these areas and the intake, the lower the chance of entrainment. The extreme case of reduced entrainment susceptibility occurs when the distance between principal spawning and/or nursery areas and the intake is so great relative to existing water current velocities that the time of transport to the vicinity of the intake would exceed the expected duration of the early life stage such that no entrainable stages would be present in the area of withdrawal.

This factor can be illustrated by example with a power plant intake located in the middle sections of a temperate estuary (Figure 2.1.1). While the fish community in the estuary can be comprised of a mix of estuarine, anadromous, freshwater, and marine species, only those species that use the area near the intake as spawning or nursery habitat would have any susceptibility to entrainment. Marine species, such as drums, croakers, and bluefish, which spawn offshore and principally enter the estuary as juveniles, would have low susceptibility to entrainment. Similarly, freshwater and anadromous species, such as shad, herrings, and freshwater minnows hat spawn in non-tidal areas and only enter the estuary as late larvae or juveniles would also have low susceptibility to entrainment.

While distance to the primary spawning and/or nursery area can be an important indicator of the fraction of the population susceptible to potential entrainment, many other factors, both hydrological and biological, interact with this factor to determine actual susceptibility to entrainment. For entrainable life stages that are planktonic (i.e., weakly swimming organisms passively transported by water currents), the hydrology of the source waterbody (e.g., current speed and direction) can have a major influence on how this factor is to be considered. For example in waterbodies with uni-directional currents (e.g., streams, rivers, and some marine systems), entrainable life stages residing in spawning and/or nursery areas located downstream of the intake would have minimal potential for entrainment. However, on the upstream side, passive transport by currents can bring entrainable organisms into the vicinity of the intake. In contrast, distance to the primary spawning or nursery areas must be considered in all relevant directions in source waterbodies with bi- or multi-directional currents. In a lake or reservoir with little active water movement, entrained organisms would be expected to come from the immediate vicinity of the intake, rather than from multiple areas within the waterbody.

In addition to the hydrologic factors discussed above, several biological factors also interact with distance to the principal spawning or nursery areas to affect potential entrainment susceptibility. For example, differences in vertical distribution can interact with the hydrology (i.e., currents) to affect the rate of transport of individuals into the intake vicinity. Many currents are not uniform in depth, and may even flow in an opposite direction at the bottom, as compared to the surface. Thus, the distance from which individuals are transported to the intake also can be a function of the vertical distribution within the water column relative to the vertical distribution of water currents. The importance of such vertical distribution patterns is discussed in more detail in a subsequent section.

The spawning characteristics and larval behavior of individual species can also interact with hydrologic conditions and distance to the principal spawning or nursery areas to affect the potential for entrainment. For example, species with characteristics or behaviors that minimize their exposure to water currents will have little opportunity for transport over long distances. Nest building species (e.g., sunfishes, catfishes), species with strongly bottom-oriented early life stages (e.g., sturgeons, some flatfishes), and species for which wetlands or vegetation beds are the primary spawning or larval habitat (e.g., pikes, killifishes, perches) are examples of species with inherently low susceptibility to entrainment. For these species, potentially entrained individuals typically are those residing within the immediate vicinity of the intake. On the other hand, species with pelagic life stages (i.e., found up in the water column) can be subject to significant transport by water currents and, consequently, entrained individuals may be drawn from areas some distance from the intake. This factor is discussed in more detail in a subsequent section.

Seasonal Occurrence

This factor refers to any seasonal pattern in the occurrence of entrainable life stages in the cooling water withdrawn from the source waterbody. For most species, spawning and the early larval period occur during specific seasons of the year. For these species, entrainment ulnerability is typically limited to a few months of the year. While the timing of the seasonal occurrence pattern for any species or life stage does not directly affect the potential for entrainment, this factor can alter the potential for AEI from entrainment by interacting with several other intake and biological factors. These potential interactions are discussed below.

Many power plants (i.e., non-baseload plants) vary electrical generation in order to meet seasonal patterns of demand. Demand may be higher during summer and lower during cooler months of the year, or the converse may be true. Typically, demand is intermediate in spring and fall. This is illustrated in Figure 2.1.2. Some plant operators reduce the number of cooling water intake pumps operating during periods of prolonged low demand, resulting in seasonal reductions in cooling water flow. The potential for seasonal patterns in cooling water flow are discussed in more detail in Section 2.1.2. As a result of these varying cooling water flows, the interaction between any seasonal pattern in relative abundance of each species and life stage and any seasonal pattern in cooling water withdrawals has the potential to substantially alter the fraction of the population entrained for that species and life stage. For example, if any species and/or life stage is present in the vicinity of the intake primarily during periods of lower cooling flow, then the potential for entrainment is reduced. This may be the case for winter- or early spring-spawning species (e.g., yellow perch, rainbow smelt, Atlantic herring, turbot, winter flounder) (Figure 2.1.2). On the other hand, higher entrainment could occur if the period of higher cooling water flow coincides with periods of higher entrainment abundance, as might be the case for summer-spawning species (e.g., minnows, redhorse, anchovies) (Figure 2.1.2).

In addition to potential seasonal patterns in cooling water flow, seasonal changes in electrical production produce changes in the amount of heat that must be removed by the cooling water system. As a result, the temperature increase through the cooling water system (delta-T) varies almost directly with electrical production. Since the magnitude of this temperature increase can directly affect the potential for entrainment survival (see Section 2.2), entrainment mortality can increase during periods of higher electrical demand. Thus, the fraction of those individuals entrained that do not survive can vary seasonally and result in substantial differences in the fraction of the entire population cropped as a result of entrainment, depending on the seasonal occurrence pattern for any individual species and life stage.

Further, any seasonal pattern in the occurrence of individual species and life stages can affect the potential for AEI from entrainment through an interaction with the ambient temperatures naturally occurring at the time of potential entrainment. This interaction can occur through one of four processes. First, growth and development rates of aquatic organisms are temperature dependent (Moyle and Cech 1996). Growth rates typically increase (and life stage durations decrease) at higher temperatures. At lower temperatures, the converse is true. As susceptibility of individuals to entrainment is typically a function of size and life stage, higher growth rates and reduced life stage durations for organisms occurring in the vicinity of any intake will reduce the overall probability of entrainment. Thus, the overall potential for AEI from entrainment could be lower for organisms occurring principally at higher relative ambient temperatures. This process is discussed in more detail later in this section. Second, natural survival rates for many small aquatic organisms often vary with temperature. Typically, there is an optimal temperature range for natural survival that is less than the total range of temperatures over which a particular species and life stage can be found. As a result, entrainment losses occurring principally outside this optimal temperature range could result in less potential for AEI since these organisms would have reduced potential to survive naturally. Third, potential for entrainment survival is a function of many factors, including acclimation temperature when thermal stress is sufficient to be lethal. Individuals acclimated to higher temperatures (up to a point) are often better able to survive exposures to elevated temperatures than individuals acclimated to lower temperatures. Thus, ambient temperatures at the time of entrainment can affect the likelihood of entrainment survival. Finally, there are upper temperature limits above which complete mortality occurs in aquatic organisms regardless of any other factors. These upper temperature limits are species and life-stage specific. Thus, when ambient temperatures at the time of entrainment are sufficiently high such that thermal additions within the cooling water system result in exceedances of these upper temperature limits, entrainment mortality may be complete. whereas at lower ambient temperatures, survival could be high, lowering the potential for AEI.

Spawning Characteristics and Larval Behavior

Several species-specific behavioral and life history characteristics among the egg and larval stages affect their susceptibility to transport with water currents. To be entrained, organisms must be transported through the cooling water system along with the cooling water flow. For this reason, species that are generally most susceptible to entrainment are those with pelagic egg and/or larval stages. Thus, any life stages or species not susceptible to transport by water currents have limited susceptibility to entrainment.

Fish exhibit a wide variety of reproductive characteristics (Moyle and Cech 1996, Wootton 1990) many of which can affect susceptibility to entrainment. For example, many species of fish have adhesive eggs that are attached to substrate until hatching. Common examples of such species include white perch, sturgeons, and some minnows. This spawning characteristic is a specific adaptation to avoid movement by water current and to maintain the eggs within an environment optimal for development and hatching success. As a result, the eggs of these species generally have negligible potential for entrainment. However, eggs of these species may occasionally be entrained as a result of wave action or extreme currents that dislodge attached eggs. As they are no longer in optimal conditions, these unattached eggs are likely to have reduced survival compared to those remaining attached, and therefore any entrainment of the unattached eggs is of reduced significance to the population.

In addition, many fish species provide significant parental protection to their eggs and larvae in order to maximize potential for survival. Often this parental care provides additional reduction in the potential for entrainment. For example, some species (e.g., salmon and trout) build redds in which the eggs are buried under sediments or gravel until they hatch. Except under unusual circumstances, these eggs would not be susceptible to entrainment. Other species build nests (e.g., sunfishes, catfishes) that are often protected by adults during the egg and early larval stages. The eggs and early larvae remain within these nests and larvae only leave once they are actively swimming and feeding. Since these nests afford some protection from normal currents, the eggs and early larval stages of these nest-building species generally have minimal susceptibility to entrainment.

In addition to the various reproductive characteristics described above, the preferred locations for spawning and/or larval development can significantly alter susceptibility to entrainment. For example, many species of fish spawn in relatively protected areas, such as shallow waters and weed beds, and the newly hatched larvae remain in these areas until they are actively feeding and swimming. Often these areas are little affected by currents and. thus, organisms in such areas would have little susceptibility to entrainment. Also, older larvae can actively seek preferred habitats that would affect their susceptibility to entrainment. For example, larvae of benthic species, such as sturgeon and catfish, actively seek out and hide under available cover along the bottom and, consequently, reduce their potential for entrainment. On the other hand, older larvae of some species, such as certain species associated with reefs and kelp beds (e.g.. rockfishes. blennies, wrasses), actively swim up into the water column from more protected spawning and early larval nursery areas. Such behavior exposes these larvae to transport by water currents and serves as an important mechanism for larval dispersal. These active movements and subsequent transport would tend to increase the potential for entrainment of these life stages.

The potential for spawning characteristics and larval behavior to affect the susceptibility of any aquatic species to entrainment, however, must be considered in light of other factors related to the design, location and operation of each individual intake. For example, intakes that draw much of their water from shallow areas might entrain a relatively greater proportion of species that use shallow waters or vegetated areas as spawning and/or nursery areas. Similarly, intakes that selectively withdraw waters from along the bottom would tend to entrain a greater proportion of species and life stages that actively seek out cover along the bottom.

Vertical Distribution/Movements

The active movement or passive transport of entrainable organisms among depths within the water column can alter the susceptibility of those organisms to entrainment. Aquatic organisms most susceptible to entrainment are those that are largely planktonic and unable to overcome either natural currents or man-made currents associated with cooling water withdrawals. However, many of the aquatic organisms of greatest concern are not randomly distributed throughout the entire water column. Consequently, these individuals could be at greater or lesser risk of involvement with the intake depending on their vertical distribution relative to the vertical zones of withdrawal for any particular intake.

Non-random distribution within the water column can result from a variety of factors, including water density differences, habitat preferences and active vertical migrations. Most aquatic organisms have a slightly higher density than the surrounding water, resulting in a natural tendency to sink. Owing to their limited swimming ability, the earliest life stages of many of these species depend upon water currents to keep them up in the water column and off of the bottom. As a result, many of these organisms tend to be found at greatest densities near the bottom, unless currents keep them suspended up in the water column. Other species use physiological mechanisms, such as oil droplets, that result in early life stages that are less dense than water and, consequently, float (Alexander 1993, Bond 1996). These mechanisms are most common among pelagic marine species and serve to maximize their survival in these systems.

As these organisms develop, greater size and swimming capacity afford them the ability to actively move up and down in the water column towards preferred water depths. Reasons for such vertical migrations are many-fold, including dispersion, predator avoidance and increased food availability (Bertness 1999, Copeland et al. 1976, Lampert and Sommer 1997, Mullin 1986, Mullin 1993, Peterson 1986). For some species, such migratory behavior results in vertical distributions that remain constant for a life stage. Examples of such patterns include marine species, such as drums, croakers, and blue crabs. which selectively use depth-varying tidal currents to move from spawning areas towards larval nursery areas. For other species such as herrings, anchovies, striped bass, copepods, and opossum shrimp, vertical migrations move individuals up and down in the water column on a regular basis. Often individuals of these species move into deeper waters near the bottom during daylight hours to avoid predators and disperse up into the water column at night to feed. Such diel vertical migrations are common among many pelagic species of fish and macroinvertebrates.

The potential for vertical distributions and movement to affect the susceptibility of any aquatic species to entrainment must be considered in light of other factors related to the design, location and operation of each individual intake. For example, offshore intakes are often designed so that cooling water is withdrawn from a specific depth stratum within the water column. On the other hand, more traditional shoreline intakes often draw from a wide range of strata. The range of depths from which the intake withdraws relative to the depth of the source waterbody can influence entrainment involvement through interaction with the vertical distribution of organisms. An intake encompassing almost all of the depth of the source waterbody would tend to draw from all depths and reduce the importance of any non-random vertical distribution. Alternatively, the importance of non-random vertical distribution might be high for an intake drawing water from a relatively narrow depth stratum compared to the overall depth of the waterbody. Finally, active diel migrations in entrainable organisms have been demonstrated in numerous studies to result in wide variation in entrainment densities over a 24-hour period (Gammon 1976, Schneider et al. 1980). Consequently, variation in cooling water flow over this same period can result in significant differences in the fraction of the population entrained, even when all other factors remain the same. Data collected on the amphipod, Gammarus spp., collected from the Hudson River estuary (Figure 2.1.3), illustrates did migration. In this study, Gammarus spp. were found to be concentrated near the bottom during the day but uniformly distributed throughout the water column at night.

Cross-sectional Distribution

Non-random distribution patterns across the source waterbody also occur among some species and life stages potentially susceptible to entrainment. These cross-sectional distributional patterns can be species-specific or even vary across life stages within a species. Consequently, individuals could be at greater or lesser risk of entrainment depending on their distribution relative to the areas of withdrawal for any particular intake.

Most commonly, non-random distributions result from a preference for spawning and/or early larval development in onshore or offshore areas or directed movements of the more motile stages towards preferred habitat for growth and survival. For example, species spawning in relatively shallow shoreline areas (e.g., darters, minnows, gobies), would have relatively low susceptibility to entrainment as eggs or early larvae if the intake draws water primarily from offshore areas. Likewise, species whose spawning takes place in far offshore waters of large waterbodies (e.g., cods, grouper, lake trout) such as the Great Lakes or an ocean would have relatively low susceptibility to entrainment at intakes located along the shore. In addition, for some river species, researchers have demonstrated differential horizontal distribution related to bed morphology and hydrology (King 1978).

The later larval stages of some fish species make directed movements away from spawning areas for a variety of reasons. For example, some species, particularly inshore marine reef and kelp bed inhabitants (e.g., wrasses and sea bass), migrate as larvae from inshore spawning areas to offshore areas where currents provide for dispersal throughout their geographic range (Bertness 1999, Swearer et al. 1999). Thus, the susceptibility to entrainment will vary by life stage within these species depending on the area of cooling water withdrawal. Often, these species return to inshore waters as early juveniles and take up residence among reefs and kelp beds. In addition. some marine species (e.g., marine drums, bluefish, blue crab) spawn in offshore waters and then migrate as larvae towards shallow, inshore, larval and juvenile nursery areas (Boehiert and Mundy 1988, Miller 1988). For these species, entrainment susceptibility is limited to the later larval and early juvenile stages for intakes located in estuarine or inshore marine waters. Finally. many species with pelagic eggs and/or larvae (e.g., striped bass, white perch) migrate towards shallow water nursery areas along the shore as late larvae or early juveniles. Once in these shallow areas, the susceptibility of these life stages to entrainment is low and few are encountered in entrainment sampling.

As with all the other factors, the potential for cross-sectional distribution to affect the susceptibility of any aquatic species to entrainment must be considered in light of other factors related to the design and location of each individual intake. For example, offshore intakes are often designed so that cooling water is withdrawn from pelagic areas of the source waterbody. For these intakes, entrainment susceptibility would tend to be limited to species with pelagic life stages. On the other hand, intakes located along the shoreline of a waterbody would typically draw from a combination of inshore and offshore areas. For these intakes, both inshore and pelagic species might be susceptible to entrainment.

Swimming Ability

The ability of an organism to swim sufficiently well so as to avoid being transported into a plant's intake with the cooling water also influences entrainment. Individuals most susceptible to entrainment are those that are planktonic. This includes permanent members of the plankton community (phytoplankton and zooplankton), as well as seasonal members of this community such as the early life stages of many larger macroinvertebrates and fish. Many members of this later group develop increased swimming abilities as they grow and become less dependent on water movements for transport and dispersal. As this occurs, their ability to maintain themselves in preferred locations increases and their susceptibility to entrainment decreases.

Many species of larger macroinvertebrates (e.g., crabs, oysters, mussels) and fish have planktonic egg and larval stages. These planktonic stages are transported about by currents. Newly hatched larvae typically have limited swimming abilities and are transported passively by these currents. As the larvae develop, their swimming abilities (maximum swim speed and endurance) increase and they begin to move about in the water column. At first, active movements are short bursts associated with feeding and predator avoidance. Large-scale movements of these life stages are still largely passive, occurring primarily through current transport. During the later larval and early juvenile stages, many of the macroinvertebrates settle out of the water column, take on a benthic existence and are no longer as susceptible to entrainment. During these same stages, the swimming ability of many fish species reaches a point where active movements exceed passive transport as the primary means of movement, and individuals begin to have the ability to seek preferred habitats. Often during this period. schooling behavior, active vertical migrations, and movement towards preferred habitats near the bottom or in shallow waters also begin. With this increase in swimming ability comes a decrease in the susceptibility to entrainment as the older and larger larvae and early juveniles begin to achieve the ability to maintain position against water currents that could transport them into cooling water intakes.

The relationship between swimming ability and susceptibility to entrainment must be considered in light of several intake factors. For example, swimming ability must be analyzed in relation to the hydrology in the vicinity of the intake. In low current systems (e.g., lakes) larvae will have the ability to maintain their position at a much earlier age than will larvae living in higher current systems (e.g., rivers and estuaries). In addition, the approach velocity of the intake must also be considered. Once organisms in the vicinity detect the intake, larvae and early juveniles should have a greater ability to actively avoid entrainment at intakes with low approach velocities compared to similar intakes with higher velocity. Further, the design and location of the intake (offshore, shoreline, recessed) will also strongly influence the ability of larvae and early juveniles to actively detect and avoid entrainment. Finally, the swimming ability of many fish species is related to the size of the individual. Thus, factors that affect the rate of growth of these early life stages (e.g., temperature) will also affect the rate of increase in swimming ability, and thus the potential duration of their susceptibility to entrainment.

Growth Rates

The rate of growth of the early life stages also influences entrainment susceptibility. Many aquatic species are susceptible to entrainment only during a limited period of their life. This susceptibility is most common during the earliest life stages. Thus, the rate at which individuals pass through these most susceptible life stages can alter the total time of entrainment susceptibility and thus the potential for AEI.

While growth, in and of itself, does not directly affect entrainment, it has potentially important interactions with several other factors that can significantly affect the potential for AEI through entrainment. This occurs because the susceptibility of individuals to entrainment can be influenced by several size-related processes. First, size-related differences in distribution and preferred habitat can affect the fraction of the population potentially susceptible to entrainment at any particular intake.

Second, vertical distribution and migration patterns, which can influence entrainment susceptibility, are also often related to size of the individuals. Third, swimming ability typically is related to size, with larger individuals having greater swimming abilities. Fourth, the size of the individual can affect whether or not it will physically pass through the intake screens and become entrained. Once individuals reach a certain size, they can no longer pass through the intake screens and, instead, may become impinged on the screens. For three-eighths inch mesh, a mesh typical of many intake traveling screens, the transition from entrainment to impingement typically occurs when the organisms reach approximately one inch long. Thus, growth will necessarily affect the size-related interactions described above.

It is not always easy to determine exactly how changes in growth rates will affect entrainment susceptibility. For example, an increase in growth rates could either increase or decrease entrainment susceptibility based on the species' preferred habitat, vertical distribution, or migration in relation to the intake location. For these processes, the magnitude and direction of change in susceptibility would be dependent on site-specific conditions as well as the species and life stages involved. On the other hand, increases in growth rates will always decrease overall entrainment by reducing the amount of time individuals are susceptible to entrainment at any specific intake. Thus, since growth rates tend to increase with warmer temperatures and higher food availability, the overall period of entrainment susceptibility would be expected to be lower when such conditions exist. This interaction is illustrated in Figure 2.1.4. In this example. a larvae that hatches at 4 mm and has a maximum entrainable size of 25 mm would have a 10-day longer period of entrainment susceptibility with a 25 percent decrease in growth rates.

Species-Specific Morphometry

The general shape of individuals among species also affects the transition from an entrainable to an impingeable size. In general, this factor is of less significance than the others described in this section. However, this factor may be very significant when entrainment is predominated by late larval or early juvenile stages.

Not all species of fish are shaped the same. Examples of differences in larval morphometry are illustrated in Figure 2.1.5. These differences in shape can result in different outcomes when different species of the same length approach an intake screen. Some species, such as the herrings, anchovies, and eels, are relatively slender for their length. Species such as these can pass through intake screens and become entrained at lengths at which other, less slender species would become impinged. Thus, the length at transition between entrainment and impingement is species-specific and dependent upon overall morphometry. However, the exact point of transition from entrainable to impingeable size is dependent on the characteristics of the screen mesh and through-screen water velocities, as well as species-specific morphometry.

2.1.2. Factors Relating to CWIS Location and Type

While the primary factors influencing the potential for involvement of entrainable life stages with an intake are biological, certain intake structure factors, combined with hydrologic factors, interact with these biological factors to influence the potential for AEI. These factors are not related to the design and location of the intake structure per se, but rather the fact that the structure has been located in an area where biological and hydrologic factors influence the probability that organisms will encounter it.

At the outset, it is important to note that there are many practical reasons why CWISs are located where they are. While cost may be one factor, engineering considerations, such as the need to protect the structure from wave or ice action, or the need to withdraw cooler bottom water to improve turbine efficiency, often are crucial. In some cases, intakes have been located specifically to place the point of water withdrawal in areas of relatively low biological productivity, thereby addressing the potential for impact during the design stage. In any case, the focus of the following discussion is not on any specific intake location, orientation, or operation, but rather factors associated with location and orientation that influence the potential for AEI.

For species/life stages that reside (at least seasonally) in the open water environment, their potential for involvement with the CWIS is dependent on two factors:

-the influence of far-field hydrologic/hydraulic conditions which determine the probability that organisms will be transported into the near-field zone of an intake's hydraulic influence, and

-the location and type of intake as they relate to the vertical and horizontal distribution of each species and life stage.

Hydrology/Hydraulics

The natural hydrology of the waterbody, and its relationship to plant hydraulics, is generally an important factor in evaluation of the potential for AEI. For a pelagic organism to become entrained, it must occur in the area of hydraulic influence of an intake. The probability that an organism will enter this area is controlled by complex hydrologic processes that extend into the far-field and are influenced by a variety of other factors. Thus, while the proximity of a primary spawning and/or nursery area can be an important influence on the fraction of a population entrained for any individual species, other factors interact with this locational factor and together determine actual susceptibility to entrainment.

In all waterbody types, entrainment potential is related to the hydrologic conditions of far-field flow direction and magnitude and their interaction with near-field, plant-induced currents. Further, large-scale, far-field hydrologic conditions in many cases influence (or determine) the zone of influence of plant-induced currents. The importance of these hydrologic parameters and their interactions are presented below.

For the purpose of this discussion, the far-field is defined as the area of the waterbody in which an intake is located that is outside the intake's zone of hydraulic influence (the zone from which a passive particle in the waterbody will be drawn into the CWIS). The near-field is defined as that zone of influence. The direction of flow in a waterbody is an important factor in the potential for entrainment of planktonic life stages in several ways. In a waterbody that is unidirectional (e.g., a non-tidal river), a non-motile organism will pass an intake relatively quickly as it moves with the flow. Therefore, the time that the organism has to become involved with the intake is short. On the other hand, an organism in a bi-directional flow regime (e.g., tidal estuaries or rivers) may take longer to pass an intake and may be subjected to potential involvement over a longer period. In both cases, the potential for entrainment is related to the net positive displacement of the organism over time. This displacement is, in turn, determined by the relative magnitude of the waterbody flow (e.g., river discharge) compared to the multi-directional influences (e.g., tidal forces). For example, the net downstream displacement of an organism in a tidal river will be faster during periods of high river discharge under a given tidal flow regime resulting in a shorter exposure to involvement with the CWIS. On the other hand, in extreme low-flow conditions (e.g., droughts) on tidal rivers, the salt wedge can move further upstream carrying organisms that would not normally be exposed to the CWIS from downstream.

The magnitude of flow in a waterbody (all directional influences included) relative to the flow volume withdrawn into an intake is also a factor in determining the potential for organism involvement with an intake (Figure 2.1.6). For example, it can be expected that an intake that withdraws one percent of the total flow of a river will have less potential for entraining organisms than one that withdraws ten percent. However, the relative proportion of flows is only one factor in defining the near-field zone of influence of an intake. Therefore, percent withdrawal does not, in itself, define the potential for organism entrainment. Important interrelated factors are the absolute magnitude (volume and velocity) of the ambient (i.e., waterbody) flow, the morphology of the waterbody and the vertical and horizontal distribution of organisms.

The magnitude of the ambient flow and the morphology of the flow path are important factors in defining the spatial expanse (i.e., shape, width and depth) of the plant-induced zone of influence. For example, if an intake is located on the outside bend of a river and ambient velocities are high, the zone of influence of the intake will be contained relatively close to the shoreline. Conversely, if the CWIS is on the inside bend, the zone of influence will be larger, particularly under low-flow conditions.

In estuarine or tidal river locations, the zone of influence of an intake will vary over time as the magnitude and direction of ambient, tidally-influenced currents vary. Therefore, the potential for involvement of organisms with an intake in these locations will also vary over time.

Intake Location

The location of an intake is important mainly as it relates to the presence or absence of aquatic organisms. Shallow water intakes (e.g., shoreline intakes) will not entrain species and life stages that occur predominantly near the bottom in deeper waters. Similarly, submerged, offshore intakes will not entrain species and life stages that are surface-oriented. As a result, the distribution and behavior of each species and life stage, coupled with hydrologic factors, is an important determinant in whether these organisms are subject to entrainment into an intake at a given location.

Intake Design and Operation

A plant's design and operation will influence the entrainment of organisms. For example, if the design incorporates fine screening technology installed specifically to prevent organism passage, the potential for entrainment will be reduced. Currently, the two most common fine mesh technologies in use at power plants are cylindrical wedge-wire screens and fine mesh traveling screens. Both screen types can have openings as small as 0.5 mm and, therefore, have the potential for blocking the passage of all life stages. The wedge-wire design is intended to act passively in that larger, mobile life stages swim around the screen while smaller, non-motile life stages roll or slide over the screen surface and are carried downstream by an ambient current. Fine mesh traveling screens actively collect organisms in the water column and carry them to a surface spraywash system that gently washes them into an organism return trough. By design, these screens prevent entrainment but cause impingement. Thus, it is important in evaluating alternative technologies for a given site to determine whether organism survival will be higher following the impingement and removal process or following entrainment through the cooling water system.

A third technology that can be considered for reducing entrainment of ichthyoplankton is the skimmer wall. Skimmer walls (Figure 2.1.7) are typically used to selectively withdraw deeper water, to keep out floating debris and ice. and to prevent cold air from entering screenhouses. Results from studies conducted at two power plants in the southeastern United States showed a substantial reduction in larval densities between sampling locations upstream and downstream of the skimmer walls (Olmsted and Adair 1981). The authors attribute the reductions to the depth of the openings created by the walls. By withdrawing water from well below the thermocline of the stratified lakes on which the plants are situated, waters from the epilimnion. where most larval fish occur in southeastern reservoirs, were not entrained into the intakes.

In addition to these technologies, several other technologies (including Gunderbooms, a fabric mat with very small pores sizes and low velocities) may be effective, depending on individual site conditions in reducing entrainment. A review of all technologies available for protecting organisms at CWIS is presented in a recent report on fish protection technologies (EPRI 1999a).

The cooling water flow rate is important in a relative sense. The potential for organism entrainment is related primarily to the near-field area of intake influence relative to far-field hydrologic conditions. Due to biological factors that influence the distribution of organisms in a water column, one cannot assume that flow rate is directly related to numbers of organisms entrained. However, in the sense that the area of influence of an intake is indirectly related to flow rate, there is a relationship between flow rate and entrainment, even if it is not one-to-one. In evaluating the potential for organisms to be entrained into a CWIS, all of the biological, hydrologic and hydraulic factors that influence the potential for entrainment must be weighed collectively. Mathematical models are available that may be useful in defining the zone of hydraulic influence of a CWIS.

At plants that operate to meet demand (i.e., non-base load), the operational schedule may influence the potential for entrainment of organisms that pass into the CWIS near-field zone of influence. Plants that are non-operational during times of peak abundance will have less potential for entrainment than plants that operate during peak abundance periods. Scheduling plant outages during periods of peak organism abundance will also reduce entrainment potential.

Footnotes

2 In 1976, EPA finalized its original § 316(b) rules. 41 Fed. Reg. 17,387 (Apr. 26, 1976). Those rules, however, were vacated in Appalachian Power Co. v. Train, 566 F.2d 451 (4th Cir. 1977) and withdrawn by the Agency. 44 Fed. Reg. 32,956 (June 7, 1979).

EPA Response

EPA acknowledges receipt and has reviewed this submission. EPA agrees that there are many factors which can affect the number of organisms impinged and entrained by cooling water intake structures at a particular site. Under today's final rule, facilities are required to submit to the permit director a Comprehensive Demonstration Study, as defined in §125.95(3)(b) that fully characterizes impingement mortality and entrainment of the cooling water intake structure. Many of the issues raised by this comment can be addressed in this Study.

2.2 FACTORS THAT AFFECT MORTALITY

Not all organisms that are entrained die. Quite to the contrary, studies have shown that entrainment survival can be high (EPRI 2000). Depending on the species and CWIS operating conditions, entrainment survival may range from 0 to as high as 100 percent in some cases. The mortality rate of entrained organisms is influenced by the specific physical, thermal, and chemical stresses to which they may be exposed during transit through the cooling water system, and by the tolerance of the organisms to those stresses. This section therefore discusses both CWIS factors and biological factors that interact to determine entrainment mortality. Because entrainment mortality varies widely based on site-specific and species-specific factors, whether a particular CWIS is causing or is likely to cause AEI may be greatly influenced by entrainment mortality.

2.2.1. Biological

A number of biological factors directly or indirectly influence an organism's likelihood of surviving transit through the CWIS. Entrained organisms are exposed to physical forces (such as changes in pressure and shear) and to rapid temperature elevations as they move through the CWIS. At power plants that must treat the cooling water flow to control biofouling. entrained organisms may also be exposed to toxic compounds (e.g.. chlorine or bromine). The tolerance of phytoplankton, invertebrate zooplankton, and the early life stages of fish to physical, thermal, and biocide exposures received during entrainment has been studied using both controlled laboratory experiments and entrainment survival sampling at operating power plants. These studies show that entrainment survival is influenced by the organisms' inherent sensitivity to entrainment stresses, by the ambient water temperature to which organisms are physiologically adapted (i.e., acclimation temperature) prior to entrainment, and for estuarine-sited power plants. by the ambient water salinity. Finally, in some situations where biofouling is especially prevalent, entrained organisms may be consumed by filter feeding organisms that grow within the CWIS.

At the outset, it is important to note that, for some species, entrainment mortality are irrelevant to the size and health of the population. For example, studies have shown that the potential for reduction in abundance or productivity of phytoplankton and microzooplankton as a result of entrainment at power plants is minimal (Tetra Tech 1978, Lankford 1990). Appreciable intake structure effects on these taxa, if any, are generally of short duration and confined to the immediate vicinity of the CWIS, due to a combination of factors such as relatively high natural abundance, rapid dispersal and mixing by water turbulence and currents, and short life-cycles, rapid generation times, and resultant high reproductive capacity (Tetra Tech 1978, Lankford 1990). Indeed, USEPA's Draft 316(b) Guidance suggested that phytoplankton and zooplankton species generally should not be selected for detailed assessment (USEPA 1977) and thus the focus of the majority of entrainment studies conducted since the early 1970s has been on macrozooplankton and fish. No more recent information has been generated that would contradict this presumption. EPA has implicitly endorsed this approach by proposing that § 316(b) monitoring requirements for new facilities should focus on nekton and the meroplankton of fish and shellfish. See 65 Fed. Reg. at 49,119, 49,121 (proposed 40 C.F.R. § 125.86, 125.87).

Organism Sensitivity to Physical Stresses

Organism sensitivity to physical stress refers to the inherent ability to withstand exposure to shear forces, pressure changes and mechanical contact with surfaces during transit through a cooling water system. Studies at a number of operating power plants employing single-pass cooling water systems during the 1970s and early 1980s measured entrainment survival of a variety of invertebrate and fish species, often encompassing several life stages and a range of sizes. These studies were performed by sampling at the intakes and discharges of the plants, in many cases using gear designed to minimize collection damage to the organisms. The proportion of each species and life stage collected alive at the discharge was compared to that at the intake to determine the effect of passage through the cooling water system. Studies often measured both the initial survival at the time of collection and subsequent survival up to 24-96 hours after collection, and analyzed both to determine the percentage of the species and life stage surviving entrainment. Samples collected at cooling water system discharge temperatures lower than the upper lethal temperature limit of the species were used to estimate survival from the physical (or mechanical) stresses of entrainment, independent of the effects of temperature.

The results of entrainment survival studies indicate that entrainment survival in the absence of thermal effects varies widely among species. For example, a review of ichthyoplankton entrainment survival estimates from 12 power plants sited on freshwater, estuarine, and marine systems indicates up to about a four-fold difference in survival rate among species entrained at each CWIS, and about an eight-fold difference among 21 taxa collected across all 12 sites (Jinks et al. 1981). Of the 13 families of fish represented in these studies, herrings, anchovies, silversides, and sand lances appeared relatively sensitive to physical effects of entrainment (survival of 23-48 percent), while the sensitivity of cods, gobies, and suckers appeared moderate (survival of 52-60 percent). Eels, carps and minnows, temperate basses, perch, drums and flounders appeared highly tolerant of entrainment, with survival in the range of 75-100 percent. A recent comprehensive review summarized entrainment survival estimates for approximately 50 different taxa, obtained from 35 study reports at 20 different power stations (EPRI 2000). Although the entrainment survival estimates were quite variable, patterns among taxa were evident (Figure 2.2.1). The mean of entrainment survival estimates for most taxa exceeded 50 percent. Mean entrainment survival values were highest (about 72-92 percent) for freshwater and estuarine macroinvertebrates, freshwater suckers, and spot. Striped bass, white perch, Atlantic tomcod, winter flounder, carps and minnows, and freshwater drum had mean moderate survival values (about 47-63 percent), while herrings and anchovies had the lowest survival, with mean values approaching 25 percent (Figure 2.2.1).

For a given species, survival from the physical effects of entrainment may also depend on the life stage or size of the entrained organisms, although data sufficient to quantify the relationship is limited to relatively few species. Where large data sets exist, such as for Hudson River striped bass and white perch, analyses indicate significant positive correlation between entrainment survival and life stage/size of the fish (EA 1989). For example, survival of entrained striped bass increased from 50 percent at about 5.5 mm total length to 90 percent at about 14.5 mm (Figure 2.2.2). In general, yolk-sac larvae had the lowest entrainment survival and early juveniles the highest.

However, experiments using pressure chambers and simulated condenser systems have shown that a wide variety of species can tolerate the large changes in pressure and shear forces that are found during normal open-cycle cooling water system operation. These studies indicate that pressure increases probably do not damage most entrained organisms and that substantial mortality (>25 percent) from pressure decreases is principally limited to exposure to subatmospheric pressures (NYU 1975, Coutant and Kedl 1975, NYU 1979). The range of variation in pressure exposures among different power plants is constrained by the need for efficient hydraulic performance. Transfer of species- and life stage-specific survival information among sites may therefore be feasible, but should consider the velocity and pressure characteristics of the cooling water system in context with those at power plants for which survival information is available.

Organism Sensitivity to Thermal Stresses

The inherent ability of entrained individuals to withstand temperature elevations during transit through the cooling water system varies from species to species. Temperature is a normal part of the habitat structure experienced by all aquatic organisms, and spatial and temporal variations in water temperature are a natural feature to which indigenous species have adapted. Aquatic organisms can survive within a range of temperatures specific to each species, called the "zone of thermal tolerance." Organisms can also adjust to the thermal environment physiologically, by shifting their tolerance range, but this acclimation has limits and ultimately a water temperature may be reached that would be lethal. The upper lethal limits of thermal tolerance for a species are typically determined by laboratory experiments and are defined as the temperature resulting in death of 5, 50, or 95 percent of the test organisms (TL5, TL50, TL95). Immobilization or death resulting from sudden increases in water temperature beyond an organism's upper tolerance limit is often referred to as "heat shock."

The tolerance of organisms to temperature elevations in the cooling water system is influenced by their genetic ability to adapt to thermal changes within their characteristic temperature range and the duration of exposure to the elevated or lowered temperature (Coutant 1972). Genetic ability to adapt to temperature changes differs among species and among life stages within a particular species (Hochachka and Somero 1971; EA 1989; Kellogg and Jinks 1985). For example, striped bass tolerate higher temperatures than salmon, and juvenile striped bass have higher tolerances than adult striped bass (EA 1978b; Coutant 1970). Therefore, entrainment survival is influenced by the thermal life histories of the relevant waterbody assemblages and the thermal tolerance limits of the species susceptible to entrainment. For example, the community in a waterbody having a narrow natural range of temperatures may have species assemblages with thermal tolerance zones that are relatively narrower than those in a waterbody with widely fluctuating natural temperatures. Conversely, species may migrate between waterbodies or between habitats within a waterbody to occupy thermal regimes suitable to their thermal tolerance range. In this latter sense, an organism's sensitivity to thermal stress also influences its spatial distribution and potential for involvement with a CWIS.

The duration of exposure is a crucial interacting factor in an organism's tolerance of temperature change (Coutant 1972). The tolerance of an organism to temperature changes is a direct function of exposure time. Organisms tolerate exposure to greater changes in temperature if the exposure is for a short period (Brett 1952; Kellogg et al. 1984). For example, striped bass acclimated to approximately 77°F survive an increase in temperature of 18°F (i.e., exposure temperature of 95° F) for 60 minutes, but tolerate an increase in temperature of 29°F (i.e., exposure temperature of 106°F) for 10 seconds

(EA 1979). This time-temperature aspect of thermal tolerance is crucial to an accurate and scientifically valid assessment of the potential for organisms to tolerate heat shock from potential exposure in a cooling water system. Therefore, species- and life stage-specific sensitivity to thermal stress must be considered in light of cooling water system design and operating factors, specifically delta-T and transit time (i.e., time for the water flow and entrained organisms to pass from the condensers back to the waterbody).

Acclimation Temperature

Acclimation temperature is the ambient water temperature to which an organism has become physiologically adapted prior to entrainment. True acclimation to changed temperature requires several days to more than a week (Brett 1941; Fry 1971; Hochachka and Somero 1971). Acclimation temperature affects aquatic organisms' upper temperature tolerance (Brett 1956; Coutant 1972; Lauer et al. 1974).

Tolerance to the short-term (seconds to hours) exposures to temperature changes that are characteristic of entrainment also depends on the organism's acclimation temperature (Lauer et al. 1974; IA 1978; Greges and Schubel 1979: Jinks et a!. 1981). Organisms acclimated to temperatures at the low end of their genetically determined range of tolerance typically can tolerate larger increases in temperature than the same organisms acclimated to temperatures near the high end of their genetically determined range of tolerance (Lauer et al. 1974). For example. striped bass post yolk-sac larvae acclimated to 68°F tolerated a 23.4°F temperature rise (i.e.. exposure temperature of 91.4°F) for five minutes, whereas when acclimated to 78.8°F. they tolerated only a 19.1°F rise (i.e., an exposure temperature of 97.9°F) for the same exposure time (EA 1978b). Nonetheless, organisms acclimated to warmer temperatures generally can tolerate higher maximum exposure temperatures than if they were acclimated to lower temperatures. For example, as illustrated above, the five-minute TL50 for striped bass post yolk-sac larvae acclimated to 68°F is 91.4°F, while the five-minute TL50 for the same species life stage acclimated to 78.8°F is 97.9°F. Another example of the relationship between acclimation temperatures and thermal tolerance (TL50) is provided by laboratory studies conducted on bluegill juveniles (Figure 2.2.3). In this study, at acclimation temperatures of 70°F, juvenile bluegill could withstand a temperature increase of approximately 30°F. At higher acclimation temperatures, individuals became less able to withstand temperature increases such that at an acclimation temperature of 92°F, bluegill juveniles were only able to withstand a 10°F temperature rise.

Therefore, evaluation of entrainment survival must consider the seasonal nature of involvement of organisms with the CWIS and the seasonal temperature regimes characteristic of the waterbody segment in which the intake is located. For example, in a warm-temperate meteorological climate, species with high tolerance of the physical stresses of entrainment may incur lower mortality if entrained during spring, when ambient temperatures are cool, than they would if entrained during summer, when ambient temperatures are much higher.

Salinity

Water salinity may be an important factor influencing entrainment survival at power plants located in the brackish water regions of estuaries, where salinity varies seasonally in response to changes in freshwater discharge and tidal height. Low to moderate levels of salinity reduce the energy input required for osmoregulation (physiological maintenance of internal water and salt balance), and thereby act as a general stress ameliorator. For example, the addition of salt has been shown to reduce mortality from physical stresses such as handling during fish rearing operations (Bowser and Buttner 1991; Kane et al. 1990; Palawski et al. 1985).

Entrainment survival studies in brackish water regions of the Hudson River suggest that the stress reducing effects of salt result in higher entrainment survival for a given species when brackish water is present than during freshwater periods (EA 1989).

Biofouling Predation

A variety of life forms are capable of colonizing the surfaces of cooling water systems, including bacteria and sessile invertebrates. Filter-feeding forms, such as barnacles, mussels, and hydroids, may prey on entrained organisms as they pass through the cooling water system, and extensive buildup of filter-feeding forms may substantially reduce entrainment survival through this predation mechanism (Kauffman et al. 1980: EA 1983). Such biofouling predation is generally limited to some sites located on high salinity waters along oceans. enclosed bays. or the lower reaches of estuaries.

Cooling water system susceptibility to biofouling (i.e., the buildup of biological growths on structures and equipment) varies widely depending on waterbody type and location. Biofouling is generally undesirable since it may reduce the efficiency of the cooling water system. Facilities may use biocides, heat treatments, or mechanical scraping to remove biological growths from the cooling water system when necessary to maintain efficient operation. However, the effect of such colonization on system performance depends on cooling water system design and on the portion of the cooling water system colonized. As a result, heavy biofouling predation may occur in portions of the cooling water system where they do not substantially impact plant performance, such as in long shallow discharge troughs or canals. When this occurs, the potential for significant predation by the biofouling organisms exists.

2.2.2. Factors Relating to the CWIS

The primary factors that influence the potential for AEI as a result of entrainment mortality include:

-the physical forces to which organisms are exposed as they pass through pumps, pipes, condensers and discharge structures;

-increased water temperature and the duration of exposure; and

-in some cases, the concentration and duration of exposure to chemical or thermal biofouling control agents.

The physical forces encountered by entrained organisms include pressure changes experienced as the organism moves along the hydraulic grade line (i.e., the line which defines the pressure head at any point within the system; Figure 2.2.4) from intake to discharge, shearing (the tearing action resulting from exposure to zones of rapid flow accelerations or decelerations, and direct (mechanical) contact with system components). The potential for organisms to be injured as a result of physical forces during passage through the cooling water system varies depending upon system design. For example, different pumps have different clearances and rotational speeds that can influence the potential for mechanical injury and shearing effects. Similarly, the velocity of flow into a condenser waterbox and turbulence in that flow as it approaches and exits the condenser tubes may influence the potential for mechanical injury.

In general, meaningful changes in water temperature occur twice during the trip from intake to discharge: during passage through the cooling water condenser (increase) and at the point of discharge into a mixing zone (decrease). The primary factor in determining temperature effects on organisms is the upper lethal temperature limit of the organism and the duration of exposure. Many aspects of cooling water system design influence temperature changes and length of exposure. In once-through systems, those with low delta-T's and short transit times are likely to cause the least entrainment mortality. In contrast, facilities with long discharge canals or tunnels increase transit time and may increase organism mortality, depending on species-specific factors. Closed-cycle cooling systems in which organisms entrained with the cooling water are repeatedly circulated through the plant's system generally result in 100 percent entrainment mortality.

Where a chemical agent (e.g., chlorine) is used to control biofouling in the cooling water system, the point of injection is typically immediately upstream or downstream of the circulating water pump. Due to the chemical concentration needed to effect biofouling control, 100 percent mortality of entrained organisms is assumed during the period of treatment. Where thermal backwashing is used (i.e., reversing flow in the intake and discharge systems), elevated temperatures are maintained for a period of time sufficient to kill shelled invertebrates such as barnacles and mussels. Therefore, total mortality of entrained organisms can again be assumed. Current state and federal regulations, however, restrict the frequency and duration of chemical or thermal treatment. Therefore, while complete entrainment mortality may occur during such treatments, it occurs for a short period of time and on an infrequent basis. For a given species and life stage, survival is influenced by the factors listed previously (primarily physical forces and thermal effects). The stresses imparted by these factors vary depending on the type of cooling water system used, the characteristics of specific system components, and the transit time through the system.

Cooling System Type

There are two basic types of cooling water systems used by power plants: open-cycle systems (Figure 2.2.4), in which cooling water passes directly through the system from the intake to the point of discharge, and closed-cycle systems, in which cooling water is recirculated within the system and is cooled via cooling towers, canals, or ponds (Figure 2.2.5). Closed-cycle plants typically withdraw a small percentage of the water that would be used in a open-cycle system at a plant of the same capacity. This so-called make-up water is used to replace water lost to evaporation in the cooling process and to maintain the chemical composition of the recycled cooling water within certain prescribed limits. While open- and closed-cycle system designs vary widely, for the purposes of addressing entrainment, these two categories are sufficient. In general, many organisms have a high potential for surviving passage through open-cycle systems, while mortality with closed-cycle systems is 100 percent.

The flow path that an organism follows in passing through an open-cycle system is as follows: entry into the intake (e.g., offshore intake connected to onshore screenwell via pipe, or shoreline intake with canal leading to screenwell); passage through trash racks (coarse openings) and traveling screens (smaller openings, typically 6 to 10 mm); passage through the circulating water pump; transit through pipes that convey the water to the condenser; passage through the condenser tubes (typically about 1-inch diameter pipes); transit through the pipe and/or other conduit that conveys the water to the point of discharge; and release into the receiving waterbody. It is within the condenser that the flow is used for cooling and the temperature of the cooling water increases. The degree of increase is determined by the design change in temperature, or "delta-T," of the plant. The delta-T is governed by overall plant design and performance requirements that are determined on a site-specific basis. The transit time through the system is determined by the velocity of flow in each system component and the length of the system from intake to discharge.

In a closed-cycle cooling system, make-up water is withdrawn through an intake structure similar in design and location to a once-through system that would be used at the same site. Since the water needed for make-up is substantially less than that needed for once-through cooling, the intake structures are proportionately smaller. However, the front and back ends of the closed-cycle system are similar to those in a once-through system: trash racks, screens, pumps and piping on the front and pipes or other conduits on the back to convey "blow-down" to the receiving waterbody. The difference between the two cooling systems is in the heat exchange unit (condenser). In a closed-cycle system, the cooling water passes through the condenser and then is transported, along with any entrained organisms, to a cooling tower, lake or pond. The water is allowed to cool prior to being recycled through the condenser. This cycle is continuously repeated providing no potential for entrained organisms to return to the natural waterbody except in the low-volume blow-down. Therefore, mortality in closed-cycle systems is complete.

CWIS Components

The primary components influencing the physical forces to which organisms are exposed as they pass through the cooling water system are the traveling water screens, pumps, piping and condensers. It should be noted that, while traveling water screens are the typical component used to handle debris in power plants and are the focus of the following discussion, some plants are equipped with fixed screens or bar racks.

Traveling Screens. In most power plants, traveling screens incorporate mesh sizes (e.g., 3/8-inch [9.5 mm] openings) through which eggs, larvae and some early juveniles (depending on species) pass with ease. In the last two decades, a small number of power plants (Brayton Point, Prairie Island, Big Bend, and Indian Point) have employed fine mesh (e.g., 0.5 to 1.0 mm) as a means of collecting early life stages and preventing entrainment through the cooling water system. Eggs and larvae collected on the screens are normally washed off the screens and deposited back in the source waterbody at a location away from the intake. In this case, survival following impingement, removal and transport of early life stages that would have been entrained through larger meshes must be weighed against the survival that would be expected if they had been entrained. For fragile species (e.g., clupeids, shad, alewife and anchovy), fine mesh screening may result in higher organism mortality than if entrainment through an open-cycle cooling water system had occurred (e.g., Bruggemeyer et a!. 1987).

Other than larger-mesh and fine mesh screens, there are a variety of screen meshes that incorporate combinations of sizes, geometries and special features that influence the manner in which they interact with organisms and debris. For example, a rectangular mesh that has been flattened on one side (referred to as "smooth-top") has shown superior debris-shedding and organism handling properties compared to conventional woven-wire, square meshes. With openings such as 1/8-inch (3.2-mm) wide by 1/2-inch (12.7-mm) high, these smooth-faced screens, in some environments, are less likely to entwine (or "pin") debris and are more likely to have debris and organisms slide freely into collection troughs. Naturally, the effectiveness of a particular screen size and geometry is influenced by the type of debris present. At the Salem Generating Station, l/8-by-1/2 inch smooth-top screens have been shown to somewhat alleviate historic debris problems while apparently contributing to the improved organism survival observed when the screens were retrofitted with other enhanced organism survival features (PSE&G 1999). Thus, different sizes and shapes of screen meshes may influence both debris loading and entrainment. However, the specific mesh used at a given site must be selected on the basis of the type and amount of debris present and the species and life stages to be protected. Additional research to further identify the relationships between mesh size and shape and impingement and entrainment, and how those relationships will vary depending upon site-specific factors may prove fruitful in this area.

Pumps and System Piping. Power plant circulating water pumps are typically low-head (i.e., provide the energy required to move the cooling water through the system), high-flow pumps that have large clearances between impellers and housings. Specific studies to identify injury and mortality as a result of passage of early life stages through the pumps have not been conducted. It is generally assumed that large pumps do not contribute substantially to overall system mortality.

Similarly, velocities in cooling water system transport piping that convey water to the condensers and from the condensers to the plant discharge outfall are relatively low and are not highly turbulent. Therefore, shear and impact forces in these locations are not considered an important factor in overall system mortality.

Condensers. Two factors influence the potential for organism stress and mortality in the condenser. The thermal factor has been previously addressed. The second factor relates to mechanical impact, pressure and shear experienced as organisms enter the condenser water box and pass into the relatively small condenser tubes. However, experiments using pressure chambers and simulated condenser systems have shown that response to pressure and shear forces is species and life-stage specific. Some species can tolerate the large changes in pressure and shear forces to which they are exposed during passage, while others cannot. (NYU 1975, Coutant and Kedi 1975, NYU 1979).

Biofouling Treatment

Some power plants add biocides, most typically chlorine or bromine, periodically to the cooling water flow to control the growth of organisms that can foul the cooling water system. Alternatively, some power plants clean the cooling water system condensers and discharge conduits by temporarily recirculating a portion of the cooling water, thereby raising the watet temperature in the cooling water system above upper temperature tolerance limits of the fouling organisms. To effectively control biofouling, the biocide concentrations and heat treatment temperatures within portions of the cooling water system must be raised to toxic levels that alsc cause mortality of entrained organisms.

The contribution of biofouling treatment to the overall mortality incurred by entrained species depends primarily on the frequency and duration of treatment, which varies widely depending on plant design and location. Biocide application is controlled by either technology-based or waterquality based federal/state pollution discharge permits, which generally also limit the frequency and duration of treatment. For example, EPA's technology-based limits for steam-electric power plants limit chlorine discharge to 0.200 mg/l for no more than a total of two hours per unit per day, unless the facility demonstrates the need for, and obtains, a variance. However, at many plants the duration and frequency of biofouling treatment required to maintain efficient plant operation is far less, and some plants do not have to treat at all. Therefore. the significance of cooling water system biofouling treatment as to entrainment survival and the potential for AEI varies.

3. FACTORS THAT AFFECT IMPINGEMENT LOSS

Organisms too large to pass through the screens that protect the cooling water systems at steam electric power plants may become entrapped against the intake screens by the flow of water. This process is known as impingement. The magnitude of impingement loss of any species to CWIS operation is a function of the involvement of the species with the intake (number or fraction impinged) and the subsequent mortality of those organisms (impingement mortality). This section discusses the primary factors influencing both impingement involvement and impingement mortality.

3.1 FACTORS THAT AFFECT INVOLVEMENT

The actual impingement of organisms by the cooling water flow involves two processes. First, the organisms must be in the area of the source waterbody from which cooling water flow is withdrawn. Second, the organisms must be entrapped against the intake by the cooling water flow. A variety of cooling system and biological factors affect these two processes, as discussed below.

3.1.1. Biological

This section discusses biological factors that generally affect potential impingement susceptibility of aquatic populations. These factors largely revolve around species and/or size considerations that can alter the susceptibility to entrapment against intake screens.

Location of Intake in Relation to Areas of Fish Concentration

The location of the specific intake at issue with respect to areas where species of concern might be concentrated in significant relative abundance is a key factor affecting potential impingement. The general presumption (which may or may not prove true, for any particular site) is that the closer these areas are to the point of water withdrawal for any species, the greater the likelihood that a high proportion of that species will be subject to impingement, assuming all other factors are constant. Conversely, the greater the distance between these areas and the intake, the lower the potential for impingement.

Concentration of individuals in the vicinity of an intake can occur for several reasons. First, the area could be a principal nursery area for juveniles. These young fish tend to be more susceptible to impingement than adults owing to their more limited swimming abilities. Second, the intake could be located near a migratory pathway. Migratory pathways have the potential to bring a significant proportion of the population to the vicinity of the intake during certain seasons of the year. For example, impingement rates for anadromous species such as river herring, American shad, salmon, and striped bass are often highest during periods of emigration as they pass through the vicinity of an intake. Third, many species of fish exhibit seasonal movement associated with spawning. These movements can bring individuals into the vicinity of a plant's intake if located near the species pathway. Finally, the intake could be near an overwintering area. In temperate areas of the country, many species of fish move to and remain in deeper areas of the waterbody during the winter. Intakes located near these areas may experience higher impingement rates during the coldest months of the year as a result of the organisms' natural cold-induced lethargy.

While distance to these areas of concentration can be an important influence on the fraction of population impinged for any individual species, other intake and biological factors interact with this factor to determine actual susceptibility to impingement. For example. as discussed in Section 3.1.2, the design and location of the intake substantially affects the actual rate of impingement for any species through such factors as approach and through-screen velocities, depth of water withdrawal, and avoidance potential. In addition, biological factors, such as the size of individuals in the vicinity of the intake, swimming ability, and depth distributions, all can alter the relative importance of the distance to areas of concentration such as principal nursery areas.

Seasonal Occurrence

This factor refers to any seasonal pattern in the occurrence of impingeable individuals in the cooling water withdrawn from the source waterbody. While the seasonal occurrence pattern for any species or life stage may not directly affect the potential for impingement, this factor can alter the potential for AEI from impingement by interacting with several other intake and biological factors. These potential interactions are discussed below.

As discussed earlier in Section 2.1.1, many power plants vary electrical generation in order to meet seasonal patterns of demand, and thus cooling water flow may be lower during periods of prolonged low demand. This is illustrated in Figure 3.1.1. In addition, the need for cooling water is reduced at some facilities owing to the greater heat transfer that can occur during the coolest months of the year. Finally, cooling water flows can vary seasonally as a result of discharge permit requirements. The potential for seasonal patterns in cooling water flow are discussed in more detail in Section 2.1.1. As a result of these varying cooling water flows, the interaction between any seasonal pattern in relative abundance of each species and age with any seasonal pattern in cooling water withdrawals has the potential to alter substantially the fraction of the population impinged for that species. For example, many species of fish exhibit spring and fall migrations (e.g., anadromous species). Such migrations could bring them into the vicinity of a cooling water intake during periods of the year when cooling water flows, and hence the potential for impingement, is reduced compared to warmer summer periods (Figure 3.1.1).

In addition to potential seasonal patterns in cooling water flow, seasonal patterns in the occurrence of individual species and ages can affect the potential for AEI from impingement through an interaction with the ambient temperatures naturally occurring at the time of potential impingement. This interaction can occur through either of two processes. First, impingement survival is a function of many factors, including acclimation temperature. Generally, impingement mortality increases at higher temperatures and, conversely, impingement survival tends to be higher when water temperatures are cooler. Thus, the ambient temperatures at the time of impingement can affect the likelihood of survival for impinged organisms. Second, aquatic organisms subject to impingement are virtually all poikilotherms (i.e., cold-blooded). Thus, their metabolic rates and activity levels vary directly with the temperature of the surrounding water. When water temperatures are well below the species' temperature range for optimum performance, these organisms can become lethargic and have limited ability to avoid impingement if they remain in the vicinity of the intake. Thus. their susceptibility to impingement can increase during the colder periods of the year. The magnitude of this increased susceptibility depends on differences between actual temperatures and those optimal for a particular species.

Vertical Distribution/Movements

The distribution and movement of impingeable organisms within the water column can alter the susceptibility of those organisms to entrapment against the intake screens. Many of the aquatic organisms of greatest concern for impingement are not randomly distributed throughout the entire water column. Consequently, these individuals experience greater or lesser risk of impingement depending on their vertical distribution relative to the vertical zones of withdrawal for any particular intake.

Non-random distribution within the water column generally results from specific habitat preferences of the individual species. For example, some species prefer to occupy areas near the bottom (benthic species) whereas others are found principally up in the water column (pelagic species). Often pelagic species exhibit strong schooling behaviors. For most intakes, pelagic species are typically more susceptible to impingement than are benthic inhabitants. These habitat preferences help to explain differences in impingement rates observed between species of similar abundance in the source waterbody.

In addition to these species-specific differences, depth distributions can vary seasonally and even within a day for some species. For example, in systems with strongly stratified thermal regimes (e.g., lakes and reservoirs), species will often seek specific preferred temperature ranges that correspond to specific depth intervals (Peterson 1986). Consequently, the depths at which these species are typically found can vary seasonally. However, in some thermally stratified systems, low dissolved oxygen values in deeper waters during the warmer months of the year can force individuals into areas of less than optimal temperatures, potentially leading to physiological stress. In addition, some systems can become strongly stratified with respect to salinity (e.g., some estuaries). In these systems, many species will inhabit preferred salinity ranges leading to vertically-stratified depth distributions. These salinity-induced distribution patterns can vary on both a short-term and seasonal basis as a result of changes in freshwater inflow. Finally, many pelagic species move up in the water column at night to feed, only to return to deeper waters during the day (Loesch 1987). These temporal differences in vertical distribution can substantially alter the susceptibility of individual populations to impingement through time. Such differences help to explain the strong temporal patterns in impingement observed for many species at many power plant intakes (e.g., Thomas and Miller 1976, Lifton and Storr 1978).

As for all other factors related to the potential for AEI, the potential for this factor to affect the susceptibility of aquatic organisms to impingement must be considered in light of the design, location, and operation of each individual intake. The range of depths from which the intake withdraws relative to the depth of the source waterbody can influence impingement involvement through interaction with the vertical distribution of organisms. For example, the importance of non-random vertical distribution might be high for an intake drawing water from a relatively narrow depth stratum compared to the overall depth of the water body. On the other hand, an intake encompassing almost all of the depth of the source waterbody would tend to draw from all depths and reduce the importance of non-random vertical distribution.

Cross-sectional Distribution

As discussed in greater detail in Section 2.1.1, non-random cross-sectional distribution patterns among the species and life stages are a factor in assessing the potential for AEI. These cross-sectional distributional patterns can be species-specific or even vary across time within a species. Consequently, individual populations could experience a greater or lesser risk of impingement depending on their distribution relative to the areas of withdrawal for any particular intake.

Most commonly, non-random distributions among species result from a preference for onshore or offshore habitats by individual species. For example, species found principally in near-shore areas would have relatively low susceptibility to impingement at an intake drawing water primarily from offshore areas (e.g., darters, minnows, gobies, silversides). Likewise, species found principally in far offshore waters in large bodies of water (e.g., lake trout, deepwater marine species), such as the Great Lakes or the oceans, would have relatively low susceptibility to impingement at intakes located along the shore. These species-specific habitat preferences can explain some of the differences in impingement rates observed between species at any individual intake.

In addition to differences in habitat preference between species, substantial changes in cross-sectional distribution may occur through time for the same species. These changes can occur on both a short-term and seasonal basis. For example, many species of fish move to inshore waters during the night to feed, only to return offshore during the day (e.g., black bass, summer flounder, striped bass). Such movements can lead to dial differences in susceptibility to impingement. In addition, predatory species move into inshore waters following schools of prey. During such times, both predators and prey can become more susceptible to impingement at shoreline intakes. On a longer time scale, many species make seasonal movements between inshore and offshore areas, particularly in temperate areas of the country (e.g., bluefish, pikes, carp, grunion). Often such movements bring the species into shallow waters during the warmer months of the year where active feeding takes place. As temperatures drop during fall and winter, many of these species migrate to deeper waters offshore for overwintering. Other species make seasonal movements between inshore and offshore areas for spawning purposes. These temporal changes in inshore and offshore distributions help to explain some of the variability in impingement susceptibility observed for many species.

Swimming Ability

An organism’s ability to swim obviously influences its potential for impingement. Individuals most susceptible to impingement tend to be younger individuals with limited swimming abilities, both in terms of maximum swim speed and endurance. As both components of an individual’s swimming ability tend to increase with size, overall susceptibility to impingement tends to decrease as the individuals become older and larger.

In general, most fish of impingeable size (typically 1 inch or longer) have a maximum swim speed greater than the approach velocity of most intakes. Consequently, these fish have the ability to swim away from the screens once they are encountered and, thus are not immediately impinged. These fish swim against the water approaching the intake in order to avoid contact with the screen. If these fish remain in front of the screens, then they continue to swim to the point of exhaustion at which point they become entrapped against the intake screen. Since the swimming endurance of fish tends to increase with size, larger individuals can swim against the approach velocity longer and have a greater likelihood of avoiding impingement altogether. Thus, smaller individuals of a species in the vicinity of the intake tend to become impinged. Thus, the size, and, consequently, the swimming ability, of individuals must be taken into account in assessing the overall susceptibility of individuals to impingement.

In addition to the influence of size, swimming ability is also affected by water temperature (Webb 1993). During colder times of the year fish metabolic processes slow down and, thus, swimming ability is reduced. Thus, susceptibility to impingement often increases as water temperatures decline in fall and winter. The effects of both water temperature and length of the fish on individual fish swimming ability is illustrated with swim speed data collected on white perch (Figure 3.1.2).

The importance of swimming ability to the potential for AEI should be evaluated in light of the approach velocity of the intake. In the absence of other intervening factors, individuals have a greater ability to actively avoid impingement at intakes with low approach velocities, as compared to a similar intake with higher velocity. Further, the design and location of the intake (offshore, shoreline, recessed) will also strongly influence the ability of individuals to actively avoid impingement. In particular, recessed intakes tend to limit the options for fish to move away from the intake. Thus, there is a greater tendency for individuals to remain in front of the screens and become impinged when encountering a recessed intake design, as compared to either shoreline or offshore intakes of similar capacity and approach velocities. These potential interactions are discussed in more detail in Section 3.1.2.

Physiological Stress

This factor refers to the stresses an aquatic organism might encounter that affect physiological processes to the point that susceptibility to impingement is increased. Such stresses are typically a result of extreme events that lead to exposure to non-routine environmental conditions. These exposures can result in stresses that adversely affect the ability of an organism to actively detect and avoid impingement.

Physiological stresses can arise from a variety of factors, including exposures to less than optimal environmental conditions. As already discussed, prolonged exposures to temperatures in excess of optimal temperatures can leave organisms in a weakened state and less able to avoid impingement, and sudden temperature drops or prolonged exposures to unusually cold temperatures can also incapacitate organisms to the point that they have difficulty avoiding impingement. Finally, exposures to low dissolved oxygen or salinities outside normal ranges can so stress individuals that their swimming capacity and ability to avoid impingement are impaired.

In addition to exposure to adverse environmental conditions, impingement susceptibility can also increase from other physiological stresses. For example, reproductive activities can stress individuals and reduce their ability to avoid impingement. Energy expended as a result of gamete production, nest or redd construction, or the actual spawning process can result in temporarily weakened individuals that are less able to avoid impingement. Further, diseases or physical damage can also weaken individuals and reduce impingement avoidance capabilities.

In general, periods of increased impingement susceptibility resulting from the physiological stresses described above are infrequent and of relatively short duration. Often, such periods of stress are somewhat predictable in their timing, as they are related to seasonal phenomena such as temperature patterns or spawning activity.

As with every other factor affecting the potential for AEI through impingement, physiological stress must be considered in light of other intervening factors. These factors, described in more detail in the previous sections, include approach velocity and intake location.

3.1.2. Factors Relating to the CWIS

Intake structural factors, as well as hydrological and chemical factors, are important in determining whether aquatic organisms become impinged. These structural factors include (1) the location and orientation of the intake structure vis a vis the shoreline and the bottom and surface of the waterbody; (2) the design features of the intake structure; (3) velocity and other hydraulic or hydrological factors; and (4) water quality factors. The following section discusses these factors in turn.

For purposes of this discussion, the “CWIS” includes both any initial inlet through which water is directed from waters of the United States (“WOUS”) to the facility (which may include jetties, breakwaters, or other structures extending into the WOUS), and inter-connected onshore structures that serve as the initial portal through which water enters the facility.

Such portals often include some type of fixed or rotating (also called “traveling”) screening system to screen out debris that could cause blockage of the condenser tubes within the cooling system and reduce condenser efficiency. Such screening systems generally are located in an onshore screenwell that also may contain a bar rack to prevent large debris from impacting the screens.

Intake Location/Orientation

The location of an intake relative to the shoreline and its orientation to the surface and bottom of the waterbody are important factors in determining which species and life stages are most likely to interact with the structure. In this regard, there are three basic configurations: (1) offshore, submerged, <FN 3> (2) shoreline, submerged, or (3) shoreline, surface (Figure 3.1.3). By virtue of its location, the offshore, submerged intake withdraws water selectively from deeper offshore areas. Therefore, the species and life stages most likely to encounter such an intake are those that inhabit or tend to pass through such areas. Shoreline intakes typically are located in shallower water. Often, skimmer walls are incorporated into CWISs in colder climates to prevent ice passage in winter. Such walls are also used to draw cooler water from greater depths. In any case, the inclusion of skimmer walls results in selective withdrawal and such shoreline intakes can be considered to be submerged. As such, surface-oriented species are less likely to encounter these intakes if the skimmer walls are of sufficient depth. On the other hand, shoreline intakes that are essentially open and pass water through the entire intake depth will not physically exclude such fish. With shoreline intakes in general (i.e.. submerged and open). the fish most likely to encounter the intake are pelagic species that inhabit shallow, near-shore areas.

The potential for involvement of fish with CWISs of a specific type in a specific location relates to how that intake is perceived by fish that might encounter it and how they react to it. The mere presence of an intake structure does not determine the potential for involvement. The location and orientation of a CWIS is more important from the standpoint of what that intake represents to fish approaching it. While intake structures are man-made and generally are considered to be “artificial,” they often have features that mimic naturally occurring structures. Such is the principle behind the highly successful use of man-made structures to create artificial habitat for fish (e.g., sunken ships, abandoned oil rigs and used cars). The behavioral response of fish to an intake is mostly related to the intake’s physical structure in conjunction with the hydraulic environment established by the interaction of the structure with ambient currents, as discussed below in Section 3.2.2.

Design Features

Various design features of intakes can be factors in determining whether fish will become involved with the CWIS and be subjected to potential impingement. The most important factors are the structural features of the CWIS. Again, these factors relate to how fish perceive and react to an intake structure. The following discusses the most important design features and the principle types of CWISs, including:

-CWISs that include offshore inlets incorporating jetties, embayments, or breakwaters and a shoreline intake portal;

-CWISs with shoreline intake inlets followed by canals leading to the intake portal;

-CWISs having both inlet and screenwells flush with the shoreline; and offshore intakes, both with and without velocity caps.

Shoreline intakes often incorporate canals, jetties <FN 4> (parallel walls, typically constructed of rock that project from the shoreline and direct flow to the screenwell), breakwaters (rock walls located offshore from the screenwell that project the CWIS from waves and ice) and embayments that are composed of natural and/or man-made materials located in WOUS, and direct water to an onshore screenwell. The tendency of fish to be attracted to, or repelled by, such features is largely a function of whether the materials and hydraulic conditions appear natural or whether some aspect of the structure signifies danger and triggers an avoidance response.

Fish moving along the shore in shallow water have been observed to be attracted to jetties and breakwaters. It is for this reason that such structures are popular with anglers. These structures serve as cover from predators and severe weather conditions, and may harbor abundant food resources. The attractiveness of jetties and breakwaters is independent of whether or not an intake structure is associated with them. There is no evidence to indicate that the impingement potential of jetty intakes is higher or lower than any other intake types. Provided that fish inhabiting jetty areas have the swimming capacity to move about at will, there is no reason to consider the structure as anything more than an extension of their natural environment.

Unlike jetty intakes that protrude into a waterbody, intake canals typically have shoreline inlets that convey water to an in-land portal (typically a screenwell). The canal sides and bottom may be natural (e.g., earth or sand) or man-made (e.g., rip rap or sheet pile). As with jetties and breakwaters, the conditions that exist in canals can be attractive to fish and invertebrates. That is, fish may choose to reside in canals for periods of time. Again, it is often assumed that the mere presence of fish in a canal makes them more vulnerable to potential impingement. If these fish have selected the canal as preferred habitat and have the swimming ability to move freely. however, there is no reason to consider them to be more at risk than at other intake types. An example of long-term residence in a CWIS comes from a study conducted at a power plant on Lake Erie. Fish enter a shoreline forebay via an offshore, submerged intake. In 1998, a mark/recapture study was conducted with smallmouth bass in the forebay. A total of 967 fish were marked and released into the forebay periodically between May and August. None of these fish were recovered from the traveling screens during this period. Fish recaptured by angling in the forebay were found to be healthy and actively feeding on other fish residing in the forebay (Cooke et al. 2001).

At some power plants, the CWIS is constructed in such a manner that it is reasonably “flush” with the shoreline. The intent of this structural configuration is to minimize potential entrapment areas and permit freer movement of fish. It is often assumed that the flush-mounted design has less potential for impinging fish than a jetty or canal intake because it minimizes entrapment areas in which fish may not be able to, or may not desire to, leave. With any intake type, if fish have the swimming capability to move about freely in the intake, the potential for impingement is related to whether they encounter conditions that stimulate a response to leave the intake. Such stimuli apparently are absent at some CWISs, given that fish can be observed swimming in front of the traveling screens in CWISs for prolonged periods even though adequate passage routes permitting escape exist. Thus, fish that ultimately impinge on screens in any intake type may not necessarily be “entrapped” but rather have not been subjected to stimuli that would encourage them to leave. The importance of such a stimulus as a factor influencing the potential for fish involvement with an intake is discussed below in Section 3.2.2.

As discussed previously, some shoreline intakes are designed to withdraw deeper water and are, therefore, considered to be submerged. The use of skimmer walls to achieve this end can result in the creation of a barner to fish that enter the intake and then seek a route of return to open water. For example, at PEPCO’s Morgantown Station, fish were observed to be entrapped behind a skimmer wall in water with low dissolved oxygen levels. When portals were cut into the sheetpile walls allowing fresh water to enter, the fish were able to find their way out of the intake.

Like the structural features of shoreline CWISs, offshore CWISs may have features that can make them more or less attractive to fish and influence the potential for involvement. Offshore intakes typically are submerged and located relatively close to the bottom. They may be open-ended pipes oriented vertically or horizontally in relation to the bottom, and they often have coarse racks to block the passage of large debris. Offshore, submerged intakes are connected to onshore screening systems via tunnels or pipes. Once fish enter these closed conduits, their fate is to arrive at the screenwell and eventually impinge. Therefore, the “point of no return” is at the offshore intake opening. Many offshore, submerged CWIS incorporate a velocity cap, which is a flat structure that sits horizontally over the intake opening. The velocity cap creates a horizontal, “net-like” flow pattern. While it has been shown that fish generally respond more actively to horizontal flow accelerations than vertical flow accelerations (USEPA 1976), there have been no quantitative studies of velocity cap versus open-pipe intakes.

In conclusion, while intake location and design influence the species and life stages of fish that are most likely to encounter an intake, other factors are dominant in determining the potential for impingement.

Footnotes

3 "Submerged" typically means that the structure is located substantially below the water surface -- e.g., a velocity cap is submerged.

4 In freshwater systems, shoreline intakes incorporating canals or jetties are not a typical design.

EPA Response

Please see response to comment 316bEFR.041.301. Today's final rule allows facilities to adjust for impingement survival in their impingement numbers. Please see the response to comment 316bEFR.305.001 for the discussion regarding entrainment-based performance standards. Please see response to comment 316bEFR.002.015 for the discussion regarding the inclusion of entrainment survival estimates in site-specific benefit analyses. Also, please see the chapter, Entrainment Survival, in the Regional Studies for Final Section 316(b) Phase II Existing Facilities Rule for more information.

[comment continued from 316bEFR.041.302]

Velocity and Related Hydraulic Phenomena

As previously noted, the structural features of an intake, coupled with ambient hydrologic conditions (i.e., tidal, river, or wind-driven velocity magnitude and direction, and turbulence levels) and hydraulic conditions established by the withdrawal of cooling water flow, are important factors in determining the potential for involvement of impingeable organisms with the CWIS.

For a fish to avoid an intake, it must receive some type of stimulus, or cue, to trigger an avoidance response. Within the range of velocities and other hydraulic phenomena occurring at most CWISs, such cues appear to be largely lacking. This is not surprising given that the hydraulic conditions which fish experience at intakes are not substantially different from those they experience in their everyday existence. In most environments, fish are subjected to velocities in the range of those found at or within CWISs (on the order of about 0.1 to 3.0 ft/sec). Further, turbulence is common in most environments, particularly in waters where instream velocities are naturally high, such as tidal estuaries and rivers. Thus, fish will tend to respond to hydraulic conditions at a CWIS in a manner similar to which they respond to any object in open water.

Flow velocity and direction at an offshore, velocity cap intake will vary mainly with ambient long-shore currents (mainly tidal and wind-driven) and intake flow rate. Hydraulic conditions (i.e., velocity magnitude and direction) will be more uniform and will vary over a much longer time scale. The velocity cap concept arose from research conducted in 1956 which indicated that fish cannot sense a vertical displacement of flow to any substantial degree. Up to that time, offshore intakes were generally open pipes built up from the ocean or lake bottom, possibly with a large-spaced trash rack over the opening. With the understanding that fish are better able to perceive velocity gradients in a horizontal direction than in a vertical direction, the velocity cap design was conceived (Figure 3.1.4). The retrofit of a velocity cap intake at the El Segundo Steam Station in California was reported to reduce impingement by 95 percent relative to the uncapped intake (Weight 1958). Based on these results, a velocity cap was designed to reduce fish entrainment at an intake for California Edison's Huntington Beach Steam Station. Prior to final design, a scale model of the proposed design was constructed to develop optimum hydraulic performance. During these tests, live fish were exposed to the capped and uncapped model intakes. The investigators noted that, without a velocity cap, small fish were entrained rapidly into the intake pipe. However, it was almost impossible to draw any fish into the pipe when the velocity cap was being used (Weight, 1958).

It is significant to note that the El Segundo Station incorporates an entrance velocity of 3.5 ft/s while the Huntington Beach intake was designed for a 2.0 ft/s entrance velocity. In fact, Weight (1958) reports: "It is the opinion of the engineers concerned that the entrance velocity is not highly critical for this type of installation as long as it is greater than a fish normally experiences. A range of 1 to 3 feet per second is recommended as acceptable for design."

This opinion is substantiated by two laboratory studies that addressed the relationship between velocity and entrapment of alewives (SWEC 1976; 1978). In these studies, two identical offshore intake structures (opening size of 5 ft wide by 2 ft high in a water depth of 6 ft) were operated at different velocities over a range from 0.5 to 2.0 ft/s. In the first study, an inverse relationship was found between inlet velocity and entrapment (Figure 3.1.6; SWEC 1976). In the second study, no correlation was found between velocity and entrapment of alewives (SWEC 1978).

A variety of studies at CWIS indicate either a lack of correlation between velocity and impingement or identification of other factors that significantly influence the number of fish impinged. For the reasons discussed above, the absolute value of the velocity approaching and entering the CWIS is not a determining factor in impingement. Rather. it is the change in velocity, if of sufficient magnitude, and the subsequent change in hydraulic conditions (e.g.. rapid flow accelerations and turbulence) that could provide the cues to fish that elicit positive rheotaxis.

This conclusion is supported by the results of a study by Loar et al. (1978), which examined impingement data for 24 power plants for which a year's worth of data were available. Velocities were calculated by dividing the plant design flow by the traveling screen area. While there were some limitations in the data relating to knowledge of how many pumps were operating during sample collections, the strong lack of correlation between velocity and the number of clupeids impinged per l06m3 (Figure 3.1.5) indicates that, over the range of velocities evaluated [6 - 88 cm/s (0.02 - 2.89 ft/s)], other factors were more influential in explaining impingement numbers. The authors report that the level of impingement varied between the units of a given power plant as well as between screens of a given unit and speculate that localized hydraulic conditions may account for these differences. By way of example, Loar et al. (1978) present data on the impingement of clupeids at the Marshall Steam Station on Lake Norman, NC. As shown on Figure 3.1.7, impingement numbers varied widely between identical units. The authors point to the presence of a large eddy adjacent to Unit 4 and again suggest that site-specific hydraulic conditions may explain the observed differences in impingement.

These data point out the potential shortcomings of using existing impingement data in determining the potential for AEI as a result of impingement losses. Unless reported data represent samples from all screens and units at a power plant, the numbers could be over- or under-estimates and may yield inaccurate estimates if used to extrapolate to non-sampled units to develop total impingement numbers. The data also demonstrate the site-specificity of impingement data — i.e., intakes of similar type, design and location may experience large differences in the numbers and species of fish impinged. Similar conclusions were reached in a study by Page et al. (1978) which presents results of a comparative assessment of impingement at two similar cooling water intakes located on the same shore of the Columbia River approximately 276m (905 ft) apart. The 100-N station intake has a total capacity of 26.4 m3/s (936 cfs), while the upstream Hanford Generating Project has a total capacity of 35.6 m3/s (1257 cfs). Flow velocities through the traveling water screens at both sites are similar, on the order of 0.7 m/s (2.3 ft/s). Therefore, it might be reasonably assumed that impingement rates would be similar. On the contrary, despite the similarity and close proximity of the two intakes, twice as many yellow perch and 30 times as many chinook salmon fry were impinged at Hanford (Figure 3.1.8).

The authors offer several possible explanations for these unexpected results. One explanation was that the Hanford intake removes more vulnerable fish from the river upstream of the 100-N intake; this was discounted since most fish impinged at Hanford are returned alive to the river and are then fully susceptible to passage to the 100-N intake. A second explanation was that fish may have been less likely to encounter the 100-N intake because it is located further from the river in a more pronounced forebay; this was discounted since removal of berms at Hanford which had previously created a similar embayment had no effect on impingement. A third possibility was that curtain walls near the upstream face of the two intakes are in slightly different locations. Experimental releases of live and dead fry in front of both intakes showed that Hanford impinged six times more fish than 100-N: however about 1.3 times more dead fish were impinged at 100-N. Impingement of more dead fish and fewer live fish at 100-N suggests that, although velocities are somewhat higher, some environmental stimulus induces fish to avoid the screens. A final explanation was that more fish pass around or through the screens at 100-N. However, diver observations and sampling downstream of the screens indicated that this was not a large problem. The authors suggest that subtle differences in velocity, circulation patterns and design and operation of the intakes may provide behavioral stimuli and induce avoidance of the screens by fish at 100-N (Page et al. 1978). In analyzing possible relationships between velocity and impingement, caution is advised in using existing velocity data due to inconsistencies in the methods used to derive and report these data. This caution stems from the fact that intake structures create complex hydraulic environments that cannot be adequately described from the standpoint of potential impingement by maximum, minimum, or mean values. Hydraulic conditions vary by intake type and design, and are influenced by plant operational and ambient hydraulic factors. For example, flow velocity and direction approaching and within a shoreline intake structure in a tidal river will vary with the orientation of the structure in the river, the presence of curtain or skimmer walls (common in northern climates), the number of pumps operating, and tidal stage (ebb, flood or slack). The hydraulic conditions in the intake will be complex and will vary continuously. Further, if the plant has a shoreline discharge. there is the potential for recirculation of warm water under certain tidal conditions. Such recirculation is not only undesirable from an operations (energy) viewpoint, but it also has been correlated to impingement potential.

As with velocity, the correlation between rate of flow (e.g., gallons per minute) into an intake and the potential for impingement has not been demonstrated. EPRI is currently developing a database of entrainment and impingement which will be used to examine relationships with flow, velocity and other factors. Results of these analyses are scheduled to be completed in the fall of 2001.

In at least some cases, it would appear that biological factors play a greater role in determining whether fish are susceptible to impingement than flow. For motile organisms, flow rate is important primarily as it relates to near-field hydraulic conditions (flow direction and magnitude) at the intake, as discussed above. While flow rate affects the area of influence of a power plant, the measurable velocity effects that have been associated with impingement potential extend a very short distance from the point of water withdrawal.

Data presented by Benda and Houtcooper (1976) on the impingement experience at sixteen power plants located on Lake Michigan and its tributaries provide an example of the lack of correlation between flow rate and impingement. While it was not the intent of the authors to correlate the numbers of fish impinged at these plants to any particular plant design or operating feature, they did supply total numbers by species and flow rates. This information is plotted on Figure 3.1.9. While the authors indicate that, within a given CWIS, there were more fish impinged on screens with larger circulating water pumps, there was little correlation between flow and numbers impinged across all sixteen plants. This lack of correlation could be attributable to other factors (e.g., relative fish abundance in the vicinity of each power plant intake). However, this example points to the difficulty of flow alone to predict impingement levels at a specific site.

Water Quality

Closely coupled to hydraulic conditions are a number of water quality parameters that influence impingement potential. Water quality appears to be a confounding factor influencing the nature and extent of impingement. The biological aspects of water quality and impingement interactions are presented in more detail in the next section of this report. The following discussion provides specific examples of how plant design and operational factors interact with water quality parameters to influence the number of fish impinged.

Temperature is one of the most important factors influencing fish impingement. This is particularly true of schooling species in inland waters, such as threadfin shad (Dorosoma petenense) and alewives that live at latitudes where temperatures approach their lower lethal Limit. A number of studies have been conducted which provide insight into other factors that might influence the nature and extent of impingement effects. As noted above, Loar et al. (1978) attempted to identify factors influencing impingement of fish at inland power plants in the southeastern United States. The authors examined impingement data from 24 power plants at which data were available for an entire year. Approximately 98 percent of the fish impinged at these plants were members of the family Clupeidae, with the major species being threadfin shad. As observed with shad at power plants in other regions, temperature was the factor most highly associated with impingement. Maximum impingement rates occurred during the winter when intake temperature dropped below 10° C. At low temperatures, threadfin shad are susceptible to stress that affects their swimming ability. The peak in impingement in the colder winter months at the plants examined indicates that temperature is the overriding parameter influencing shad impingement in this region of the country.

Other authors have reported similar results. Lifton and Storr (1978) present impingement data for the C. R. Huntley Plant on the Niagara River near Buffalo, NY (Figure 3.1.10). A significant inverse correlation was found between temperature and the number of alewives, gizzard shad, and smelt impinged at this shoreline intake; however, other factors also were found to be correlated to numbers of fish impinged. Sky cover was found to be inversely correlated with impingement at a statistically significant level. The authors concluded that, with increased cloud cover, there is less activity of daylight-active fish, and that lack of a proper twilight level fails to trigger normal activity patterns for nighttime-active fish. Wind direction and intensity also were correlated with impingement at statistically significant levels at the Huntley Plant. Storm activity and strong north or northwest winds resulted in increased impingement while east and south winds resulted in lower impingement levels (Lifton and Storr 1978). The authors found similar relationships at the R. E. Ginna Power Plant which has a submerged velocity cap intake located offshore at a depth of 9.1 m (30 ft). In addition, wave height was found to be correlated with impingement, and the authors suggest that wave-induced turbulence and possibly increased turbidity interfere with the fish's normal ability to detect the intake and avoid it (Lifton and Storr 1978).

At the Monroe Power Plant on Lake Erie, Eisele and Malaric (1978) examined the relationship between gizzard shad impingement and a variety of operational and environmental factors. This plant withdraws cooling water from the lake via a river and intake canal. Large episodes of shad were noted during the 1973-1977 period. Stepwise multiple regression of 612 observations of impingement indicated that intake water temperature was the only variable that contributed significantly to the variation in shad density. As temperature decreased, impingement increased. Such observations have been made with gizzard shad at other power plants. The authors noted, however, that most shad runs at Monroe occurred during intentional warm-water recirculation or wind-driven recirculation of the thermal plume to the intake and suggest that increased numbers were related to an attraction to this warm water. Further analysis of selected data from periods of peak shad abundance showed that water transparency significantly contributed to variations in shad density. They suggest that reduced transparency causes a lack of visual orientation that leads to higher impingement (Eisele and Malaric 1978).

Other environmental parameters have been associated with impingement levels. For example, Cannon and Lauer (1976) found impingement of fish to be closely related to salinity at the Indian Point Power Plant on the Hudson River in New York. They note that over wintering fish. Particularly white perch, prefer the freshwater/saltwater interface of the salt front that moves up and down the river past the plant’s intakes in response to tides and river flows. When the salt front is in the vicinity of the plant, higher impingement rates usually result (Figure 3.1.11). This is a case where habitat preference has a strong influence on susceptibility to impingement.

3.2 FACTORS THAT AFFECT MORTALITY

The proportion of organisms that survive impingement and are returned to the source water body alive is an obviously important factor influencing the potential for AEI. The survival of impinged organisms depends on intake screen design and operation, and on the tolerance of the organisms to impingement stresses. This section therefore discusses CWIS factors and biological factors that interact to determine impingement survival.

3.2.1. Biological

The impingement process exposes organisms to the risk of injury and death from suffocation, mechanical abrasion and generalized physiological stress, including exhaustion. Studies at operating power plants have shown that impingement survival is influenced by the organisms’ inherent sensitivity to impingement stresses, by seasonal factors presumably influencing the condition of fish prior to impingement, and, for estuarine-sited power plants, by the ambient water salinity.

Species Sensitivity

Survival of impinged fish and macro invertebrates varies widely among species and, therefore, the influence of impingement on AEI must be considered on a species-specific basis. In general, organisms that have traditionally been found to be hardy in terms of their resistance to collection and handling stress (e.g., blue crab, hogchoker, catfish) are also tolerant of impingement stresses, while those that have traditionally been difficult to collect and keep alive (e.g., Atlantic menhaden, bay anchovy, threadfin shad) are sensitive to impingement.

Studies that have been conducted at operating power plants indicate that the rate of organisms surviving impingement generally varies at least several-fold among species at a given site, with a maximum reported range of 0 percent to 100 percent survival. An example of the range in impingement survival across species at one power plant is provided in Figure 3.2.1. For a given species, survival from the physical effects of impingement may also depend on the size or age of the impinged organisms.

The actual impingement survival realized by each species and life stage is greatly influenced by intake screen design and operating conditions that affect the physical stresses present during impingement (See Section 3.2.2). For example, for vertical traveling screens there is generally a substantial increase in organism survival associated with decreased time between screenwashes. continuous screen rotation providing the highest survival (Chase 1975: King et al. 1978: Tatham et al. 1978). When screens are stationary for long periods of time, impinged organisms may become moribund in repeated attempts to free themselves and may suffocate against the screen. Conventional vertical traveling screens at existing power plants typically are engineered for intermittent washes, often automatically triggered by hydraulic head differential as debris builds up at the face of the screens. Continuous operation of these screens is possible. but they generally require upgrading of mechanical components, or complete replacement to assure reliable operation in a continuous mode.

Survival is also improved by incorporating stress reduction features such as lifting buckets and low-pressure screenwash systems that separate fish from debris (see Section 3.2.2). Conversely, some power plants have no provision in the intake design for returning organisms to the source waterbody, and therefore none survive impingement. In addition, the proximity of cooling water intake and discharge, together with the hydrodynamics of the waterbody in the vicinity of the station, influences the extent to which organisms are reimpinged after return to the waterbody. Multiple impingement exposures tend to reduce survival as a result of cumulative stress and injury.

Salinity

As for entrainment, water salinity may be an important factor influencing impingement survival in the brackish water regions of estuaries, where salinity varies seasonally in response to changes in freshwater discharge and tidal height. Low to moderate levels of salinity reduce the energy input required for osmoregulation, and thereby act as a general stress ameliorator. The addition of salt has been shown to reduce mortality from physical stresses (Bowser and Buttner 1991; Kane et al. 1990; Palawski et al. 1985).

Impingement survival studies in brackish water regions of the Hudson River suggest that the stress reducing effects of salt result in higher impingement survival of some species when brackish water is present than during freshwater periods (ORU 1977). For example, white perch impingement survival was found to be positively correlated with water salinity at the time of impingement. Survival 96 hours after impingement ranged from 7 to 42 percent when the intake water was less than about 0.1 parts per thousand (ppt) mean salinity (essentially freshwater) and was generally greater than 60 percent when salinity exceeded about 0.3 ppt.

Other Factors

Impingement survival of individual species has been observed to vary widely at different times of year. Several potential sources of the variation have been suggested in the literature, although studies to verify the causes of seasonal variations have generally not been conducted. One important factor is the intake screen loadings of debris and organisms with hard exoskeletons (e.g., crabs) which appear to cause an increase in injury and death, reducing survival of other impinged species (Landry and Strawn 1974). Occurrence of debris and its blockage of intake screens is a highly site-specific factor.

The physiological state of organisms at the time of impingement may also affect their survival. In particular, seasonal water temperatures near the upper or lower temperature tolerance limit of the species may increase their sensitivity to the subsequent stress of impingement, thereby lowering impingement survival relative to that observed at other times of the year. In temperate zones, many species are unable to fully adapt physiologically to the wide changes in water temperature which occur seasonally. Although many of these species adapt behaviorally by seasonal migration to habitats with more favorable temperatures, some portion of their populations often reside in waters quite close to the limits of heir thermal tolerance. As a result, these organisms are susceptible to natural seasonal mortality, especially in particularly cold winters or hot summers, and may therefore die whether or not they are impinged. For example, Lankford (1997) has shown that Atlantic croaker, which use bays and estuaries during summer and fall months, can become highly stressed and more susceptible to impingement when water temperatures are lowest.

3.2.2. Factors Relating to the CWIS

As discussed in Section 3.1.2, fish that cannot leave an intake, or that are not provided with the stimuli to induce them to leave, ultimately will impinge on a screening device. Most Swiss contain traveling water screens that are designed to screen out debris that can cause blockage of the condenser tubes and reduce condenser efficiency. A typical through-flow screen design is shown on Figure 2.1.7. The CWIS factors that influence the potential for impingement mortality are addressed individually in the following discussion.

Fish Species and Life Stage

The survival of fish impinged on traveling screens varies widely by species and life stage. Some species have been shown to be relatively fragile and suffer high mortality regardless of screen design and operation. For example, mortality of juvenile herring (Genus Alosa; e.g., blueback herring and alewives) has been high at many CWISs over a wide geographic range. On the other hand, some species have demonstrated high impingement survival, such as flounders, sunfishes and catfishes. In addition, macroinvertebrates, which represent a major proportion of total organisms impinged at some CWISs, display survival rates approaching 100 percent (e.g., blue crabs). (Thomas and Miller 1976; Murray and Jinnette 1978; LMS 1991). Thus, it is not possible to predict mortality based solely on CWIS design and operation. Rather, each species and life stage must be evaluated relative to its inherent potential for injury and stress in combination with design and operational factors at a given CWIS.

Fish Behavior In Relation to the Intake

Behavioral characteristics vary widely by species and life stage. Behavior not only influences how quickly a fish might impinge, but also the degree to which injury may occur that will influence survival. Actively-migrating anadromous species, such as juvenile river herring, prior to impinging (Cooke et al. 2001). Such prolonged swimming may have a negative physiological impact on fish that eventually leads to reduced swimming capability and impingement. Such stress might also be expected to influence survival potential. The relationship between exercise and fatigue resulting from physiological stress in fish has been extensively studied in laboratory experiments over many decades. However, the relationship between swimming duration and time to impingement and survival potential in power plant screenwells has not be defined. Fish behavior also influences survival potential once a fish is impinged. Regardless of the design screen approach velocity in most screenwells, the force of the water flowing through the screen generally is powerful enough to prevent escape once a fish is impinged on the screen mesh. However, depending on fish species and size, many fish actively respond to becoming impinged by trying to free themselves. The resulting oscillatory motion of the fish does not allow it to free itself from the forces of the flow holding it on the mesh. However, due to local variations in flow direction and magnitude, the struggling behavior of the fish can result in lateral movement along the screen face. The result of such movement can produce both negative and positive results. On the negative side, movement of fish over a screen mesh can result in de-scaling and possible injury to the eye, fins and other soft tissue that can, in turn, reduce survival potential. The classification of species as “fragile” results from the fact that such species are particularly susceptible to scale loss that negatively impacts their ability to osmoregulate and exposes them to infection.

On the positive side, Fletcher (1990) showed in laboratory studies that, in selected species, struggling behavior resulted in a downward movement along the screen mesh that directed them to the fish lifting bucket attached to each of his experimental screen panels. By redesigning the bucket to create a calm zone, fish were found to seek shelter and remain in the bucket as the screen’s rotation carried them upward to the water surface and spraywash fish removal system. Thus, the natural behavior of fish should be evaluated in optimizing the design features of traveling screens. It should be noted that Fletcher’s work is one of the few attempts that have been made to observe and understand how fish interact with screens and how these observed behaviors might lead to design improvements. Additional work of this type is warranted.

Screen Type and Operation

The traveling screens in use at most CWISs in the United States are through-flow or dual-flow design. In the through-flow screen design, the screen is set perpendicular to the approach flow and fish are collected on the upstream, ascending screen face. With dual-flow screens, the screen is oriented horizontal to the approach flow. Water passes through both ascending and descending screen faces and exits the screen through a single discharge port. The screens are rotated periodically for cleaning (e.g., once per shift) or are designed to rotate when debris blockage results in a preset differential headloss (i.e., the drop in water elevation from the upstream to the downstream side of the screen) across the screen. As such, fish that collect on the screens may remain impinged for long periods of time. Most species cannot respire effectively under such conditions and experience mortality due to suffocation.

During periodic screen washing, the screen panels move to the water surface and then through a high-pressure (e.g., 100 psi) spraywash system which removes debris and fish to a trough for transport to a trash basket. Fish that are alive at this point can be injured or killed by this spraywash procedure. Further, as the screen panels clear the water surface. impinged fish can fall back into the water and be re-impinged. Those fish that enter the debris trough are sluiced back to the receiving water at a location away from the intake. In some cases, the fish are collected in a trash basket where they typically suffer total mortality if the basket is emptied only occasionally.

A variety of screen modifications, and the associated development of effective fish transport systems, has led to improvements in screening technology that can result in high organism survival rates. These improvements include:

-Alternative screen mesh designs that minimize abrasion and enhance fish removal:

-continuous screen operation to minimize impingement duration;

-the addition of fish lifting buckets to each screen panel to contain fish in water as they are carried to the removal system, as described above;

-the incorporation of low-pressure (e.g., 10-15 psi) fish removal spraywash systems to minimize injury to fish; and

-the addition of fish transport pipes or troughs which convey recovered fish to a safe release location.

Research is ongoing in this area, and continued improvements in survival are expected. Therefore, while the screening system remains a contributing factor in organism survival at CWISs, new designs are available that can greatly reduce the potential for AEI resulting from these systems.

Screen Mesh Type and Size/Debris

In the past, screen meshes at CWISs consisted of woven wire with square openings on the order of 6 to 13 mm. Given concern over the potential for AEI as a result of fish impingement losses, researchers over the past three decades have investigated changes in mesh size and type to improve organism survival. Fine mesh screens (e.g., 0.5 to 2.0 mm) have been employed to protect early life stages of fish and invertebrates.

The type of mesh used affects the survival potential of fish in several ways. First, coarse mesh woven wire tends to be abrasive by design. Second, with their large wire spacings, the impingement forces on fish are distributed across relatively few screen elements resulting in the characteristic “grill marks” that are observed on fish subjected to prolonged impingement. Finally, the debris handling characteristics of screen meshes vary widely. Coarse, square mesh designs tend to result in the “pinning” of debris more than finer, square or oblong mesh designs. Pinned debris can reduce the effectiveness of low-pressure spray wash systems causing fish to carry over to the high-pressure spray wash. The use of mesh designs that minimize pinning and readily shed debris (e.g., fine or oblong mesh) can result in the sloughing of debris into the fish collection trough. On the other hand, these meshes tend to be less injurious to impinged organisms. Therefore, the selection of mesh type and size at a given site must balance fish protection and debris handling needs and take into consideration the type and amount of debris present and the species and life stages to be protected.

It is important to point out that fine mesh screens designed to protect early life stages result in the impingement of these smaller organisms that are entrained through coarser meshes. Therefore, fine mesh screens are only of biological benefit if the impingement survival of the affected species and life stages exceeds that which would result if they were allowed to pass through the circulating water system.

Fish Return Systems

As stated previously, modified traveling screens installed to protect fish must have an adequate organism return system that will convey collected fish to a safe release location. The conveyance is typically a smooth-surfaced trough or pipe that transports organisms in water for release at a distance from the CWIS that will minimize recirculation. Therefore, near-field hydraulic conditions must be understood when siting a discharge point. It is useful to return fish into moving water that will disperse them quickly and reduce the potential for predation by other fish and birds.

Other Fish Protection Technologies

A wide variety of fish protection technologies have been developed for possible use in reducing impingement losses and thereby preventing the potential for AEI at CWISs (EPRI 1999a). In addition to the fish collection screening systems described above, these technologies include diversions systems that actively guide fish to bypasses (e.g., angled screens and louvers), physical barriers that passively prevent fish passage (e.g., wedge-wire screens, submerged weirs and barrier nets), and behavioral barriers that take advantage of natural behavioral patterns in fish to cause repulsion or attraction (e.g., sound and strobe lights). These technologies have been installed at a relatively small number of power plants, as presented below. Biological effectiveness has been found to be site- and species/life stage-specific as presented in the following discussion.

Angled Fish Diversion Screens. A variety of species have been shown to guide effectively on angled screens given suitable hydraulic conditions. Angled screen systems have been installed and biologically evaluated at a number of cooling water intakes on a prototype and full-scale basis. Full-scale angled screens are in use at Oswego Steam Station — Unit 6 (LMS 1992) and at Brayton Point Station (Davis et al. 1988). Angled screen diversion efficiency and survival at these sites varies by species but has, been generally relatively high for the many species evaluated. Survival following diversion and pumping (as required to return fish to their natural environment) has been more variable. Overall survival rates of relatively fragile species following diversion has been low. Hardier species exhibit higher survival rates resulting in overall system efficiency values (diversion and survival) ranging from 50 to nearly 100%.

Physical Barrier Nets. Under the proper hydraulic conditions and without heavy debris loading. barrier nets have been effective in blocking fish passage into water intakes. At the Ludington Pumped Storage Plant on Lake Michigan, a 2.5-mile long barrier net, set in open water around the intake jetties, has been successful in reducing entrainment of all fish species that occur in the vicinity of the intake (Reider et al. 1997). The net was first deployed in 1989. Modifications to the design in subsequent years led to a net effectiveness for target species (five salmonid species. yellow perch, rainbow smelt, alewife and chub) of over 80% since 1991, with an effectiveness of 96% in 1995 and 1996.

At the Chalk Point Station, a double net system was installed to reduce impingement of fish and crabs. Losses were estimated by assigning a dollar value to each organism by species according to Maryland's regulations (Loos 1986). All fish species impinged and 15 percent of blue crabs impinged were assumed killed. River trawl data (relative abundance) was used to create a relationship between impingement of blue crabs on the traveling screens and their abundance in the river. This relationship was used to compute the expected impingement based on the abundance of crabs in the river for that year. The expected impingement after modifications were made to the barrier net system was 919,000 crabs, while the actual number of crabs impinged was 142,000. This represented an 84 percent reduction in expected crab impingement after the second barrier net was deployed.

Sound Behavioral Barrier. Recent fish protection studies involving underwater sound technologies have focused on the use of new types of low- and high-frequency acoustic systems that have not previously been available for commercial use. High-frequency (120kHz) sound has been shown to effectively and repeatedly repel members of the Genus Alosa (American shad, alewife and blueback herring) at sites throughout the United States (Nestler et al. 1992; Dunning 1997; Con Edison 1994).

Other studies have not shown sound to be consistently effective in repelling species such as largemouth bass, smallmouth bass, yellow perch, walleye, rainbow trout (EPRI 1998), gizzard shad, Atlantic herring, and bay anchovy (Con Edison 1994). Given the species-specific responses to different frequencies that have been evaluated and the variable results that often have been produced, additional research is warranted at any sites where there is little or no data to indicate that the species of concern may respond to sound.

Therefore, when reviewing potential for AEI at a given plant, consideration must be given to the effectiveness of existing technologies that have been installed to increase survival.

4. FACTORS THAT AFFECT POPULATION RESPONSE

The response of a population to the loss of individual organisms is a function both of the characteristics of the individual fish and of the population as a whole. In terms of population dynamics, the ultimate measure of the value of an organism is its potential contribution to future generations. The higher that contribution, the more important the population-level effect of harming that organism. Conversely, the lower the contribution of the organism to potential future generations, the smaller the effect. All other factors being equal, populations with very short generation times recover more rapidly from reductions in abundance than do populations with long generation times, and populations with high capacities to compensate for unpredictable

This section identifies the major biological factors that can be expected to influence the responses of populations to entrainment and impingement loss. Although several methods for assessing the impacts of power plants on fish populations are introduced to illustrate the influences of these factors, the section does not include a compendium of all possible assessment approaches. Readers interested in such a compendium should consult EPRI's Catalog of Assessment Methods for Evaluating the Effects of Power Plant Operations on Aquatic Communities (EPRI 1999b).

4.1 LIFE STAGE OR AGE OF ORGANISM

The effect on a population of the death of an individual organism is strongly dependent on the• life stage or age of that organism at the time of its death. Eggs and larvae of fishes typically suffer extremely high mortality rates. More than 99.9 percent of the young spawned by a typical female fish can be expected to die prior to adulthood. The effect on a population resulting from the death of a single egg or larva is, therefore, low. The effect resulting from the death of a fish increases with the age of that fish. The simplest way to illustrate this concept is to consider the expected future egg production of an individual female fish at age x:

Equation 1
[see hard copy for equation]

The influence of age on future egg production can be easily illustrated using the values provided in Table 4-1 that summarizes the life history of a hypothetical fish species in which all females become sexually mature at one year of age. The probability of survival from the egg stage (age 0) to an age of one year is only one in a thousand, but the probability of survival thereafter is 0.5 per year until the fish reach five years of age. All fish that reach age 5 die without further reproduction. Between ages 1 and 5, the fecundity of each fish increases with age.

In this example, a one-year-old female will produce 2,000 eggs. If she lives to age 2 she will produce 2,400 more eggs, but her probability of surviving another year is only 0.5. if she lives to age 3 she will produce another 2,800 eggs, but her probability of surviving for two years is only 0.25 (i.e., 0.5 x 0.5). Her total expected egg production is calculated by multiplying her expected fecundity at each future age by the probability that she will survive to reach that age:

E1 =2,000+(0.5x2,400)+(0.5x0.5x2,800)+(0.5x0.5xo.5x3,200)+(0.5x0.5x0.5x05x0)—4,300

The death of a one-year-old fish, therefore, deprives future generations of more than 4,000 eggs on average. A newly spawned egg has a far lower potential lifetime egg production. If she survives to age 1, her potential egg production will be equal to that of a fish that is already one year old, but her probability of surviving to age 1 is very low. The lifetime reproductive potential of a newly spawned female egg is much lower, because only one out of every thousand eggs will survive to age 1. The lifetime reproductive potential of an egg. using equation (I). is:

E0 = (0.0001x 2,000) +(0.0001x 0.5 x 2,400)+(0.0001x 0.5 x 0.5 x 2.800)+(0.0001x 0.5 x 0.5 x 0.5 x 3.200)+(0.0001x0.5x0.5x0.5x0.5x0)=E1 x0.0001=4.3

Hence, in this hypothetical, the death of an egg deprives future generations of just over four eggs on average. Once a fish reaches age 5 reproduction ceases and, therefore,

E5 =0

The death of a fish older than the maximum reproductive age has no effect at all on future generations.

Although this example has been simplified for illustrative purposes, the general principle applies equally to actual fish populations: the death of a very young fish has a much smaller effect on the population than does the death of a sexually mature fish. Within the first year of life, the value of each fish to the population increases with each successive life stage, because the probability that it will survive to reproduce increases with age. For life stages vulnerable to entrainment, the effect of entrainment on the population is least on eggs and greatest on entrainable juveniles. Fish vulnerable to impingement are larger and older than entrainable life stages, and the potential population effect of impinging a given fish is substantially larger than the effect of entraining it at an earlier age. The species that are most vulnerable to population- level effects from impingement are those for which fish are vulnerable to impingement throughout their entire lifespan. Forage fish such as bay anchovy and threadfin shad, or small predators such as white perch, are examples of such species.

Estimated effects of entrainment and impingement on Hudson River fish populations provide excellent examples of the importance of life stage and age in determining the population-level consequences of entrainment and impingement. Densities of white perch eggs and larvae in the Hudson River are much higher than densities of juveniles (Klauda et al. 1988), and large numbers of white perch larvae are entrained at Hudson River power plants. Given the relative densities of the different life stages in the river, the number of white perch that are impinged must be substantially smaller than the number entrained. However, because these fish have survived the early life stages of high mortality, their value to the population is higher and the population effect of impingement — measured as the conditional mortality rate (fraction of the annual production removed, see Section

4.6) — is at least as high and perhaps higher than the population effect of entrainment (Barnthouse a al. 1984).

In determining the ultimate importance of this factor to the potential for AEI, this factor must be considered in light of several other biological factors. For example, compensatory processes (see below) vary with life stage, and are often especially important in early life stages of fish. In addition, the susceptibility of fish to entrainment compared to impingement varies with life stage. Eggs and larvae are normally vulnerable to entrainment, but not to impingement. Exceptions may occur with certain intake technologies (e.g., fine-mesh screens) in which the mesh size of traveling screens is small enough to impinge larvae. Small juvenile fish (~20-40 mm in length, depending on mesh size and body shape) may also be susceptible to entrainment, while larger juveniles and adults are primarily impinged rather than entrained.

4.2 LIFE HISTORY STRATEGY

The term “life history” refers to the suite of characteristics of species that determine their long-term rates of population growth or decline. Among these are longevity, age-specific rates of survival and reproduction, seasonal patterns of reproduction, and sex ratios. Evolutionary biologists have long known that these characteristics are subject to natural selection. and that when life history traits of many organisms are compared, they tend to fall into a small number of distinct groups (Cole 1954). The most familiar grouping of life history patterns is the “r-K continuum” pattern described by Pianka (1970). According to Pianka, most species can be described as falling somewhere between two opposite life history types or strategies: ‘K-strategists” are characterized by short life span, early sexual maturity, large clutch or brood sizes, and high annual reproductive effort. Examples would include many weeds, most insects, and some species of fish. Examples of fish that could be described as r-strategists would include bay anchovy, threadfin shad, and many fish that inhabit small, ephemeral streams. Such species are able to rapidly colonize new environments and are able to rebound quickly after disturbances that kill many or most individual organisms. Their population sizes are usually highly variable in space and time. “K-strategists” are characterized by long life span, delayed sexual maturity, small clutches or broods, and low annual reproductive effort. Familiar examples include trees, condors, and elephants. Such species are slow to colonize new or variable environments, but can attain large population sizes in stable environments. Adults of K-strategist species tend to be large in size and to have relatively low rates of natural mortality. Fish, because of their relatively high fecundities compared to terrestrial vertebrates, have been difficult to place in the r-K continuum. Large, long-lived fishes such as sturgeons and paddlefish share many characteristics of K-strategists, but produce too many eggs to fit the pattern perfectly.

Winemiller and Rose (1992) proposed a “triangular continuum” to describe life history patterns in North American fish species. In comparing life history characteristics of 200 species of freshwater, estuarine, and marine fishes, the authors found three general types of species: “opportunistic,” “equilibrium,” and “periodic.” The opportunistic strategy involves early maturation, frequent reproduction over an extended spawning season, and rapid larval growth. Adults are small in size, generally have short life spans, and suffer high levels of mortality due to predation. Anchovies, killifishes, and mosquitofishes represent extreme examples of this strategy. The equilibrium strategy involves low fecundity, high juvenile survivorship, and parental care. Extreme equilibrium strategists among fishes are relatively small and inhabit very stable environments, such as caves and coral reefs. Species such as largemouth bass and channel catfish, as well as other members of the families

Centrarchidae and Ictaluridae, are less extreme examples. In these species, male fish build and guard nests; these behaviors greatly reduce the vulnerability of eggs and larvae to predators. The opportunistic and equilibrium strategies are similar to the r and K strategies described by Pianka (1970). The periodic strategy involves delayed maturation, large body size, and high fecundity. The individual eggs are usually small and mortality in early life stages of these species is usually high and highly variable between years. Adults have very long life spans and low natural mortality rates; populations are sustained by "dominant year classes" that occur infrequently when environmental conditions are favorable. Striped bass is an extreme example of this strategy, however, many anadromous and coastal species (e.g., weakfish, American shad, and winter flounder) possess some or most of the characteristics of periodic strategists.

The triangular continuum is more easily applicable to fish than the traditional r-K continuum because it readily accommodates many fish species — specifically, the "periodic" strategists - that do not fit neatly into the traditional theory. It has recently been extended to amphibians and used to assess the relative vulnerability of different types of oviparous (egg-laying) vertebrates to adverse effects of toxic chemicals (Rose et al. 1999).

The potential responses of fish populations to entrainment and impingement mortality are, in part, related to life history strategy. Both opportunistic and periodic strategists possess adaptations that enable them to exploit spatially and temporally varying environments and to persist in spite of high levels of natural mortality. Small-bodied, opportunistic species, such as bay anchovy, sustain high natural mortality rates at all ages. Populations of these species may be relatively insensitive to entrainment and impingement mortality, provided that these rates are much lower than natural mortality rates. Large-bodied, periodic species, such as striped bass and many other anadromous species, sustain high natural mortality rates at early life stages and may be relatively insensitive to additional mortality imposed on those life stages. Equilibrium strategists would be expected to have greater potential for population effect from mortality imposed on early life stages, because this strategy involves maximizing early life stage survival.

Periodic and opportunistic strategists are often among the most abundant species in entrainment and impingement collections at power plants and are commonly selected for inclusions in assessments of the potential for AEI. For example, of the species included in the Hudson River studies (Barnthouse et a!. l988b), striped bass, American shad; alewife, and blueback herring are periodic strategists. The bay anchovy and Atlantic tomcod are opportunistic strategists. The white perch is intermediate between opportunistic and periodic species. Among other commonly entrained or impinged species, the Atlantic silversides, Atlantic menhaden, threadfin shad, and other small forage species would all be classified as opportunistic species according to Winemiller and Rose (1992).

Equilibrium strategists such as salmonids, centrarchids, and ictalurids, which have relatively low fecundity and provide parental care to eggs and larvae, are often found in the vicinities of power plants sited on lakes, rivers, or reservoirs.

The importance of this factor to the potential for AEI requires consideration of other, potentially interacting, biological factors. For example, many periodic and opportunistic species produce large numbers of small eggs and larvae. These life stages are highly susceptible to entrainment, especially if they inhabit the pelagic zone. On the other hand, larvae of nest-building species (e.g., salmonids, centrarchids, and ictalurids) are much less susceptible to entrainment. Smallbodied opportunistic species that inhabit the pelagic zone can be highly susceptible to impingement.

In addition, several lines of evidence suggest that the compensatory capabilities of fishes are related to life history. The periodic life history strategy appears to be especially common among fish species that sustain high rates of commercial exploitation (Mertz and Myers 1998). In some cases, species have sustained rates of fishing mortality that are several times higher than their rates of natural mortality (Mertz and Myers 1998). Some opportunistic species. e.g., herrings and anchovies, also have sustained high rates of natural mortality. Exploitation at these rates would not be possible if these species did not possess significant compensatory capabilities. Research on compensatory mechanisms in fish representative of the periodic and opportunistic life history types has shown that relatively small changes in the survival rates of early life stages of these species can offset relatively large changes in mortality imposed on other life stages (Cowan et al. 1993, Cowan et al. 1999).

4.3 MEAN GENERATION TIME

Generation time is defined by Andrewartha and Birch (1954) as ". . .the mean period elapsing from the birth of the parents to the birth of the offspring." In terms of birth and survival rates,

Equation 2
[see hard copy for equation]

In other words, the mean generation time is determined by the time required for the average female to reach sexual maturity, the average number of offspring born at each reproductive age, and the probability that a female will survive to reach that age.

The rate of recovery of a population from a disturbance that greatly reduces its abundance, or from a reduction in fishing effort intended to promote an increase in abundance, is related to generation time. Species with short generation times recover much more rapidly than species with long generation times. Species with short generation times can, for example, be expected to recover more rapidly from episodes of high entrainment or impingement mortality than would species with long generation times. Bay anchovy, threadfin shad, and other small fishes have mean generation times of approximately one year or even less under favorable conditions. Recovery of these populations from either natural disasters or episodes of entrainment or impingement would be expected to be rapid. Striped bass, although living for up to 30 years, become sexually mature in 5 to 7 years and so have an intermediate generation time. The Atlantic Coast striped bass population was observed to recover fully from severe depletion within approximately two generations following the imposition of strict fishing regulations in the mid-1980s (Atlantic States Marine Fisheries Commission 1994). The Atlantic sturgeon, which requires 10-20 years to reach sexual maturity (Boreman 1997a), has a correspondingly long generation time. This species is rarely impinged or entrained. However, overfishing has severely depleted most East Coast populations. Although fisheries managers have imposed a harvest ban, several decades will probably be required for these populations to recover.

This factor has important interactions with other biological factors. For example. generation time is related to life history type. Opportunistic species. by definition, have very short generation times. Generation times in periodic species are highly variable, however, ranging from 2-3 years for more rapidly-maturing species, such as weakfish, to more than 10 years for slow-maturing species, such as paddlefish, Atlantic sturgeon and white sturgeon.

4.4 COMPENSATORY RESERVE

Any biological population that persists despite natural fluctuations in the environment must exhibit some degree of increase or decrease in survival or reproduction in response to increases or decreases in population density. The density-dependence of survival and reproduction. also known as "biological compensation," is fundamental to the understanding and management of biological populations. It is compensation that permits fish populations to sustain themselves in spite of intensive harvesting by man. The study of compensation has a very long history in fisheries science; the most commonly used approaches to quantifying compensation were developed more than 50 years ago (Ricker 1954, Beverton and Holt 1957).

The term "compensatory reserve," as defined by Christensen and Goodyear (1988), refers to the excess reproductive capacity of the average female fish, above and beyond the minimum capacity required to replace herself. When environmental conditions are ideal, the average fish can produce far more offspring than are needed to replace her. If the size of the population is lower than the size that can be supported by the environment (i.e., the "carrying capacity" of the environment), the population will grow. If the population is already as large as can be supported, density-dependent reductions in the fecundity of the adults or increases in the mortality rates of the offspring reduce the numbers of surviving young produced by each female. Additional mortality caused by fishing or power plants acts to reduce the size of a population, resulting in compensatory increases in survival and reproduction that offset the additional mortality. As long as the compensatory reserve of the average fish is not depleted, the population will persist. if, however, high levels of additional mortality deplete the compensatory reserve, density-dependent processes will not be able to offset this mortality and the population will decline toward extinction. Such declines have frequently been observed in populations that have been subjected to severe overfishing.

Density-dependent processes act to offset the influences of mortality, e.g., entrainment, impingement, or fishing, on the abundance of populations. The amount of the offset is difficult to predict quantitatively, but qualitatively it is related to the magnitude of the compensatory reserve present in a population and to the relationship between the life stages affected by the additional mortality and the life stages within which compensatory processes are occurring. McFadden (1977) reviewed 17 published studies documenting density-dependent responses of fish populations to fishing and to experimentally-induced variations in population abundance. In recent years, a number of investigators have used "individual-based" population models to synthesize information concerning compensatory mechanisms at the level of the individual fish and to explore the population-level consequences of these mechanisms. Species studied have included smallmouth bass (DeAngelis et al. 1991), striped bass (Cowan et al. 1993). bay anchovy (Cowan et al. 1999), and yellow perch (Rose et al. 1999).

The applicability of compensation to assessments of effects of power plants on fish populations was first discussed by McFadden (1977) and Goodyear (1977). Models that directly incorporate compensation have been used to assess impacts of entrainment and impingement on the Niantic River winter flounder population (NUSCO 1992) and on the Hudson River striped bass population (Lawler 1988, Savidge et al. 1988). At the time these models were developed, however, the available data concerning the life history and stock characteristics of most coastal fish stocks were sparse and unreliable. In the case of striped bass, models in which compensation was assumed to be very strong (implying low potential for impacts related to power plants) and models in which compensation was assumed to be very weak (implying high potential for impacts related to power plants) provided equally good fits to the available data (Christensen and Goodyear 1988). Because of the infeasibility of directly quantifying compensation from the data available for typical fish populations, Goodyear (1977) proposed an approach, which he termed the "compensation ratio" approach, for indirectly estimating the impact of a power plant (or any other source of mortality) on the compensatory reserve of a fish species. An essentially identical approach, termed the "spawning stock biomass per recruit" (SSBPR) approach (Goodyear 1993, Mace and Sissenwine 1993), is commonly used today. The SSBPR approach is widely used as an indirect method of estimating the impact of fishing on the compensatory reserves of species for which the available data will not support a fully quantitative assessment (National Research Council 1998). This approach can be applied to any species for which basic life history information is available. Although it cannot be used to predict reductions in abundance due to fishing or operation of power plants, it can be used to assess whether existing rates of additional mortality due to fishing or power plants are high enough to threaten the long-term sustainability of populations.

Since the 1970s, major advances have occurred both in understanding the mechanisms responsible for compensation, and in incorporating compensation in quantitative models used in fisheries management. Myers and Cadigan (1993), for example, showed that density-dependent mortality in the juvenile stages is crucial for population regulation in some marine demersal (bottom-dwelling) fish. DeAngelis et al. (1979) and MacCall (1981) demonstrated the importance of cannibalism as a compensatory mechanism in other fish populations. Rose et al. (1999) showed that density-dependent processes acting throughout the life cycle of yellow perch — including density-dependent predation by walleye — act together to regulate the abundance of perch. Myers et a!. (1999) developed estimates of compensatory reserve for 246 different fish populations. Pace et al (1993) found evidence for strong density-dependence in the post yolk-sac larval stage of striped bass in the Hudson River.

A variety of methods are now available for developing fish population models that incorporate compensation (Hilborn and Walters 1992). The most widely used approach for directly quantifying the compensatory reserve of a fish population is the "spawner-recruit" approach (Ricker 1954, Beverton and Holt 1957). The spawner-recruit approach relates the abundance of adult fish (the spawners) to the abundance of their offspring (the recruits). Application of this approach requires a series of observations of spawner abundance and resulting recruit abundance from a population. These observations are fitted to a mathematical model and then used to predict the effects of changes in mortality rates on the future abundance of spawners and recruits.

The Atlantic States Marine Fisheries Commission now uses a spawner-recruit model to establish permissible fishing mortality rates for striped bass (Stock Assessment Review Committee 1998). Similar models have been developed for American shad (Crecco and Savoy 1987) and weakfish (Stock Assessment Review Committee 1998).

In practice, high natural variability in recruit abundance, independent of density-dependent effects, often prevents useful predictions from being derived from the stock-recruitment approach. Recently, Myers and Mertz (1998) described the use of a statistical technique known as “meta-analysis” to estimate the compensatory reserve present in poorly-studied species from spawner-recruit data for related but better-studied species. This approach has not, to date, been used by fisheries managers but it is potentially applicable both to fisheries management and to the assessment of power plant effects.

Theoretically, regardless of the magnitude of compensatory reserve present in a population. compensatory processes are more effective in offsetting additional mortality if that mortality is imposed prior to the life stages in which compensatory processes are occurring. For example. mortality due to entrainment of eggs and early larvae may be readily offset by density-dependent increases in the growth rate and survivorship of older larvae (due to reduced competition between larvae) and juveniles. If early juvenile fish are entrained or impinged, compensation occurring in the earlier larval stages cannot act to offset this mortality. Compensation can still occur due to density-dependent growth of the surviving juveniles, but the effectiveness of this compensation will be lessened compared to the compensation possible if the entrainment had occurred prior to this stage.

Compensatory processes interact with many other biological factors to affect the potential for AEI. For example, the specific compensatory mechanisms operating within fish populations vary with life history strategy and trophic position. In species representative of periodic or opportunistic life history strategies, in which there is little or no parental investment in offspring survival, density-dependent mortality can be especially important in early life stages. In nest-building species such as smallmouth bass and other members of the Centrarchidae (largemouth bass, bluegill, sunfishes), nest abandonment is a more important cause of early life-stage mortality than is density-dependent growth or predation. Nest abandonment is influenced by the health of the male fish that guard the nests and by the quality of the nest site; both of these factors represent compensatory mechanisms operating in the adult fish. Cannibalism can be an important compensatory mechanism in predatory fish such as largemouth bass and walleye.

The magnitude of the compensatory reserve of a population, as distinct from the specific mechanisms that operate in the population, is strongly influenced by the presence of other stresses acting on the population. The most important of these stresses is usually fishing, but contaminants that reduce the survival or fecundity of fish can also reduce the compensatory reserve (Barnthouse et al. 1987). This topic is further discussed in Section 4.6 below.

4.5 GEOGRAPHIC POPULATION STRUCTURE

Geographic population structure refers to the large-scale geographic distribution of the organisms that comprise a self-reproducing population. Some aquatic populations are confined to specific waterbodies (e.g., lakes or reservoirs) and, except for emigration and immigration of small numbers of individuals, are isolated from other populations of the same species. In other populations, individuals may be distributed over very large regions during most of the year, congregating in specific locations only for spawning. The degree of geographic concentration or dispersal of organisms within a population affects the fraction of the population that is susceptible to entrainment and impingement.

Populations that are widely dispersed are less susceptible to population-level impacts of entrainment and impingement than are populations that are concentrated within the waterbody from which cooling water is withdrawn. In many species, the degree of geographic dispersal of individuals varies seasonally. Fish may aggregate in specific areas for spawning, or may use specific migration corridors. Water withdrawals from areas in which a population is concentrated in the vicinity of the intake can have a comparatively large effect on populations. Water withdrawals from areas used by widely dispersed populations, in contrast, may have comparatively small effects on populations, even if large numbers of organisms are entrained or impinged.

For example, in anadromous fish species such as striped bass, American shad, and the various species of Atlantic and Pacific salmon, adult fish return to the river or estuary in which they were spawned. Each such river or estuary supports a discrete spawning population that only infrequently exchanges individuals with neighboring populations. Depending on the distribution of early life stages relative to cooling-water intake structures, most or all of the population may be susceptible to entrainment or impingement. In other species that use estuaries, such as Atlantic menhaden, weakfish, spot, and croaker, spawning occurs in coastal waters and the young fish that enter estuaries do not represent discrete populations. In these species, all of the fish present in Atlantic coastal waters are, effectively, a single population. Only a fraction of the population is present in any given estuary, greatly reducing the overall susceptibility of the population to any given power plant. In many fish species that use intertidal and subtidal zones along the Pacific coast (e.g., rock bass), larvae are transported long distances by currents before settling out in favorable habitats. The reproducing population of these species may also be characterized as geographically dispersed, rather than localized.

In freshwater, populations are more likely to be localized in discrete waterbodies. In nonmigratory species (e.g., largemouth bass and other centrarchids), the population present in any lake, pond, or river can be considered to be a discrete population. In large rivers that have been dammed for navigational purposes, the population within each navigational pool may be considered to be a localized spawning population. Population structures of migratory freshwater species, such as sturgeons and paddlefish, have been less-well characterized.

4.6 OTHER STRESSES

The sustainability of a population is influenced by all of the stresses imposed on it by natural conditions (e.g., floods, drought) and man's activities. The response of a population to additional mortality caused by entrainment and impingement is affected by the existence and magnitude of other stresses. By stress, we mean any other influence that reduces the capacity of the population to replace itself. Effects that reduce the replacement capacity of organisms include increases in mortality and reductions in fecundity. Reductions in growth can indirectly affect both survival and fecundity. Sources of stress that commonly affect fish populations include harvesting, environmental contamination, habitat alteration, and introductions of non-native species.

Goodyear (1977) showed that both effects of exploitation of adult fish and of entrainment/impingement of early life stages decrease the lifetime reproductive potential of female fish. He demonstrated a method for combining the effects of these two sources of stress and calculating the tradeoffs required to maintain a given "safe" level of reproductive potential. Barnthouse et al. (1987, 1988a) extended Goodyear's method to include effects of toxic chemicals that reduce survival or fecundity. Boreman (l997b) reviewed several related methods for combining effects of fishing with effects of pollutants. Schaaf et al. (1993) assessed the effects of pollutant-related habitat destruction on several Atlantic coastal fish stocks with different life history characteristics.

Any stressor that affects the survival, growth, or reproduction of the members of a population reduces the capacity of that population to cope with normal environmental variability or to new stresses. Within the conceptual framework of population dynamics, these types of stresses reduce the compensatory reserve of populations. Stresses that have small effects compared to the pre-existing compensatory reserve may reduce the ability of the population to cope with future stresses, but they will not cause irreversible population decline. If, however, the total burden of stresses exceeds the compensatory reserve, decline will occur. The potential lifetime egg production of an individual one-year-old fish, as described in Section 4.1, provides a convenient means of illustrating the effects of combined stressors on the sustainability of a population. Stresses such as fishing, power plants, and environmental contaminants reduce the potential lifetime egg production of a fish by reducing its probability of survival, reducing the number of viable eggs produced at any given age, or reducing the probability that a spawned egg will survive to adulthood.

As noted by Goodyear (1993), the Spawning Stock Biomass per Recruit (SSBPR) index used in fisheries management can be expressed in terms of either biomass or egg production. Expressed as egg production, SSBPR is the same as the expected lifetime egg production of a one-year-old fish, as described in Section 4.1. Analyses of data for a variety of harvested fish populations (Clark 1991, Mace and Sissenwine 1993) indicate that SSBPR can be used to define conservative, “default” biological reference points for regulating fishing mortality. The maximum sustained yield in many fish populations occurs at rates of fishing mortality that reduce SSBPR to about 35 percent to 40 percent of the level characteristic of an unfished population. In other words, if the fish population described in Table 4-1 were a harvested species, maximum sustained yield would be expected to occur at a rate of fishing mortality that would reduce the lifetime egg production of a one-year-old fish to about 35 percent of the unfished value, or from 4,300 to 1,505. Many fish populations can sustain levels of fishing mortality that reduce SSBPR to as low as 20 percent of the level characteristic of an unfished population (Mace and Sissenwine 1993). This level is referred to as a “recruitment overfishing reference point.” As long as SSBPR remains above this level, compensatory increases rates of survival and reproduction are expected to permit the average female fish to replace herself. If SSBPR falls below that level, there is a risk that the compensatory reserve of the population will be exceeded, the average female will not be able to replace herself, and the population will become depleted. If the population described in Table 4-1 were a “typical” fish, lifetime egg production per one-year-old fish could be reduced to 860 without completely depleting the compensatory reserve of the population. The number of young fish recruited into the population each year would not significantly decrease, and the population would persist. If. however, egg production fell below that level, recruitment might begin to decline, and the continued persistence of the population might be threatened.

Power plant effects are often expressed in terms of a “conditional mortality rate” (CMR) that combines effects of entrainment and impingement. As explained by Barnthouse et al. (1984), the CMR is a measure of the mortality caused by entrainment and impingement. independent of all other sources of mortality affecting a population. If only young-of-the-year fish are vulnerable to entrainment and impingement, then the CMR is a measure of the fractional reduction in abundance of 1-year-old fish due to entrainment and impingement. In other words. a CMR of 0.1 indicates that for every 1,000 one-year-old fish expected to be produced in the absence of power plant operations, 100 fish will be lost due to entrainment and impingement. Removing 10 percent of the young produced by a fish before they become one-year-olds is equivalent to removing 10 percent of the eggs produced by that fish that spawned them. If, in the absence of power plant operations, 1,000,000 eggs would have been required to produce 1,000 one-year-old fish, then reducing the number of survivors by 10% (from 1000 to 900) is equivalent to reducing egg production by 10%, from 1,000,000 to 900,000. This means that a CMR of 0.1 is also equivalent to a 10 percent reduction in SSBPR. A CMR of 0.1 would reduce SSBPR (expressed as lifetime egg production) for the population in Table 4-1 by 10 percent, from 4,300 to 3,870. It should be noted that none of these calculations include adjustments to account for density-dependent mortality. Density-dependent mortality occurring prior to the time during which entrainment and impingement occur would have no effect on the results. However, if mortality during or subsequent to the period during which entrainment and impingement occur is density-dependent, then the loss of some individuals due to station-related mortality will result in increased survival of those organisms that are not entrained or impinged. In this case the CMR, as usually calculated, would overestimate the actual impact of station losses on the abundance of one-year-old fish. The timing of station losses relative to periods in which compensatory mechanisms are operating is an important issue in applying spawner-recruit models in power-plant impact assessments. However, the timing of compensation has no effect on the application or interpretation of the SSBPR approach.

A 10 percent reduction in the SSBPR of an unharvested or unstressed population would, according to current understanding of fish population dynamics, have a negligible effect on the compensatory reserve of that population. If imposed on a population that is already under stress due to overfishing or environmental contaminants, however, the additional mortality caused by entrainment and impingement could be important. Figure 4.1 shows the relationship between SSBPR and fishing mortality (1) for a population that is harvested but is unaffected by other stresses, (2) a population that is harvested and exposed to toxic chemicals that reduce the fecundity of each fish by 20 percent, and (3) a population that is harvested, exposed to chemicals, and subjected to a 0.1 CMR due to entrainment and impingement. Fishing mortality is expressed, in standard fisheries terminology, as "F," the instantaneous rate of fishing mortality (Ricker, 1975). All fish that are one year old or older are assumed to be equally vulnerable to fishing.

As shown in Figure 4.1, SSBPR declines continuously with increasing F. For any given value of F, the added effects of contaminants and fishing reduce SSBPR below the level that would exist if harvesting were the only stress imposed on the population. When F is low, the remaining SSBPR is well above the recruitment overfishing reference point (SSBPR = 20 percent of the unfished value). Even if the population were being harvested at a rate intended to produce maximum sustained yield (SSBPR = 35 percent of the unfished value), the added effects of contaminants and power plants would still not cause the remaining SSBPR to fall below the reference point. However, if the population were over harvested (F = 0.8 or higher). fishing alone could nearly deplete the compensatory reserve of the population and the additional effects of other stresses could reduce SSBPR to the point where the spawning population could no longer replace itself and the population would decline.

The purpose of the above hypothetical example is to illustrate the concept that multiple stresses can combine to cause serious adverse effects on populations, even when the individual stresses evaluated in isolation may appear inconsequential. In particular, fish populations that are already in jeopardy because of overfishing are more vulnerable to additional effects of other stresses such as power plants, toxic chemicals, introduced species, and habitat degradation. The more of these stresses affecting a population, the more likely it is that any additional stresses (or increases in the intensity of existing stresses) will cause the population to decline.

Many, if not most, exploited fish populations are subject to multiple stresses. The major estuaries of the Atlantic, Gulf, and Pacific coasts all provide spawning and nursery habitat for important fish species, and almost all have been adversely affected by impaired water quality related to urban development. The Great Lakes have been similarly affected. The catastrophic decline in the native fisheries of the Great Lakes — including the extinction of some formerly abundant species — has been attributed to a combination of overfishing, toxic chemicals, and introductions of non-native species. (Holling 1973). Multiple stresses have probably contributed to historic declines in abundance of many estuarmne-dependent species, although the relative importance of the different stressors is usually unknown. The recent recovery of the Delaware River striped bass population, which was nearly extirpated in the 1960s, has been attributed to a combination of improvements in water quality and reductions in fishing mortality (Weisberg and Burton 1993, Weisberg et al. 1996).

Consideration of multiple stressors is important both for evaluating effects of entrainment and impingement on populations and for evaluating the susceptibility of individual fish to entrainment and impingement. In the population context, the compensatory reserve of a population is affected by all of the stressors that affect survival and reproduction. The stressors can affect different life stages. In the context of individual susceptibility, stresses that affect the health or mobility of an organism can increase its susceptibility to entrainment or impingement. The susceptibility of the organism to the intake structure itself can be increased, and the survival of entrained or impinged organisms can be decreased.

The above discussion does not imply that all populations subjected to multiple stresses are at a high risk if exposed to additional mortality due to entrainment and impingement. A large fraction of target species in 316(b) studies support intensive commercial or recreational fisheries, moreover, because many power plants are sited in industrialized regions, a large fraction are also exposed to stresses related to water quality and habitat modification. The continued growth of the Atlantic coastal striped bass population (ASMFC 1999) and the recent growth of the Atlantic coastal weakfish population (ASMFC 2000) are excellent examples. Both species use heavily industrialized estuaries for parts of their life cycles and both are exposed to entrainment and impingement at power plants. Yet both species recovered rapidly following reductions in fishing effort that were imposed because of previous overfishing.

TABLE 4.1. MORTALITY AND REPRODUCTION PARAMETERS FOR A HYPOTHETICAL FISH SPECIES

5. FACTORS THAT AFFECT SOCIETAL VALUATION

As part of an assessment of the potential for AEI, a determination must be made as to whether or not population-level effects resulting from entrainment and impingement losses are sufficiently large so as to be considered adverse. EPA has defined adverse effects as effects that are of concern because of the amount of risk that they pose to valued structural or functional characteristics of ecological systems (USEPA 1998). However, whether or not population effects are large enough to be of concern can only be determined through decision making that takes place in the context of human values. Consequently, determination of adversity ultimately involves societal judgments about the acceptability of population responses, or effects, on valued biological resources and community characteristics. Therefore, the nature and magnitude of population responses that are considered undesirable may depend in part on the relative value, or societal valuation, placed on individual species or habitats.

Societal valuations involve economic, legal, and quality of life issues that can best be thought of as management factors influencing the threshold of acceptability. Among the more important of such factors for evaluating AEI are a species' commercial value, recreational value, and ecological role (i.e., for the structure and functioning of the community). Species rarity and the uniqueness of the source waterbody habitat near the intake can also be important influencing factors.

5.1 COMMERCIAL VALUE

Species that are harvested for sale as food, bait, or use in other products are commonly viewed as having special importance in AEI assessment due to their obvious economic value. For this reason, EPA's draft § 316(b) guidance (USEPA 1977) recommends that commercially or recreationally important species be among those species selected for the assessment of AEI.

Specific consideration of commercial species is also justified because they are subjected to the combined stresses of fishing and CWIS mortality (Section 4.6). In this sense. CWIS mortality and fishing mortality compete for the available compensatory reserve of the population. Thus, populations of commercially harvested species can be more sensitive to entrainment and impingement effects (other biological factors being equal) because a portion of their compensatory reserve (see Section 4.4) is used in the commercial harvest. Where fisheries heavily exploit populations of commercially important species, compensatory reserves available to offset mortality from other uses may be limited. In such cases. resource allocation and balancing of beneficial uses are important resource management considerations that, as yet, have been largely unaddressed.

The economic value of commercially important species is generally based on landings and market value (i.e., dollars/lb). Species with high commercial value tend to be principally found in coastal marine and estuarine systems and very large freshwater bodies such as the Great Lakes. Commercially important species occupy a wide variety of feeding niches and trophic positions in the aquatic community. For example, Atlantic menhaden are primarily plantivores feeding on a mixture of phytoplankton and planktonic invertebrates, whereas flounder species are primarily top-level predators which feed on crustaceans, mollusks, and fish.

5.2 RECREATIONAL/CULTURAL VALUE

Species sought by anglers frequently are an important consideration in AEI assessments. This is due in part to the direct economic value of the sport fishing industry, but also to the broader quality of life value that society places on recreational enjoyment. Therefore, the value per fish that some segments of society ascribe to recreationally important species is relatively high. In addition, some recreationally important species, such as striped bass, American shad, and channel catfish are also harvested commercially. As a reflection of this societal emphasis, EPA's draft § 316(b) guidance (USEPA 1977) recommends that, of the species potentially involved with the intake structure, commercially or recreationally important species be among those species selected for the assessment of AEI.

As for commercially important species, specific consideration of recreational species is also justified because they are subjected to the combined stresses of fishing and CWIS mortality, and a portion of their compensatory reserve (see Section 4.4) is used in the recreational harvest. Where combined sport and commercial fisheries heavily exploit populations of recreationally important species, compensatory reserves available to offset mortality from other uses may be limited.

The economic value of recreationally important species is generally based on an assessment of replacement value, or the amount of money that anglers judge would be required to dissuade them from fishing (dollars/day). Species with high recreational value inhabit all types and sizes of waterbodies. The most important of the sport fish species tend to be top-level predators in the aquatic community. Examples include weakfish, walleye, largemouth bass, and striped bass. Because of their position at the top of the food chain, recreational species are generally considered good indicators of adverse effects potentially caused by CWIS operation on lower trophic levels. That is, if adverse effects were occurring on primary producers (e.g., phytoplankton, kelp, submerged vascular plants) or on plant eaters, detritus eaters, or lower level predators, those effects would also be observed in the top-level predators. for which the lower trophic levels provide food and shelter.

Some species (e.g., catfish, salmon) may also be the target of subsistence fishing by indigenous peoples or other special population segments that traditionally rely on fishing. and as a result be ascribed substantial cultural value. In these cases, resource valuation may become intertwined with human rights issues and result in either an increase or decrease in the level of protection afforded to the species.

5.3 IMPORTANCE OF ECOLOGICAL ROLE

Societal valuation generally increases directly with the level of biological organization potentially effected. Effects that are imposed on higher levels of biological organization are generally perceived as more undesirable than those imposed at lower organizational levels. For example, organism mortality is more undesirable than sublethal effects, population effects more undesirable than organism mortality, and effects on the community as a whole more undesirable than effects on an individual population.

As a result of this distinction among biotic scales, higher value may be placed on species that play a pivotal role in the structure or functioning of the community, and they may receive more protective treatment in AEI assessment. As a reflection of this societal emphasis, EPA’s draft 316(b) guidance recommends that, of species involved with the intake structure, species critical to the structure and function of the ecological system be among those species selected for detailed assessment of AEI (USEPA 1977).

Ecologists have described the community as a complex assembly of component guilds, or roles, whose interactions with one another determine each community’s organizational characteristics. Guilds are defined based on food-web relationships, and consist of groups of species exploiting a common resource base in a similar fashion (Krebs 1994). Species within each guild can sometimes be viewed as interchangeable members, or functional equivalents, in terms of their relationship and effect on the rest of the community. Thus where guilds consist of many species, ecological redundancy is high, and CWIS effects on any one species population would be expected to have little effect on the community as a whole. Conversely, where a guild is occupied by a single species and that role is critical to the community, effects on that species population may cause substantial changes in the community. Such important species are called “keystone species” because their activities control community composition (Lampert and Sommer 1997). Such species typically would receive greater protective treatment in AEI assessment because of the ecological importance of their role. The composition of species guilds and the importance of keystone species varies among biological communities and therefore influence on AEI determinations is quite site specific.

5.4 PRESENCE OF THREATENED OR ENDANGERED SPECIES

As a result of concerns that man’s activities are leading to the unwanted extinction of species, Congress passed the Endangered Species Act in 1973 (ESA). This Act defined two categories of species, those that are “endangered” and those that are “threatened.” Endangered species were defined as ". . .any species [including subspecies or qualifying distinct population segment] that is in danger of extinction throughout all or a significant portion of its range.” ESA §3(6). Threatened species were defined as “... any species that is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range.” ESA §3(20). These two classes of species, threatened and endangered, are afforded special protection in an effort to prevent extinction and to allow for their recovery.

Since passage of the ESA, considerable effort has been expended to provide for the protection of any qualifying species and the public has become acutely aware of the need to protect species that are threatened or endangered. Thus, in considering the potential for AEI resulting from entrainment and impingement, threatened and endangered species typically receive special consideration. It is for this reason that these species were identified as a specific category for selection of species for the assessment under EPA’s draft 316(b) guidance (USEPA 1977). For this single category, the potential for AEI is typically defined at the individual level as opposed to the population level. Because of the potential risk of extinction, the loss of even a single individual is considered unacceptable unless such a loss is specifically permitted and will not jeopardize the continued recovery of the species.

5.5 LOCATION OF SPECIAL STATUS HABITAT

This factor refers to the distance from the intake to any habitats or areas of the source waterbody that are specifically designated by an agency as having a special status or importance in supporting aquatic life. Many state natural resource agencies assign waterbodies or segments of waterbodies to a special status based on the quality of the habitat or the natural resources they contain. Examples of such special status waters include Significant Habitat Units, Trophy Fishing Waters, Blue Ribbon Trout Streams, and Marine Sanctuaries. Typically, these special status waters are afforded additional protection under state law.

As a result of this special status designation and the additional efforts expended for their protection, these areas commonly receive special consideration in the assessment of AEI resulting from entrainment and impingement. While the population-level consequences of entrainment and impingement will remain the same, a special status designation means that regulatory agencies, and typically the public at large, place a greater value on the resources in these areas. Hence, an equivalent level of loss from entrainment or impingement in these special status areas would have a greater likelihood of being considered adverse than if it had occurred elsewhere.

EPA Response

This comment is a continuation of Comment 316bEFR.041.304. Please see EPA's response to that comment.

Regarding compensation and compensatory reserve in the context of EPA's benefits analysis for the 316b Phase 2 rule, please see response to Comment 316bEFR.025.015. Regarding fish population modeling, please see response to Comment 316bEFR.005.009.

EPA disagrees that widely dispersed populations are necessarily less susceptible to population-level impacts of I&E. Frequently, regional stocks are vulnerable to multiple CWIS, which can lead to significant cumulative effects. In fact, the Atlantic States Marine Fisheries Commission (ASMFC) has concern about this issue and is currently evaluating the potential cumulative impacts of multiple CWIS on the Atlantic Coast stock of Atlantic menhaden (Lisa Kline, Director of Research and Statistics, ASMFC, personal communication).

EPA agrees with the commenter that "Any stressor that affects the survival, growth, or reproduction of the members of a population reduces the capacity of that population to cope with normal environmental variability and new stresses." This is one of EPA's main concerns about the impingement and entrainment of large numbers of aquatic organisms. As to what the effects of I&E may be at the population-level, EPA agrees that it will depend on many factors, including any potential compensatory response, current population size, and the interacting effects of other stressors. Thus, a conditional mortality rate of 0.1 may be unimportant for one population or highly significant for another, depending on a host of factors. Therefore, generalizations about the importance of any given magnitude of effect are not possible, but will depend on the particular circumstances.

For EPA’s response to comments on societal judgment regarding acceptability of individual species mortality versus population effects, please see response to comment 316bEFR.306.302. See also the June 2, 2003 memorandum to L. Tudor “Description of Natural Resource Damage Assessment Studies that Present Willingness to Pay Estimates for Preventing Species Mortality” (DCN #6-2502).

Information on the methods EPA used to estimate commercial value, recreational, and ecological value of species affected by I&E is provided in the Regional Analysis Document prepared for the final Phase II rule (DCN #6-0003). See Chapter A10: Commercial Fishing Benefits; See Chapter A11: Estimating Benefits with a Random Utility Model (RUM); See Chapter A9: Economic Benefits Categories and Valuation Methods; Chapter A12: Non-use Meta-Analysis Methodology; See Chapter A 13: Threatened and Endangered Species Analysis Methods.

Cooling system costs (e.g., dry, wet, recirculating)

ENGINEERING COST ESTIMATE FOR RETROFITTING CLOSED-CYCLE COOLING SYSTEMS AT EXISTING FACILITIES

Shaw, Stone & Webster, Inc.

8/5/02

1 EXECUTIVE SUMMARY

This report presents a summary of project costs associated with retrofitting closed-cycle cooling towers to existing power generation facilities. This information is intended to assist UWAG/EPRI and utility companies assess the economic impact of retrofitting cooling towers to U.S. generating units with existing once-through cooling systems.

The cost estimates utilize a number of cooling tower retrofit case studies developed for existing generating units. The cost figures compiled in this report attempts to represent conservative costs for cooling retrofit projects, not bounding site-specific costs. In particular, the units addressed in the case studies have sufficient land available in close proximity to the condenser/circulating water system, no plume abatement is required, and the existing circulating piping can be used in the closed cycle system without reinforcement. Site-specific factors that can have a significant effect, such as local plume abatement requirements and physical cooling tower location constraints, are discussed in Section 3.

Over 1,000 plants were included in this study and the total cooling tower retrofit costs for this population is approximately $25 to $28 billion in 2002 dollars. Sections 3 and 8 identify a number of site-specific issues that can result in significantly increased implementation costs. Attachment 3 is a survey of utilities where potential site-specific issues have been identified, which further supports the treatment of the costs reported in this study (Attachment 2) as low-end estimates assuming minimum site-specific conditions that are known to escalate cost.

Table 8-1 provides at range of O&M costs (including energy penalty costs) in the range of $5 to $12 million 2002 dollars per year. These estimates are from utility experience at several nuclear plants, however, the actual costs for individual plants may vary based upon size, water source, electricity prices, and design.

2 INTRODUCTION

This report presents a summary of project costs associated with retrofitting closed-cycle cooling towers to existing power generation facilities. This information is intended to assist UWAG/EPRI and the utility owner/operators assess the economic impact of retrofitting cooling towers to U.S. generating units with existing once-through cooling systems. It should be noted that the EPA's Proposed Regulations to Establish Requirements for Cooling Water Intake Structures at Phase II

Existing Facilities, do not propose options that require retrofitting of cooling towers, but such alternative options are addressed in EPA's Phase II Economics and Benefits Analysis Document EPA-812-R-02-001.

The cost information summarized in this report and detailed in Attachment 2 will assist UWAG/EPRI and the utility owner/operators in developing a response to the proposed rule regarding the overall project cost associated with the retrofit of closed cycle cooling. The cost estimates utilize a number of cooling tower retrofit case studies developed for existing generating units. The cost figures compiled in this report represent conservative costs for cooling retrofit projects, not bounding site-specific costs. In particular, the units addressed in the case studies have sufficient land available in close proximity to the condenser/circulating water system, no plume abatement is required, and the existing circulating piping can be used in the closed cycle system without reinforcement. Site-specific factors that can have a significant effect, such as local plume abatement requirements and physical cooling tower location constraints, are discussed in Section 3. Based on one detailed site-specific cost study performed in the early 90's (and reconfirmed in the late 90's), site-specific factors, as discussed above, can easily result in site-specific costs double the baseline costs presented. Most site-specific conditions would tend to increase retrofit costs, over those developed in the case studies.

The UDI database was used to identify all existing U.S. generating units with once through cooling systems, which could potentially require a cooling tower retrofit. However, the information from the UDI database was updated based on current information on generating units. For example, some nuclear units included in the UDI database, have been decommissioned and are therefore excluded from Attachment 2. Six cooling tower retrofit case studies covering a range of unit sizes (detailed in Attachment 1), provide the cost basis for the Attachment 2 cooling tower retrofit cost estimates for potentially impacted US plants. Current capital costs developed in these studies are scaled based on condenser flowrate to estimate the retrofit cost for each once through unit in the database. The case study closest in condenser flowrate is selected for each database unit. An additional factor to adjust for regional labor rates is applied to the estimated labor costs. In one case, where a more detailed retrofit study was performed by Stone & Webster (Salem Units 1 & 2) it was demonstrated that these factors could more than double the cost estimate (See Attachment 2). Refer to Attachment I for additional information on costing methodology.

Section 7 includes representative schedules describing the major interfaces; engineering and construction activities, and plant outage requirements to implement a typical cooling tower retrofit projects.

3 SITE SPECIFIC ISSUES FOR RETROFITING CLOSED CYCLE COOLING

The retrofit installation of either natural or mechanical cooling towers entails an extraordinary engineering and construction effort requiring construction of new facilities and extensive demolition of existing Circulating Water (CW) System components and piping. A cooling tower retrofit will be costly and require a lengthy permitting, engineering, procurement and construction time period. Although in some cases Natural Draft Cooling Towers would be the design of choice, the cost of retrofitting Mechanical Draft Cooling Towers is used throughout this study. Although Natural Draft Cooling Towers would typically result in higher capital costs, longer construction periods, and more significant performance impacts than Mechanical Draft Cooling Towers; their reliability and long term maintenance and operation cost saving make them a more attractive choice for large "baseload" operated plants in northern locations. The following sections provide a brief summary of some of the major considerations and impacts associated with retrofitting closed cycle cooling at operating facilities.

Attachment 3 provides the results of a Utility Survey of the approach used in this report that identifies a number of potential site-specific issues that could result in higher costs than that presented in Attachment 2 due to one or more of the below implementation issues.

3.1 Cooling Tower Design

The difference between the temperature of the cooled water discharged from a cooling tower and the ambient air wet bulb temperature is called the cooling tower “approach” temperature. The approach temperature that is actually attainable at a particular installation depends on the type and size of the cooling tower, the quantity of water flow to be cooled and the change in water temperature to be achieved through cooling, and the local wet bulb temperature. The wet bulb temperature is the lowest temperature at which evaporation can occur for the specific conditions of the atmosphere. All of the approach factors, except those related to climate (i.e., local wet bulb temperature), are essentially fixed.

Since climatic factors are outside an operator’s control, an approach temperature can only be used by engineers as a design criterion, and cannot be applied as an operating requirement.

Natural draft towers induce an ambient air flow by virtue of a chimney effect i.e., the draft produced by the combined height of the shell and the difference in mixture density between the warm, wet exhaust from the tower’s fill section and the outside ambient air. Those effects are limited and, in turn, limit the air flow attainable by natural draft towers compared to mechanical draft towers. The current state of the art design for a natural draft tower is an approach temperature of 14°F.

Mechanical draft towers can attain a slightly lower approach temperature than a natural draft tower because of its greater ability to develop higher cooling air flows through use of huge mechanical fans. Even so, the actual attainable design approach temperature of a mechanical draft tower is limited to approximately 7°F. The approach temperature desired has a significant affect on cooling tower cost as indicated in the following figure. Figure 1 illustrates the theoretical impact of design approach on costs for both natural and mechanical draft towers. In this figure, the base (100%) cooling tower costs are based on a 7 F approach temperature for mechanical draft cooling towers and approximately 14 F approach temperature for the natural draft towers at design operating conditions.

FIGURE 1 APPROACH EFFECTS ON COOLING TOWER COSTS
[see hard copy for figure]

Whether natural or mechanical draft, the cooling effect of wet cooling towers is mainly due to evaporation, so the coolest temperature that the circulating water theoretically can reach is the wet bulb temperature. In real practice, however, the resulting cooled water temperature of a large tower can only “approach” the local wet bulb temperature (i.e. the wet bulb temperature can not be reached). The approach temperature that can be achieved is influenced by several major engineering and construction considerations including:

-quantity and quality of the water to be cooled,
-physical size of the structure,
-amount of fresh air that can be practically induced to flow through the tower,
-degree to which the water can be initially dispersed,
-degree and extent of the warm water’s contact with the cooling ai,r
-residence time of air/water contact,
-relative direction of the air and water, and
-amount of moisture the air can hold at 100% relative humidity.

3.2 System and Equipment Design

Retrofitting an existing facility for closed-cycle cooling does not simply mean the addition of cooling towers; rather, several other conditions must be considered. In contrast to a once-through (or open-cycle) cooling system design, the cooling tower designer usually reduces the circulated water quantity in order for the cooling towers to be efficient, economic, and cost-effective. Currently operating open cycle cooling units were designed for relatively high circulating water flow rates and low system pressures; the closed-cycle system, however, would be need to be designed for approximately two to four times higher pressure, regardless of whether the flow is reduced or not.

Additional site-specific factors are listed below to illustrate why retrofitting cooling towers to an existing facility is both technically difficult and costly.

-Condensers are comprised of thousands of small diameter tubes (equivalent to hundreds of miles per plant). A typical condenser shell for a large plant is approximately 20 ft high, 30 ft wide, and 65 ft long and there can be as many as 6 shells per unit. Each condenser shell can weigh as much as 160 tons and may require wholesale change-out with a new design to accommodate two-passes and a considerably higher tube side pressure. This may require extensive renovations even to gain access to the condenser shell, including temporary bracing and demolition of piping and components associated with the existing condensers.

-Existing circulating water systems are permanently installed without consideration for major piping design changes or replacement. Most of the piping and components are concrete and are supported on (if not embedded in) reinforced concrete foundations. Removal of existing plant equipment would likely be required to gain access for demolition of existing piping and major thrust blocks (concrete pipe supports), so as to facilitate installation of new circulating water system piping to/from the cooling towers. At one facility these thrust blocks are approximately 14 feet high, 10 feet wide, and 140 feet long. Preliminary engineering evaluations for two conventional natural draft towers at one facility suggest the retrofit would require excavating more than 250,000 cubic yards of soil and installing more than four miles of 7-foot diameter pipe as just one phase of a project of this magnitude.

-Cooling tower construction is regulated, monitored and controlled by many permitting agencies. Regulatory constraints (e.g., air quality permit approvals) could delay the start/completion of any project, even assuming that permits can be obtained, which is by no means certain. At nuclear power plants, the retrofit would also be monitored by the Nuclear Regulatory Commission. Documentation, review requirements and procedures are very extensive and stringent.

-Continuous chlorination of the circulating water would be required, most likely requiring a new chlorination system and a new dechlorination system on the tower blowdown.

-Another major consequence of the retrofit is that the circulating water could be at a significantly higher hydraulic pressure. The higher operating pressure is needed to overcome the friction loss of approximately 4,000-ft of additional piping (going back and forth to the cooling tower), and the static energy to overcome the height to the hot water distribution headers of the tower, and in some cases the added condenser tubing pressure loss where it is necessary to convert the condenser from a single pass to a two pass configuration to improve efficiency or because of plant configuration constraints.

3.3 Circulating Water System

In an electric generating station the main cooling water system is one of the first systems to be designed and installed. Careful consideration is given to the availability of a reliable source of cooling water to be used to condense the exhaust steam from the steam turbine(s) and remove heat from other equipment. The designs of many of the station's major capital cost components are inter-related to the cooling water supply system's capability. Therefore, any subsequent change to the cooling water system can have a significant impact on the plant's ability to perform at expected design conditions. Even minor changes to the cooling water supply (for example a temperature increase a few degrees above design or a reduction in flow) can result in a large decrease in the plant's ability to achieve its rated capacity. Because cooling water systems are one of the first systems to be installed during plant construction, many other plant systems, structures and components are built around and over the system making retrofitting to closed-cycle cooling complicated and expensive.

3.4 Condenser Modifications

A single pass condenser has cooling water entering one end of the condenser and passing through all tubes of the condenser in a single direction. The heated water exits at the opposite end of the condenser. A two pass condenser has cooling water entering the condenser and passing through one half of the condenser tubes in one direction and then reversing direction in the "reverse" water box and passing back through the other half of the condenser tubes in the opposite direction. The heated water exits the condenser through discharge nozzles located at the same end as the inlet nozzles.

Under certain retrofits scenarios it may be necessary to convert the existing single pass condenser to a two-pass configuration for efficiency reasons or condenser thermal design limitations. If conversion to two-pass configuration is necessary, extensive cooling water piping modifications may be required.

The two-pass arrangement would require CW system isolation valves to be moved to the inlet side of the water boxes to enable tube bundle isolation for periodic maintenance. Since the inlet and outlet nozzles are on the same end of the condenser, extensive circulating water pipe modifications within the turbine building would be required as part of the conversion.

3.5 Construction Issues

A closed-cycle cooling system retrofit could require extensive excavation and subsurface construction. Due to the depths of the subsurface construction activity (about 16 feet), groundwater would continuously infiltrate the excavations and groundwater would have to be continuously pumped out of the excavated areas during construction.

Site geological conditions have a major impact on construction costs. Rock excavation and the requirement for pile foundations are two examples.

Large amounts of excavation and construction will be required in a highly congested area with a need to assure safety if in the vicinity of high voltage transmission lines. Many underground facilities (piping, electrical ducts, etc.) may need to be avoided or rerouted. The majority of construction work is outdoors, and, therefore, the schedules and estimates are at risk for weather impacts that are difficult to accurately account for.

3.6 Additional Considerations

If mechanical draft towers were installed, a separate electrical/power system, powered from the existing switchyard, may be required because of the electrical power requirements and remote location of the pumps and fans relative to the existing distribution system.

The use of saltwater or brackish water in a cooling water system requires special corrosion-resistant materials. Continuous chemical treatment of the recirculating brackish cooling water would be required during Station operation to inhibit the corrosion that would otherwise occur. The allowable concentration factor in a salt water cooling tower is 1.5, as compared with 8 for a freshwater tower. Salt water towers, therefore, require significantly higher capacity makeup and blowdown systems.

4 UNCERTAINTIES AND RISKS

The scale of the required cooling system is a major factor in the projected difficulty. This scale is reflected in the quantity and size of piping, the depth and size (length and width) of the pipe trenches, number and length of supporting piles, the size and number of cooling towers, and the amount of reinforced concrete required. Another important factor that significantly exacerbates the complexity is the inherent permanence and site-specific design of the original cooling system.

Labor and equipment shortages pose a significant source of uncertainty. This source of uncertainty has not been included in the schedules. This may also impact the cost estimates, due to the necessity to pay premium rates for labor and equipment during delays not accounted for in the cost estimates.

Due to the large quantity of material and equipment needed to install cooling towers, there exists a source of uncertainty with respect to being able to obtain all materials and equipment in a timely manner in order to meet schedule requirements. Procurement problems may also cause impacts on the cost estimates due to the necessity to pay higher rates for expedited deliveries or make substitutions in favor of more expensive items to meet schedule requirements (taking into due consideration the goal to keep total project costs to a minimum).

5 LICENSING / PERMITTING

Major environmental factors that would influence the permitting cycle and approvals required to convert to closed-cycle cooling are:

-The height and visual obtrusion of the towers

-The impacts of the make-up and blowdown systems on marine biota and populations
-Tower plume effects due to size, frequency, or trajectory
-Salt drift from the towers on the nearby surroundings in case of salt or brackish water lowers.
-Noise impacts on neighbors
-Impact of particulate emissions on the air quality

Licensing the station with cooling towers requires a number of local, state and federal approvals. A period of two years or more could be required to obtain the necessary permits.

Licensing and permitting requirements pose a major source of uncertainty. It is assumed that the designs used as a basis for the cost estimates and schedules will be approved by the regulatory authorities. If not, there will be an unanticipated cost impact. In addition, depending upon the particular permit and schedule, there is the potential for very significant schedule impacts due to delays in obtaining permits.

6 STATION CAPACITY DERATING AND ENERGY LOSS

Retrofitting a closed-cycle cooling system will reduce energy output. This is the result of increased back pressure on the turbine exhaust due to the increasing of the cooling water temperature and increased electrical loads associated with the operation of the closed-cycle cooling system. This is the case because the low pressure turbine-blade path is not optimized for the exhaust conditions that will be associated with a cooling tower.

A site-specific case study shows that capacity penalties will fluctuate during the year between I and 3 %, for both natural and mechanical draft tower configurations, as indicated in Tables 1 and 2. The added (auxiliary) power required to operate the circulating water pumps and (in the case of installed mechanical draft towers) fans will also result in a decrease in plant generation output capability. Further details regarding capacity losses and auxiliary power penalties for the case study plant are provided in Table 3.

[see hard copy for tables 1-3]

7 PROJECT SCHEDULES

Based upon experience from a number of construction jobs, and with consideration of potential site-specific factors, the following discussion provides an overview of a representative project schedule and related logic for a cooling tower retrofit project at a large steam electric generating station.

REPRESENTATIVE COOLING TOWER RETROFIT PROJECT KEY SCHEDULE DATES
[see hard copy for table]

Schedule Considerations

The schedule duration for the on-line engineering, procurement, and construction activities, including new circulating water pipe installation from the cooling tower to the tie in location (with the existing pipe), and any pumphouse structural work were estimated based on a past plant-specific case study.

The cooling tower pumps have a long lead time (approximately one year) for vendor engineering and fabrication. The start of outage is driven by long duration construction and procurement activities.

The tie-in outage is scheduled sufficiently long after the final construction, environmental, and/or NRC permits have been obtained to complete all engineering and on-line construction activities including tower erection and major pipe runs. Tie-in outage activities may include: CW system tie-in, CWS pipe reinforcement, and condenser modifications. The tie-in outage duration is estimated to be approximately two to nine months, including one to two months for testing and start-up once the actual construction activities are completed.

To ensure that all of the necessary work needed to be completed during the CW system/condenser modification tie-in outage, it may be prudent to perform selected construction and modification activities during an earlier scheduled maintenance outage.

Schedule risk is high on such a project due to the magnitude and nature of the activities. Examples of uncertainty that could affect schedule include:

-Installation of up to 4 miles of new large diameter CWS piping
-Reinforcement and reconfiguration of CWS piping in the turbine building, if necessary.
-De-watering
-Weather delays
-The potential for other building and component interference's could cause construction delays and affect the overall schedule. Although site walkdowns and drawing reviews during the engineering phase might eliminate some of the potential problems, experience indicates that unforeseen interferences and below grade utilities that may need to be relocated are a very real threat to the schedule.

8 COST ISSUES

8.1 General

Attachment 2 provides a summary table of projected "baseline" costs for retrofitting closed cycle cooling towers to generating plants in the US. The approach used ensures that the labor, material, and equipment costs associated with a closed cycle retrofit are representative of that to be expected if such a retrofit were required. This section, in conjunction with Attachment 1, provides the basis for the cost estimates used in this study.

The retrofit of mechanical draft cooling towers to a generating unit with an existing once through cooling water system presents several major considerations; the following assumptions were used to develop the costs presented in Attachment 2:

-In so far as possible, the conceptual arrangements assumed as a basis for this study utilize existing piping and components under and within the confines of the turbine buildings.

-A gravity flow design from an elevated cooling tower basin, through the condenser to a new pump station located downstream of the condenser is assumed in order not to exceed the design pressure of condenser water boxes and existing circulating water conduits located under and within the turbine building.

-The CW system conceptual design uses a single set of pumps located in a new pump structure. The single set of pumps will deliver CW from the condenser discharge up to the tower fill distribution system.

-Cooling tower efficiency normally dictates higher condenser CW return temperatures than available from a single CW pass of the condenser (typical of open cycle cooling systems). Conversion of an existing single pass condenser to a two pass arrangement would be required in most cases to achieve this higher CW return temperature. Such a conversion would normally require extensive modifications if not replacement of the existing condenser. However for this study it has been assumed that the existing water piping systems including single pass condenser tube bundles will not be replaced.

-Existing circulating water piping not used in the closed loop system is assumed to be abandoned

-New circulating water piping is assumed to be fiberglass, buried in sheet pile trenches with concrete slabs for support and ballast.

-All major structures including the cooling tower basins are supported on pile foundations.

-Space for the cooling towers is available on station property within 2000 ft. of the station. Costs do not include purchase of land for the cooling towers and associated equipment.

-All costs are in 2002 dollars

8.2 Capital Costs

Although in some cases Natural Draft Cooling Towers would be the design of choice (because of reduced O&M costs) the cost of retrofitting Mechanical Draft Cooling Towers has been used throughout.

Estimated costs for cooling towers are based on vendor quotes for non-plume abated mechanical draft cooling towers constructed of fiberglass. Plume abatement technology could potentially double the cost of the cooling towers.

New circulating water piping will be required to/from the cooling tower pump house. Tower auxiliary systems, such as cooling tower blow-down and make-up and chemical treatment, were incorporated into the study.

8.3 Implementation Costs

Retrofitting a once-through cooling water system for closed-cycle cooling requires the construction of cooling towers, supporting systems and structures such as pump houses, and sufficient circulating water piping to form a closed loop system. Below is a list of implementation items that could affect the cost estimate.

The retrofit requires extensive excavation and subsurface construction. In low lying areas, groundwater intrusion would have to be pumped out.

Implementation is performed in two phases -- a new construction phase and a demolition and reconstruction phase.

The retrofit project requires the installation of thousands of feet of large diameter circulating water piping to connect the cooling towers to the existing cooling water system.

Electric substation, and substantial electrical cabling would also need to be installed to provide support for the closed-cycle cooling system operation. Portions of existing circulating water piping may need to be reinforced by welding corrosion-resistant steel plates inside the pipe.

Condenser modifications may be required.

Replacement power costs would also be incurred during the extended outage associated with demolition, reconstruction and tie-in.

Attachment 3 provides data from a recent Utility Survey performed as part of this study that identifies a number of potential site-specific issues that could result in higher costs due to one or more of the above implementation issues.

8.4 Operating and Maintenance

This section identifies and discusses the major categories of recurring annual operating and maintenance costs associated with both natural and mechanical draft tower designs. Estimates are based on input from several different operating plants. Table 8-1 summarizes typical cooling tower O&M costs.

Table 8-1. Cooling Tower Operating and Maintenance Costs
[see hard copy for table]

The operating costs estimated in Table 8-1 are associated with:

-Frequent detailed inspections of the internals, externals and air moving equipment (applicable to mechanical draft tower design only); and

-Continuous chemical treatment of recirculating brackish water

-The operation, sampling, testing and cost of chemicals that provide continuous chemical control of the water circulated through the station towers each day.

-Maintenance costs are appreciable because of the large quantity of materials and equipment associated with what would be an immense installation of cooling equipment. These costs are expended in upkeep, repairs and modifications to the structure, fill section, lighting, chemical control systems, hot water spray distribution system, fans, motors, switchgear, drift eliminators and basin. Make-up and blowdown system components which serve the tower complex also require periodic upkeep and repair.

9 CONCLUSION

Conservative capital costs to retrofit plant once-through cooling systems to closed cycle cooling tower is provided in Attachment 2. Over 1,000 plants were included in this study and the total cooling tower retrofit costs for this population is approximately $25 to $28 billion 2002 dollars. The 3 billion dollar range accounts for the fact that plants listed in the UDI database as having a “combined” or “mixed” type of cooling system may already have cooling tower technology that can either fully or partially accommodate closed cycle operation. As noted in Section 3 and 8 above, a number of site specific issues can result in significantly increased implementation costs, and therefore the costs estimated in Attachment 2 are considered conservative estimates. Attachment 3 is a survey of utilities where potential site-specific issues have been identified, which further supports the treatment of Attachment 2 costs as low-end estimates assuming minimum site-specific conditions that are known to escalate cost.

Table 8-1 provides at range of O&M costs (including energy penalty costs) in the range of $5 to $12 million 2002 dollars per year. These estimates are from utility experience at several nuclear plants, and the actual costs for individual plants may vary based upon size, water source, electricity prices, and design.

EPA Response

See response to comment 316b.EFR.208.002.

Attachment 1

Cooling Tower Retrofit Comparison Plant Cost Basis

Cost data from six comparison projects formed the empirical cost basis for the retrofit capital cost estimates provided in Attachment 2. The methodology for estimating capital costs and the cost breakdowns for each of the comparison plants are provided in this attachment. Comparison Plants Xl, X2 and X3 are different capacity fossil units located on estuaries. Comparison plants X4 and X5 are ocean site nuclear facilities, and finally X6 is a helper tower design proposed for a river site.

Methodology for Estimating Capital Costs

Estimated capital costs for retrofitting cooling towers for U.S. plants are provided in Attachment 2. Starting with the UDI database, in-scope plants for the purposes of this study were selected if they met the following criterion:

-Not already a closed cycle plant, and
-Capacity Factor >15%, and
-CW Intake Flowrate greater than 50 MGD.

Overall capital cost estimates for each in-scope plant was made by selecting the best comparison plant (case study plant with closest matching condenser flowrate) and adjusting the estimated retrofit for the comparison plant by applying a "cost scale factor" equal to the ratio of the condenser flowrates.

Labor cost adjustment factors for regions of the United States, based on RS Mean Labor Rates for the Construction Industry: 2001, are used to make regional adjustments to the estimated labor costs as follows:

Region	Labor Cost Adjustment Factor
Northeast (NE)	1.0
Southeast (SE)	0.6
North Central (NC)	0.9
South Central (SC)	0.65
Northwest (NW)	0.8
Southwest (SW)	0.9
California	1.1

Although in some cases, natural draft cooling towers would be the design of choice, the cost of retrofitting mechanical draft cooling towers has been used throughout. Stone & Webster has recently investigated the retrofitting of mechanical draft and natural draft cooling towers at several nuclear and fossil generating facilities located in the Northeast (NE) Region and South Central (SC) Region of the United States. Only the mechanical draft retrofit case studies have been used in this report. In each of these cases, preliminary designs were developed in sufficient detail to allow major equipment sizing and quantity estimates, which were used to develop order of magnitude cost estimates for retrofits. These costs have a 20% adder for contingency and indeterminates. For all case study facilities, the retrofit designs utilized all existing circulating water conduits in and under the turbine building and no major modifications to the condenser were included. This was achieved by elevating the cooling towers such that the systems utilized gravity flow from the cooling tower basin through the condenser. It was also assumed that no modifications of the turbine would be required. The following sections discuss the design features of the comparison plant retrofit designs utilized as a cost basis for this study.

Design Features for Cooling Tower Retrofit at Comparison Plants Xl. X2, and X3

These units are part of a large fossil generating facility located in the northeast region of the US. The existing units have once through circulating water systems with single pass condensers. Cooling water is salt water. The proposed cooling towers will be salt water towers. The existing circulating water conduits are reinforced concrete. A major design objective for the retrofit design was to utilize the existing single pass condenser and the portions of the existing circulating water conduits located under and within the confines of the turbine building. The low design pressures for the existing circulating water piping and condenser water boxes dictated that a gravity flow system from the cooling tower basins be used in order to not exceed the existing system design pressures. An existing elevated fill area is available on the site property approximately 1000 ft. from the station on which to locate the cooling towers.

New cooling tower pump stations utilizing dry pit pumps are constructed adjacent to the turbine buildings to pump the heated discharge from the condensers up to the cooling tower fill.

New circulating water piping is assumed to be fiberglass, buried in sheet pile trenches with concrete slabs for support and ballast.

All major structures including the cooling tower basins are supported on pile foundations.

The cooling towers are non-plume abated rectangular wet mechanical draft cooling towers arranged in two back-to-back rows in a common basin.

Specific unit parameters are as follows:

Station/Unit	Condenser Flow (cfs)	Distance to Cooling Tower
X1	390	1000ft
X2	624	1000 ft
X3	580	1000 ft

Design Features for Cooling Tower Retrofit at Comparison Plants X4 and X5

These units are nuclear generating units, which are part of a three unit nuclear generating facility located in the northeast region of the US. The existing units have once through circulating water systems with single pass condensers. Cooling water is salt water. The proposed retrofitted cooling towers would be salt water towers. A major design objective for the retrofit design was to utilize the existing single pass condensers and the portions of the existing circulating water conduits located under and within the confines of the turbine building. Differences in design pressures for existing circulating water conduit and condenser water boxes and other features required a significantly different design concept for the retrofitted cooling tower systems. The station site has an adequate area for the cooling towers about 2000 ft. from the station.

In plant X5 the condenser water passages and the existing circulating water conduits have sufficient design pressure margin to allow for the significantly higher pressures in the retrofit closed loop system. Existing valving and cross connects at the condenser allowed for conversion to two pass with no equipment changes. These features allow for a standard cooling tower loop with a single new pump station located at the cooling tower basin. The condenser would be converted to two pass operation in the retrofitted closed loop system.

In plant X4 the design pressures for the condenser water boxes and existing circulating water conduit are not adequate for the higher pressures for a standard closed loop arrangement. Plant X4 would require two new pump stations; one at the cooling tower and one at the discharge to pump heated water back to the cooling tower in push-pull arrangement. The condenser would continue to operate single pass in the retrofit cooling tower system.

The site is under laid with rock so extensive amounts of rock excavation are assumed.

The cooling towers are non-plume abated rectangular wet mechanical draft cooling towers arranged in two back-to-back rows in a common basin.

Specific unit parameters are as follows:

Station/Unit	Condenser Flow (cfs)	Distance to Cooling Tower
X4	1274	2000 ft.
X5	2000	2000 ft.

Design Features for Cooling Tower Retrofit at Comparison Plantss X6

Comparison Unit X6 is a three-cell helper tower system, which cools a portion of the heated discharge from the condenser and reintroduces the cooled water back into the discharge stream. The station is a nuclear generating facility located in the mid-western United States. The site has adequate area for the cooling tower adjacent to the station. All equipment and piping for the proposed retrofit, except for the connections in and out of the existing discharge tunnel are external to existing facilities.

The retrofit helper tower system consists of the three cell non-plume abated mechanical draft cooling tower, a new pumping facility, interconnecting piping and new electrical and control equipment for cooling tower fan and pump motors. The design system flow is 80 cfs and the cooling tower is located approximately 300 ft. from the station.

Review of EPA's Methods for Extrapolating Baseline Loss Estimates at Case Study Facilities to National Baseline Loss Estimates

Prepared for Utility Water Act Group

Prepared by D.G. Heimbuch, Ph.D., PBS&J, Beltsville, MD

5 August 2002

I. Introduction

This report presents a review of EPA's methodology for extrapolating estimates of baseline economic losses at case study facilities to estimates of national baseline economic losses due to impingement and entrainment ("I&E"). The objective of the review is to assess the validity of EPA's extrapolation methodology, and to determine the effect of any identified errors on EPA's estimates of national baseline economic losses.

The primary documents examined as part of the review were Chapter C3 (National Extrapolations of Baseline Economic Losses) and Chapter C2 (Summary of Case Study Results) of EPA's Economic and Benefits Analysis ("EBA") <FN 1>, and Chapters B3, C3 and D3 (Evaluation of I&E Data for the Delaware Estuary, Ohio River and Tampa Bay Case Study Facilities) of EPA's Case Study Analysis ("CSA") <FN 2>.

This review does not include 1) an assessment of the validity of the entrainment and impingement data EPA used, 2) an assessment of EPA's estimates of age-i equivalents, pounds lost to the fishery, and production foregone, or 3) an assessment of benefit transfer techniques applied by EPA. Assessments of the validity of EPA's assumptions regarding entrainment survival rate estimates, and the validity of EPA's random utility model estimates, habitat replacement cost estimates, and societal revealed preference estimates (which factor into EPA's national baseline estimates) are also beyond the scope of this review. Other reviewers of EPA's CSA and EBA reports are addressing the validity of these estimates, methods and assumptions.

The remainder of this report is organized into three main parts. Section II provides an overview of EPA's methodology for (1) extrapolating from baseline loss estimates for individual facilities and, in one case, from multiple facilities on a given waterbody, and (2) extrapolating from those to develop national baseline economic loss estimates. Section II also contains a discussion of terminology and definitions used in this report. Section III contains a discussion of EPA's method for computing national baseline estimates, a discussion of the validity of EPA's extrapolation methodology, and a list of concerns regarding EPA's methodology. The effects of identified concerns on EPA's national baseline loss estimates are presented in Section IV.

II. Review of EPA's Methodology for Estimating the Value of National Baseline Losses

A. Overview of EPA's Overall Methodology

EPA computed estimates of the dollar value of national baseline losses due to I&E through what appears to have been the use of a multi-step methodology. Following is a description of each step, as this reviewer understands it. <FN 3>

-Step 1: EPA compiled historical data on entrainment and impingement at 18 case study facilities (Table 1) that are presented as being representative of 539 facilities in five waterbody types (Estuary — Non Gulf, Estuary - Gulf Coast, Freshwater, Great Lakes, and Ocean). Although EPA provided a brief, general discussion of its rationale for selecting case study facilities (EBA Chapter C1), EPA did not explain in any detail how or why it chose those sites, nor does it explain why it compiled data from some facilities within a watershed and not for others for which data are available (e.g., see Conectiv, 2002).

-Step 2: EPA generated estimates of baseline annual biological losses due to entrainment and impingement for each case study facility.

-Step 3: EPA estimated a range for the economic value of the baseline biological losses at each facility through the use of benefit transfer techniques.

-Step 4: EPA adjusted its initial estimates of dollar value of biological losses through the use of alternative valuation techniques and assumptions.

-Step 5: For two waterbody types (Estuary — Gulf Coast and Freshwater), EPA estimated the baseline annual biological losses for all in-scope facilities within the case study waterbody, based on data from the case study facilities. EPA then estimated the dollar value of those biological losses.

-Step 6: EPA extrapolated from the estimates of dollar value of baseline biological losses at the case study facilities (or in the case of the Estuary — Gulf Coast and Freshwater waterbody types from the estimate of dollar value of baseline biological losses at all in-scope facilities within the case study waterbodies) to all in-scope facilities within each waterbody type.

-Step 7: For each waterbody type EPA selected specific values from within the range of estimated baseline economic losses (the selected values were referred to as "best" estimates). EPA then summed the waterbody type "best" estimates to produce its national baseline "best" estimate.

This report addresses the fifth step (excluding the assignment of dollar value to the extrapolated biological losses) and the sixth and seventh steps of EPA's methodology, i.e., EPA's extrapolation methods used to compute national "best" estimates of baseline economic losses based on estimates from the case study facilities. It should be noted that because this review focuses on EPA's extrapolation methods (and not on EPA's methods for estimating biological losses and economic losses), EPA's estimates of those losses are used in some analyses presented in this report. However, this use of EPA's estimates in this report is not an endorsement of those estimates.

As noted in reviews by Barnthouse (2002) and Heimbuch (2002), EPA's estimates of biological losses are seriously flawed and biased. EPA's estimates incorrectly ignore entrainment survival and density dependent compensation (Barnthouse, 2002), two omissions which cause its estimates to be biased high. Furthermore, EPA's estimates of harvest foregone, production foregone and equivalent age-l fish were computed using inappropriate equations and input values (Barnthouse, 2002, and Heimbuch, 2002).

EPA's methods for estimating the economic value of biological losses also are seriously flawed and biased. EPA's habitat replacement cost method, its method for estimating the economic value of commercial catch, and its method for determining non-use value are fatally flawed (Stavins, 2002; Desvousges, 2002; and Harrison et. al., 2002). EPA's methods for determining the economic value of forage fish and its basic benefits transfer methods have also been seriously criticized (Harrison et. al., 2002; Strand, 2002; Stavins, 2002; and Desvousges, 2002).

B. Terminology and Defintions

The term "losses" was used by EPA to refer to both biological losses (e.g., "Each case study section reports EPA's estimate of the number of age 1 equivalent fish that are lost to I&E at the case study facilities and the economic value of these losses." EBA page C2-l), and economic losses (e.g., "Best Estimate Baseline Losses (in thousands, $2001)" EBA, Table C3-6). To avoid confusion in this report, the term "losses" is always qualified as being either biological losses (i.e., referring to estimated numbers or pounds of fish) or economic losses (i.e., referring to the estimated dollar value of the fish).

This reviewer was unable to find a succinct definition of "baseline losses" in the chapters of the EPA reports he reviewed. However, EPA's description of its intended use of the national baseline loss estimates (EBA Chapter C4 page C4-1) provides an indication of what the "baseline losses" were meant to represent:

Using the national baseline loss estimates reported in Chapter C3: National Extrapolation of Baseline Losses, EPA estimated the potential national benefits of each regulatory option by applying a set of estimated percent reductions to baseline losses.

The percent reduction in baseline losses for each facility reflects EPA's assessment of (1) regulatory baseline conditions at the facility (i.e., current practices and technologies in place), and (2) the percent reduction in impingement and entrainment that EPA estimated would be achieved at each facility that the Agency believes would be adopted under each regulatory option.

Based on this narrative it appears that the term "baseline losses" was meant to refer to estimated economic losses due to I&E given current facility practices and technologies.

The term "in-scope facility" refers to the any of the "539 utility and non-utility steam electric power generating facilities identified in EPA's 2000 Section 316(b) Industry Survey as being potentially covered by this proposed rule." (EBA Chapter A1, page A1-1). All other CWIS facilities (e.g., manufacturing facilities and electric generating facilities with design intake flows less than 50 MGD) are referred to as "out of scope facilities".

EPA used the term "case study facility" to refer to all CWIS facilities within a case study waterbody (e.g., CSA Chapter B1, Figure B1-2) and also to refer to only those facilities with I&E data that EPA used in its analyses (e.g., CSA Chapter C1). To avoid confusion in this report, the term “case study facility” is used only to refer to in-scope facilities with I&E data that EPA used in its analyses.

The term “reference facility” is used in this report to refer to a facility with I&E data upon which EPA based its extrapolation of economic losses to other in-scope facilities (that were not case study facilities). Only a subset of case study facilities are reference facilities. The I&E data from some case study facilities (i.e., Seabrook, Brayton Point, Contra Costa and Pittsburg) were used to produce baseline economic loss estimates for those facilities only, and were not used to extrapolate economic losses to other in-scope facilities.

C. EPA’s Methods of Extrapolation from Case Study Facilities

For each of the five waterbody types, EPA computed a separate estimate of baseline economic losses by summing estimates for individual facilities and groups of facilities within the waterbody type. EPA used three somewhat different methods for computing the waterbody-specific estimates (see Table 2). All three methods involved extrapolating the economic loss estimates from one or more reference facilities (selected from the case study facilities) to the economic losses at other in-scope facilities within the waterbody type (it is not clear from EPA’s Case Study Analysis and Economic Benefits Analysis reports why EPA used different approaches for different waterbody types).

The method of estimation for the Estuary — Non Gulf, Great Lakes and Ocean waterbody types was to base the extrapolation on the estimated economic losses at a single reference facility. For the Estuary — Non Gulf waterbody type, the extrapolation was based on estimated economic losses at the Salem facility. For the Great Lakes waterbody type the extrapolation was based on estimates of economic losses at the Whiting facility. For the Ocean waterbody type the extrapolation was based on estimates of economic losses at the Pilgrim facility.

The method of estimation for the Estuary — Gulf Coast waterbody type was to base the extrapolation on the combined estimated economic losses for all in-scope facilities within the case study waterbody (i.e., Tampa Bay). EPA’s combined estimate of the baseline economic losses for the in-scope Tampa Bay facilities was computed by extrapolating the biological loss estimates from only one case study facility (Big Bend) to all four in-scope Tampa Bay facilities, i.e., Big Bend, Bartow, Gannon and Hooker’s Point (see Table 3). The extrapolated biological losses for the four in-scope facilities then were translated into estimated economic losses for the four in-scope facilities.

The method of estimation for the Freshwater waterbody type was to base the extrapolation on the combined estimated economic losses for all in-scope facilities within the case study waterbody (i.e., Ohio River). In contrast to EPA’s method for extrapolating economic losses in Tampa Bay, EPA’s combined estimate of the baseline economic losses for the in-scope Ohio River facilities was computed by extrapolating the biological loss estimates from all nine case study facilities (i.e., Cardinal, Clifty Creek, Kammer, Kyger, Miami Fort, Philip Spom, Tanners Creek, W.C. Beckjord and Sammis) to the 29 in-scope facilities (see Table 4). The extrapolated biological losses for the 29 in-scope facilities then were translated into estimated economic losses for the 29 in-scope facilities.

III. Review of EPA’s Extrapolation Methods and Choice of “Best” National Estimates

This section contains a more in-depth review of EPA’s extrapolation methods. Section III begins with a review of EPA's methods for extrapolating from biological losses at the individual case study facilities to combined biological losses (on which the national extrapolations were based) for Tampa Bay and for the Ohio River. Section III.B contains a discussion of EPA's method for extrapolating from the estimated economic losses at the reference facility (or group of facilities, as was the case for the Estuary —Gulf and Freshwater waterbody types) to the national baseline economic loss estimates. Section III.C contains a discussion of EPA's methods for choosing "best" estimates, and Section III.D is a summary of identified concerns.

A. Extrapolations of Biological Losses from Single Case Study Facilities to Grouped Reference Facilities (On Which Extrapolations to Waterbody Types Were Based)

1. Tampa Bay

This section contains a summary of concerns regarding EPA's extrapolation method for Tampa Bay facilities (Section III.A.1.a). Because the documentation of EPA's extrapolation method (CSA, Chapter D3) is incomplete (e.g., no equations were provided and intake flow values were omitted due to EPA's stated concerns about confidential business information ("CBI")), details of EPA's method had to be inferred from EPA's cursory narrative descriptions. Section III.A.1.b (below) contains an algebraic interpretation of EPA's method that was inferred from EPA's narrative descriptions. The identified concerns are based on this interpretation of EPA's method.

a. Concerns Regarding EPA's Method of Extrapolating Biological Losses for Tampa Bay Facilities

EPA's extrapolation method for Tampa Bay is based on the assumption that the loss (expressed as pounds lost to the fishery, production foregone or age-1 equivalents) per MGD of intake flow is the same at all four of the Tampa Bay case study facilities (i.e., Bartow, Hooker's Point, Big Bend and Gannon).

Hartman (2002) challenged the validity of this assumption given the locations of the four facilities within the Tampa Bay estuary (i.e., the Hooker's Point and Gannon facilities are in upper Hillsborough Bay near the city of Tampa, the Bartow facility is on the western shore between Old Tampa Bay and Middle Tampa Bay, and the Big Bend facility is on the eastern shore between Hillsborough Bay and Middle Tampa Bay) and the range of environmental conditions (e.g. salinity, water clarity, dissolved oxygen, and water depth) at those locations.

b. Interpretation and Critique of EPA's Method of Extrapolating Biological Losses for Tampa Bay Facilities

EPA estimated baseline biological losses for the Gannon, Bartow and Hooker's Point facilities based on baseline biological losses at the Big Bend facility and on intake flow rates (MGD) at the four facilities. Given EPA's description of its extrapolation method (CSA page D3-15), it appears that EPA estimated the total baseline biological losses for the four reference facilities as the product of the baseline biological losses at the Big Bend facility and the ratio of 1) the sum of the intake flow rates for the four facilities to 2) the intake flow rate for the Big Bend facility:

[see hard copy for equation 1]

EPA justified its method of extrapolation for Tampa Bay facilities with the following assumption (CSA page D3-15):

"Because intake characteristics, the fish community, and hydrodynamic conditions associated with the CWIS of Tampa Bay are similar, EPA assumed that I&E at Big Bend is representative of I&E at other Tampa Bay CWIS and that I&E is strictly proportional to intake flow."

However, EPA provided no data to validate its claim of similarity in intake characteristics, fish community and hydrodynamic conditions.

Stated another way, EPA's assumption was that the loss rate (i.e., loss per unit of intake flow) was the same at each of the four facilities:

[see hard copy for equation]

If this assumption were satisfied, equation (1) would produce unbiased estimates of the total biological losses for the four Tampa Bay case study facilities. But EPA provides no data supporting its assumptions, and available data suggest that the assumptions are not well-founded (e.g. see Hartman, 2002).

Because EPA's documentation (CSA, Chapter D3) of its method is incomplete (i.e., its narrative description is ambiguous and no equations were provided) and EPA did not list the facility-specific intake flow rates it used in its calculations, this reviewer could not verify using the data presented in CSA, Chapter D3 that equation (1) accurately represents the methodology EPA applied.

2. Ohio River

This section contains a summary of concerns regarding EPA's extrapolation method for Ohio River facilities (Section III.A.2.a). Because the documentation of EPA's extrapolation method (CSA, Chapter C3) is incomplete (e.g., no equations were provided and intake flow values for many facilities were omitted due to stated CBI concerns), details of EPA's method had to be inferred from EPA's cursory narrative descriptions. Section III.A.2.b (below) contains an algebraic interpretation of EPA's method that was inferred from EPA's narrative descriptions. The identified concerns are based on this interpretation of EPA's method.

EPA's Ohio River case study identified nine case study facilities and 29 in-scope facilities located on 14 navigational pools (defined by locks and dams). As part of its extrapolation method, EPA defined 6 pool groups that collectively contained all 29 in-scope facilities, and that had at least one case study facility per pool group (see Table 5).

a. Concerns Regarding EPA's Method of Extrapolating Biological Losses for Ohio River Facilities

EPA's extrapolation method for Ohio River facilities was based on the following assumptions (CSA page C3-22):

".. .I&E is strictly proportional to intake flow and that I&E at the 9 Ohio River case study facilities are representative of I&E at other CWIS in the same or nearby pools."

EPA did not provide data to support its assumption that I&E biological losses at the case study facilities were representative of I&E biological losses throughout a pool group. Hartman (2002) challenged this assumption based on ecological conditions in the pools and the substantial distance between some case study facilities and in-scope facilities (e.g., as indicated in Table 5, the Shawnee facility is over 500 miles downriver of the Clifty Creek facility — the case study facility on which EPA based its estimates of I&E biological losses at the Shawnee facility).

If EPA's assumptions were satisfied, the relationship between I&E biological losses and intake flows for facilities within the same pool would be linear with a positive slope and an intercept equal to zero. Therefore, the validity of the assumptions can be addressed by examining data from pools that contained at least three case study facilities (the minimum number needed to identify a linear relationship). EPA identified six navigational pools that contained at least one case study facility. Of those six pools, four contained one case study facility, one contained two case study facilities, and only one (Markland pool) contained three case study facilities.

A plot of the I&E biological losses (expressed in terms of production foregone, which was the component that made the largest contribution to the value of I&E biological losses for the Ohio River facilities) versus the operational intake flows for case study facilities within the Markland pool is depicted in Figure 1. The plot clearly shows that EPA's assumptions were not satisfied.

b. Interpretation and Critique of EPA 's Method of Extrapolating Biological Losses for Ohio River Facilities

EPA estimated the baseline biological losses for 29 in-scope facilities on the Ohio River based on estimated biological losses at the nine case study facilities on the Ohio River. The nine case study facilities are located within six pool groups (defined by EPA), and EPA conducted a separate extrapolation from the case study facilities to the in-scope facilities for each of the six pool groups (see Table 5). EPA apparently used this approach to account for possible differences in the fish communities that inhabited each of the pool groups.

Given EPA's description of its extrapolation method, it appears that EPA estimated the total baseline biological losses for the 29 reference facilities as the sum of the pool group-specific extrapolations:

[see hard copy for equations 2 and 3]

As noted above, EPA justified its method of extrapolation for Ohio River facilities with the following assumption (CSA page C3-22):

" … I&E is strictly proportional to intake flow and that I&E at the 9 Ohio River case study facilities are representative of I&E at other CWIS in the same or nearby pools."

Stated another way, EPA's assumption was that the biological loss at each facility within a pool group was equal to the intake flow rate for the facility times a constant loss rate, CLRp (numbers of fish per unit volume of intake flow) for the pool group:

[see hard copy for equation]

If this assumption were satisfied, equation (3) would be a reasonable estimator for the total biological losses within a pool group. However, as discussed above, the available data on I&E biological losses within the Markland pool indicate that this assumption was not met. Furthermore, the range of ecological conditions present within the pool groups (Hartman, 2002) suggest this assumption would not be satisfied.

Because EPA's documentation (CSA, Chapter C3) of its method is incomplete (i.e., EPA did not provide detailed equations), and EPA did not list all facility-specific intake flow rates it used in its calculations, a comprehensive verification of equations (2) and (3) was not possible. However, in response to questions this reviewer posed to EPA regarding apparent inconsistencies in its tabulated results in Chapter C3 of the CSA (document entitled "RESPONSE TO UWAG QUESTIONS RE: PHASE II PROPOSAL RECORD -- Revised July 3, 2002"), EPA conceded that it had made errors in its calculations for the Robert C. Byrd pool group and the Markland pool group.

B. Extrapolations of Economic Losses from Case Study Facilities to All In-scope Facilities within a Given Waterbody Type

This section reviews EPA's methods for extrapolating from estimated economic losses at selected case study facilities (i.e., reference facilities) to the economic losses at other in-scope facilities within a waterbody type. As indicated in Table 2, EPA used a combination of facility-specific estimates of economic losses and extrapolated values for its estimate of overall economic losses within each waterbody type. For each waterbody type, EPA identified a reference facility or group of reference facilities on which to base its extrapolation to in-scope facilities for which it did not have facility-specific estimates of economic losses. For example, for the Estuary — Non Gulf waterbody type (which includes 78 in-scope facilities), EPA had facility-specific economic loss estimates for the Salem, Brayton Point, Contra Costa and Pilgrim facilities and chose Salem as the reference facility on which to base its extrapolations to the remaining 74 in-scope facilities.

For the Estuary — Non Gulf, Great Lake and Ocean waterbody types, EPA assigned dollar values <FN 4> to its estimates of biological losses at the Salem, Whiting and Pilgrim facilities, respectively, and based its extrapolations on those estimates of economic losses. For the Freshwater waterbody type, EPA assigned dollar values to its estimate of biological losses at the 29 in-scope facilities on the Ohio River (discussed above), and based its extrapolation on that estimate of economic losses. For the Estuary -- Gulf Coast waterbody type, EPA assigned dollar values to its estimate of biological losses at the four in-scope facilities in Tampa Bay (discussed above), and based its extrapolation on that estimate of economic losses.

EPA used two methods for its extrapolations from reference facilities to other in-scope facilities. Depending on the waterbody type, EPA either used the average of the national estimates from the two extrapolation methods, or chose one method to use as its "best" estimate.

EPA's first extrapolation method (Flow Index extrapolation) was to estimate the national baseline economic losses based on the baseline economic losses at the reference facilities and on the operational intake flows at the reference facilities and at all other in-scope facilities. For this extrapolation method, EPA divided its estimate of economic loss at the reference facility (or group of facilities) by its Flow Index for the reference facility (or group of facilities). This method is equivalent to computing the economic losses per unit volume of intake flow ($/operational MGD) at the reference facilities and then multiplying that amount times the total of operational intake flows for all in-scope facilities.

EPA's second method (Angling Index extrapolation) was to estimate the national baseline economic losses based on the baseline economic losses at the reference facilities and on the number of angler days of recreational angling that occurred within 120 miles of the reference facilities in comparison to the sum of the number of angler days that occurred within 120 miles of each of the other in-scope facilities. For this extrapolation method, EPA divided its estimate of economic loss at the reference facility (or group of facilities) by its Angling Index for the reference facility (or group of facilities). This method is equivalent to computing the economic losses per angler day (in the vicinity of the facility) at the reference facility and then multiplying that amount times the sum of the number of angler days in the vicinity of each in-scope facility.

EPA's documentation of the Flow Index extrapolation method and of the Angling Index extrapolation method was not sufficiently complete or detailed (e.g. no equations were provided, key underlying assumptions were not listed, and key input parameter values were not reported) to support a thorough review of EPA's assumptions and estimates of national baseline economic losses. Therefore, this reviewer inferred the details of EPA's method from EPA's narrative descriptions. Key underlying assumptions of EPA's methods then were derived from the inferred details of EPA's methods.

In the following two sections (III.B.1 Flow Index Extrapolation and III.B.2 Angling Index Extrapolation), concerns regarding the validity of EPA's extrapolation methods are identified based on the key underlying assumptions of the methods. Following the discussion of the concerns regarding each method is a discussion of details and assumptions of EPA's method that were inferred from EPA's narrative descriptions.

1. Flow Index Extrapolation

This section contains a summary of major concerns regarding EPA's Flow Index method (Section III.B.1.a). Because the documentation of EPA's Flow Index method of extrapolation (EBA, Chapter C3) is incomplete, and was not presented in mathematical form, details of EPA's method had to be inferred from EPA's cursory narrative descriptions, and from tabulated values presented in EPA's reports. Section III.B.1.b (below) contains an algebraic interpretation of EPA's method that was inferred from EPA's narrative descriptions. The identified concerns listed below are based on this interpretation of EPA's method.

a. Concerns Regarding EPA‘s Flow Index Method of Extrapolation

EPA's Flow Index method could be a valid method for estimating total baseline economic losses for a waterbody type if(l) the estimated economic loss per MGD at the reference facility (or group of reference facilities), on which the extrapolation is based, were an unbiased estimate of the average economic loss per MGD over the other in-scope facilities within the waterbody type, and (2) economic losses were directly proportional to intake flow. This reviewer found no indication that EPA tested either of these assumptions. Furthermore, EPA did not use the generally accepted practice of randomly sampling (to select its reference facilities), which would have helped to address the first assumption. And, with the exception of the Freshwater waterbody type, EPA based its extrapolations on data from a single reference facility, i.e., it had a sample size of one. The lack of randomization and the extremely small sample size almost guarantees that EPA’s assumption was not satisfied <FN 5>.

B. Interpretation and Critique of EPA's Flow Index Method of Extrapolation

According to EPA's description of its Flow Index (EBA page C3-2), the Flow Index was computed separately for all in-scope facilities within each waterbody type as:

[see hard copy for equation]

EPA claimed that "dividing by the baseline [economic] loss at a case study site by the flow index yields an estimate of the total baseline [economic] loss at all facilities drawing cooling water from the same type of waterbody." (EBA page C3-2). Accordingly, EPA's estimate (based on its Flow Index) of the vlaue of the toal baseline economic losses at facilities within a waterbody type was computed as:

[see hard copy for equation]

Although not stated in its description of its national extrapolations (EBA Chapter C3), it appears that EPA's justification for this method of extrapolation is based on the assumption it relied on in its Case Studies for Delaware Estuary, the Ohio River, and Tampa Bay: "EPA assumed that … I&E is strictly proportional to intake flow" (CSA pages B3-10, C3-22, and D3-15), i.e.,

[see hard copy for equations]

Equations 6 and 7 show that if:

-The average economic losses per MGD ($ per MGD) at facility I is equal to the average economic loss per MGD over all in-scope facilities,
-Economic losses are strictly proportional to flow,
-Baseline economic losses (in dollars) at a facility are proportional to the biological losses), and
-All input parameter estimates are accurate and precise,

then EPA’s estimator would be a valid method for estimating national baseline economic losses. EPA provided no indication that it tested any of these assumptions.

2. Angling Index Extrapolation

This section contains a summary of major concerns regarding EPA’s Angling Index method <FN 6> (Section III.B.2.a). As was the case for EPA’s Flow Index method, the documentation of EPA’s Flow Index method of extrapolation (EBA, Chapter C3) is incomplete and details of EPA’s method had to be inferred from EPA’s cursory narrative descriptions, and from tabulated values presented in EPA’s reports. Section III.B.2.b (below) contains an algebraic interpretation of EPA’s method that was inferred from EPA’s narrative descriptions. The identified concerns listed below are based on this interpretation of EPA’s method.

a. Concerns Regarding EPA's Angling Index Method of Extrapolation

1) Multiple-Counting of Angler Days

Although EPA's description of its Angling Index is not very thorough, the description given indicates that the denominator of the Index is the sum of angler days over all in-scope facilities within a waterbody type: "the angling index is a measure of the facility's percentage share of the total angling days estimated at all in-scope facilities located on a similar waterbody" (EBA page C3-3). And as noted above, the number of angler days for each facility is the sum of angler days within a 120 mile radius of the facility: "EPA then defined the area for each facility to include the county the facility is located in and any other county with at least 50 percent of its population residing within 120 miles of the facility" (EBA page C3-2), and "EPA then summed angling days across all counties in a facility's area to yield estimated angling days" (EBA page C3-2).

Since many facilities are within 120 miles of each other (e.g., see CSA Figure Gl2 which depicts several facilities within 50 miles of each other), EPA's method for computing the Angling Index would multiple-count angler days. The extent of this problem appears to be very widespread as indicated by analyses conducted by Edison Electric Institute (see Attachment).

Multiple-counting angler days would have the effect of artificially reducing the magnitude of the Angling Index for any specific station (because the denominator would always include multiple-counted angler days). An Angling Index value that is biased low would cause EPA's extrapolation to be biased high because EPA divided the economic losses at the reference facility (or group of facilities) by the Angling Index for the reference facility (or group of facilities).

Consider the following hypothetical example, which illustrates the bias in this method. Suppose three facilities (#1, #2, and #3) are included in a waterbody type. Counties A, B and C are within 120 miles of the reference facility (facility #1), counties D, E, and F are within 120 miles of facility #2, and counties E, F and G are within 120 miles of facility #3. Further suppose that there are 100, 50, 50, 100,200,200, and 100 angler days in counties A, B, C, D, E, F and G, respectively. A total of 800 angler days are spent by residents of the counties within 120 miles of the three facilities, 200 angler days are spent by residents within 120 miles of the reference facility, 500 angler days are spent by residents within 120 miles of facility #2, and 500 angler days are spent by residents within 120 mile of facility #3. The Angling Index for the reference facility should be 0.25 (i.e. 200/800), and the extrapolated economic losses should be 4 times (i.e., 1/0.25) the economic losses at the reference facility. However, if the Angling Index is computed as described by EPA, the angler days in counties E and F would be counted twice (because they are within 120 miles of facility #2 and facility #3). Therefore, EPA would compute the Angling Index for the reference facility to be 0.167 (i.e. 200/[200+500+500]), and the extrapolated economic losses would be 6 times (i.e. 1/0.167) the economic losses at the reference facility.

EPA noted the problem of multiple-counting angler days in reference to the Freshwater case study facilities (CSA page C3-3):

Because of the large number of facilities in the Ohio study and their proximity to each other, EPA used a slightly different method to estimate angling activity at these facilities. Rather than calculating the angling days within the 120-mile radius of each individual facility, EPA instead summed the angling days in all counties within 120 miles of any of the 29 Ohio facilities and divided this by the number of angling near any freshwater facility nationwide. Essentially, this method treats the 29 Ohio facilities as one large facility for the purposed of calculating an angling index. This eliminates the problem of multiple-counting of angling days in counties that occurs because the Ohio facilities are so close to each other.

However, although aware of this problem, EPA apparently did not address it for any other waterbody type. Furthermore, EPA's method for addressing the problem for Ohio River facilities does not fully address the problem, since the denominator of its Angling Index would still include multiple-counting of non-Ohio River facilities.

The bias that can be introduced by this type of multiple-counting can be very large. For example, the Hope Creek facility (one of the in-scope facilities within the Estuary — Non Gulf waterbody type) is located directly adjacent to the Salem facility within the Delaware estuary. Due to the very close proximity of the two facilities, the angler days assigned by EPA to the Hope Creek facility would be the same angler days EPA assigned to the Salem facility. Accordingly, the number of angler days within 120 miles of the Hope Creek facility would be the same as the number of angler days within 120 miles of the Salem facility. Therefore, EPA's Angling Index method would predict that the economic losses at the Hope Creek facility would be the same as the economic losses at the Salem facility. This result is preposterous because the Hope Creek facility uses a cooling tower, whereas Salem uses once-through cooling. Not only does EPA's method double-count the angler days, it completely ignores the fundamental difference in the cooling systems of the two facilities.

2) Representativeness of Reference Facilities

As was the case with EPA's Flow Index method, a necessary assumption of its Angling Index method is that EPA's reference facilities are representative of all in-scope facilities. This reviewer found no indication that EPA tested this assumption. Since (with the exception of the Freshwater waterbody type) EPA based its extrapolations on data from a single reference facility (i.e., it had a sample size of one), and did not randomly select its reference facilities, it is very likely that EPA's assumption was not satisfied.

A comparison of the reference facilities to all case study facilities provides a limited basis for assessing the representativeness of the selected reference facilities. The comparison should be in terms of the product of the reduction in recreational catch and the proportionality constant which relates the dollar value per fish and the number of angler days (see section III.B.2.b, below). However, because the biological losses may be independent of the proportionality constant, an initial assessment of the representativeness of the reference facilities can be based on estimates of reductions in recreational catch alone.

An examination of EPA's recreational loss estimates for the case study facilities indicates that the reference facilities EPA selected were not representative (Figure 2). For each of the waterbody types the reference facility EPA selected had the highest biological losses of all Case Study facilities in the waterbody type. If the selected reference facilities had higher biological losses than the average for all facilities within a waterbody type (as suggested by this very limited comparison based on case study facilities), then the use these reference facilities would produce estimates that would be biased high.

3) Recreational Value as a Proportion of Total Value

As indicated below, EPA's Angling Index method does not produce meaningful extrapolations because it was applied to estimates of economic losses that included commercial, nonuse and production foregone, as well as recreational components. However, if the non-recreational components contributed little to the estimates of baseline economic losses, then as a practical matter, EPA's Angling Index method might still be a reasonable approach. To assess this possibility, the percentage of the value of baseline biological losses (from benefits transfer estimates) attributable to the loss of recreational catch was examined. As indicated in Figure 3, the value of lost recreational catch generally was much less than half of the total value of baseline biological losses. Therefore, EPA's Angling Index is not a valid method for extrapolation in this case.

4) Assumptions Underlying Angling Index Values

According to EPA's description of its Angling Index, the following assumptions were made:

-The number of days per year spent fishing by residents of Rural counties is the same for residents of all counties within a state, regardless of the county's proximity to water.
-All residents of a county are either Rural or Urban.
-The proportion of anglers that are from Rural counties is the same in all states of the nation.
-Each facility impacts a fishery that is utilized by all anglers who live within 120 miles of the facility.

In its description of its Angling Index, EPA did not justify any of these assumptions and did not address the sensitivity of its estimates to these assumptions.

b. Interpretation and Critique of EPA's Angling Index Method of Extrapolation

According to EPA's description of its Angling Index (EBA pages C3-2 and C3-3), the Angling Index (computed separately for each waterbody type) was defined as:

[see hard copy for equation]

EPA claimed that "dividing the baseline [economic] loss at a case study site by the angling index yields a second estimate of the total baseline [economic] loss at all facilities drawing cooling from the same type of waterbody." (EBA page C3-3). Accordingly, EPA's estimate (based on its Angling Index) of the total baseline economic loss at all facilities within a waterbody type was computed as:

[see hard copy for equation]

EPA did not justify the use of its estimator, nor did it discuss the properties of its estimator. In general, equation (14) would not produce valid estimates of total baseline economic losses. Some relationship between angler days and the baseline economic losses at each facility would need to exist in order for equation (14) to be a valid estimator of national baseline economic losses.

EPA's heuristic arguments for its method of estimation (e.g., "the number of angler days in the area ... reflects the degree to which there is a demand (value) by local residents to use the fishery that is impacted," EBA page C3-2), suggest that EPA justified its method with the assumption that the average value per fish caught by recreational anglers is correlated with the "demand by local residents to use the fishery" (EBA page C3-2). Given this assumption, the average value per fish caught could be expressed as a function of the number of angler days. The following function (i.e., the average value per fish caught being proportional to the number of angler days) is a simple representation of that type of relationship:

[see hard copy for equations]

Equations (19) and (22) show that if the biological losses (expressed in terms of reduction in recreational catch) times the proportionality constant at facility i are equal to the average (over all in-scope facilities) of the product of biological losses times the proportionality constant then EPA's estimator could be an acceptable means for estimating total baseline economic losses. This would be the case if the following assumptions were met: 1) the value per fish caught is proportional to the number of angler days, 2) the economic loss at a facility is equal to the product of the average recreational value per fish caught and the reduction in recreational catch due to entrainment and impingement, and 3) all input parameter estimates were accurate and precise. EPA provided no indication that it attempted to test any of these assumptions.

Furthermore, EPA's estimates of baseline economic losses for each facility are not based exclusively on reductions in recreational catch. EPA defined the baseline economic losses to include components for reductions in commercial harvest, non-use value and forage, in addition to the reduction in recreational catch:

[see hard copy for equation]

Nevertheless, EPA applied its Angling Index to the total baseline economic losses at the reference facilities:

[see hard copy for equations]

In contrast to the arguable existence of a correlation between the value per fish of recreational catch and the number of angler days, there is no basis to assume a direct relationship exists between the number of angler days and the value per pound of commercial harvest or forage. Therefore, although the first term in equation (25) could (under the special conditions describe above) be an acceptable estimator of the value of the recreational baseline losses for the waterbody type, the second term in equation (25) does not reduce to any meaningful quantity. Therefore, EPA's Angling Index should not have been applied to the portions of the baseline economic losses attributable to reductions in commercial harvest and forage, since doing so produces a meaningless quantity.

C. EPA's Choice of "Best" Estimates from Range of Values

In the final step of its methodology, EPA selected "best" estimates of the value of national baseline economic losses from the range of values it had compiled. For the Estuary — Non Gulf, Estuary — Gulf Coast, and Freshwater waterbody types, EPA used the mid-point of its low and high values for its "best" estimate. However, for the Great Lakes and Ocean waterbody types, EPA chose its high estimates of value (which were based on HRC estimates) to be the "best" estimates. EPA stated that the HRC estimates were preferred over the benefits transfer estimates because: "The HRC estimates cover losses for a much larger percentage of fish lost due to I&E, whereas the benefits transfer approach addressed losses only for a small share of the impacted fish." (EBA page C3-10). This rationale appears to directly contradict EPA's rationale for using the benefits transfer approach for its initial estimates of economic losses. EPA repeatedly claimed (CSA pages B4-1, C4-1, D4-1, F4-1, G4-1, H4-1, I4-1) that by considering recreational catch, commercial landings and production foregone in its baseline economic losses (using benefits transfer techniques) EPA captured "the total economic impact of I&E". Furthermore, EPA's choice of high values only (i.e., HRC estimates) for Great Lakes and Ocean waterbody types is inconsistent with its use of the midpoint of high and low values for Estuary — Non Gulf waterbody types, which includes the Brayton Point facility (for which EPA computed HRC estimates). Finally, reviewers of EPA's HRC method (Stavins, 2002; Desvousges, 2002; and Strand, 2002) have concluded that the method is fatally flawed and should not be used as a benefit assessment method.

D. Summary of Concerns with EPA's Extrapolation Methods

This review has identified four major concerns regarding EPA's extrapolation method. First, the assumptions upon which EPA's extrapolations for the Tampa Bay and Ohio River waterbodies were based are not likely to be valid. The fish community in the vicinity of the Big Bend facility is likely not representative of the fish community within Old Tampa Bay and Hillsborough Bay (an assumption required by EPA's method). The data that EPA presented for case study facilities within the Markland pool (the only pool containing at least three case study facilities) of the Ohio River indicate that I&E biological losses are not proportional to intake flows (an assumption required by EPA's method).

Second, EPA did not ensure representativeness of reference facilities by randomly selecting the facilities on which to base its extrapolations. Furthermore, EPA (with the exception of the Freshwater waterbody type) based its extrapolations on data from a single reference facility (i.e., EPA used a sample size of one).

Third, EPA's Flow Index rests on the key assumptions that (1) impingement and entrainment are strictly proportional to flow and (2) the economic value of those losses is strictly proportional to flow. EPA tested neither assumption, and analysis of the only data set sufficient for this reviewer to conduct an evaluation indicate that the first assumption, at least, is not supported. Given the close relationship between the first and second assumptions, it appears equally likely that the second assumption also is not warranted.

The fourth major concern is EPA's use of its Angling Index as a basis for extrapolation. Although it may have some superficial heuristic appeal, EPA's Angling Index method is simply not a valid method for estimating national baseline economic losses. If used at all, it should only be applied to the portion of value lost that is attributable to reductions in recreational catch. Even in that case, the Angling Index method likely would produce biased results because the biological losses at the reference facilities appear to be substantially higher than the average biological losses at other case study facilities. Furthermore, EPA's method of applying its Angling Index is biased because it includes multiple-counting of angling days. The effect on estimates of national baseline economic losses of eliminating the use of EPA's Angling Index method is examined in the following section.

The fifth major concern is with EPA's basis for choosing "best" estimates. EPA's rationale for using the high estimates (rather than a mid-point of high and low estimates) for the Great Lakes and Ocean waterbody types seems to contradict its rationale for using benefits transfer techniques for its initial estimates of the value of baseline economic losses. Moreover, EPA's sole reliance on the HRC estimates ignores the range of estimates of value that it compiled. The effect of using a midpoint of high and low estimates for all waterbody types, rather than using only high estimates for Great Lakes and Ocean waterbody types, is examined in the following section.

IV. Effects of Identified Concerns with EPA's Extrapolation Methods on Estimates of National Baseline Economic Losses

Five major concerns with EPA's methods for estimating national baseline economic losses were identified in previous sections of this report. Although there is reason to question the validity of EPA's Tampa Bay and Ohio River loss estimates, the data and information presented in the Case Study and Economic and Benefits Analysis reports do not support a quantitative assessment of the effects (on estimates of national baseline economic losses) of possible errors in those estimates. The same is true regarding the effects of apparent violations in assumptions of the Flow Index extrapolation method.

As indicated above, EPA's Angling Index extrapolation method is not a valid method for estimating national baseline economic losses. Also, EPA's method for selecting "best" estimates is inconsistent, poorly justified and therefore appears very arbitrary. A quantitative assessment of the effects of eliminating the Angling Index extrapolation method and of standardizing the choice of "best" estimates is possible given the data and in formation presented in the EPA reports. The sensitivity of EPA's estimates of national baseline economic losses to the Angling Index extrapolation method and to EPA's method for choosing "best" estimates is presented below.

EPA reported its "best" estimate of national baseline economic losses (for the 539 in-scope facilities) due to entrainment and impingement to be $1,521,000,000 (from EBA Table C3-6). The use of midpoints as "best" estimates for all waterbody types (rather than using the upper bound estimates as "best" estimates for the Great Lakes and Ocean waterbody types) reduces the national baseline estimate from $1,521,000,000 to $1,350,000,000 (Figure 4). Elimination of the use of EPA's Angling Index method of extrapolation (and use of only the Flow Index method for extrapolation) further reduces the national baseline estimate to $1,081,000,000.

EPA's use of the invalid Angling Index method (rather than using only the Flow Index method) coupled with its inconsistent method for choosing "best" estimates (rather than using midpoints of high and low estimates for all waterbody types) had the effect of increasing its national baseline estimates by over 40%.

Footnotes

1 EPA-821-R-02-001. Economic and Benefits Analysis for the Proposed Section 316(b) Phase II Existing Facilities Rule. Office of Water. USEPA. February 2002.

2 EPA-82 1-R-02-002. Case Study Analysis for the Proposed Section 316(b) Phase II Existing Facilities.

3 The steps as described in this report, and the order of those steps, are intended to facilitate this review of EPA's methodology, and are not intended to reflect EPA's chronology (which was not documented in the CSA and EBA reports)

for computing its national baseline loss estimates.

4 EPA used several techniques (e.g., benefit transfer method, random utility model, habitat replacement cost method) for assigning dollar values to biological losses; see Desvousges (2002), Harrison et.al. (2002), Stavins (2002) and Strand (2002) for reviews of these techniques.

5 As indicated in EBA Table C3-3, EPA used its estimates of the economic losses (from the CSA report) rather than extrapolated values for the Brayton Point, Contra Costa, Pittsburgh, Monroe and Seabrook facilities. A comparison of extrapolated values (estimated by this reviewer using EPA's Flow Index extrapolation method and design intake flows) for these facilities to EPA's estimates (from the CSA report) for these facilities showed a negative correlation. If the assumptions of the Flow Index extrapolation method were satisfied, the extrapolated and estimated values should have showed a strong positive correlation. The negative correlation suggested the assumptions of EPA's Flow Index extrapolation method and/or the assumptions of its facility-specific estimation methods were not satisfied. However, because EPA did not present its estimates of operational flows (due to stated CBI concerns), and this reviewer's analysis therefore was conducted with design flows, the results of the analysis should be considered with caution.

6 Also see Desvousges (2002) for an independent review of EPA's Angling Index Extrapolation method.

EPA Response

The commenter requests a succinct definition of "baseline losses". The commenter is correct that baseline losses can be correctly interpreted as "estimated economic losses due to I&E given current facility practices and technologies."

The commenter is correct that term "case study facility" was used to refer to all CWIS facilities within a case study waterbody and also to refer to facilities with I&E data that EPA used in its analyses. The latter definition is the correct one as pertains to the extrapolation of results and is the definition used in the analysis for the final rule.

The commenter raises several points that are addressed in EPA's responses to other comments. Please see responses to these comments as follows:

The commenter raises questions about the number of case studies that were performed and how facilities were chosen for use in the extrapolation of benefits. In the cost-benefit analysis for the final 316(b) Phase II rule, EPA analyzed data for a much larger number of facilities (46 for the final rule, compared to 18 for the proposed rule). Extrapolations were made based on several facilty-specific factors, including flow and waterbody type. For EPA's response to comments on the methods used for extrapolating results please refer to EPA's response to comments #316bEFR.041.041 and #316bEFR.041.037. On a related note, the angling index is no longer used in extrapolation of benefits.

For EPA's response to comments on assumptions about entrainment survival, please refer to the response to comment #316bEFR.305.506.

For EPA'S response to comments on compensation, please refer to #316bEFR.025.015.

For EPA's response to comments on valuing forage fish, please refer to #316bEFR.005.028

For EPA's response to comments on valuing commercial fishing benefits and losses, please refer to the response to comment #316bEFR.005.029.

For a discussion of issues related to non-use valuation, please see Chapters A12, Non-use Meta-analysis Methodology, and A9, Economic Benefit Categories and Valuation Methods of the final Phase II Regional Studies Document (DCN #6-0003); and Chapter D1 of the final Phase II EBA document (DCN #6-0002) regarding break-even analysis. See also, EPA's response to comments on the habitat replacement cost (HRC) method (#316bEFR.005.035) and the societal revealed preference method (#316bEFR.005.006).

Benefit Estimation Methodology

Comments on the Benefit Estimates Of EPA's Proposed Phase II 316(b) Rule

Prepared by:

William H. Desvousges, Donna M. Clark, Matthew F. Bingham, Ateesha F. Mohamed, Sean M. Small, David F. Ludwig

Triangle Economic Research

1. EXECUTIVE SUMMARY

1.1 Introduction

Triangle Economic Research has prepared this report for the Utility Water Act Group (UWAG) members involved in commenting on the U.S. Environmental Protection Agency's (EPA's) proposed 316(b) Rule for Phase II Existing Facilities. Cooling water intake structures (CWIS) are regulated under Section 316(b) of the Clean Water Act. This statute directs the EPA to assure that the location, design, construction and capacity of CWIS reflect the best technology available (BTA) for minimizing adverse environmental impact (AEI). The EPA is developing national technology standards in three phases: Phase I for new facilities, Phase II for existing electric generating plants that use large amounts of cooling water, and Phase III for manufacturing plants and existing electric generating plants that use smaller amounts of cooling water. The Phase II Rule applies to existing electric generating plants with a design cooling water intake flow of 50 million gallons per day or greater. The EPA estimates that this regulation will affect nearly 550 electric power plants nationwide. These plants represent approximately $75 billion in electric industry revenues and account for 50 percent of the total electricity produced in the United States.

EPA's proposed Phase II Rule would establish national standards to require percentage reductions in impingement mortality and entrainment associated with the use of these structures. Impingement occurs when fish and aquatic species become trapped on equipment at the entrance of the cooling system. Entrainment occurs when aquatic organisms, eggs, and larvae are taken into the cooling system, through the heat exchangers, and discharged back into the waterbody. The proposed rule bases required reductions in I&E on a plant's waterbody source, capacity and capacity utilization rate. The proposed rule, referred to as Option 3, outlines the following performance standards:

1) Facilities that reduce their CWIS design intake flow commensurate with a closed-cycle, recirculating cooling system (cooling tower) are not subject to further requirements.

2) Facilities with a capacity utilization rate less than 15 percent must reduce impingement mortality by 80—95 percent.

3) Facilities located in an estuary, tidal river, ocean or Great Lake must reduce impingement mortality

by 80—95 percent and entrainment by 60—90 percent.

4) Facilities located in a freshwater river or stream with a design intake flow greater than 5 percent of mean annual flow must reduce impingement mortality by 80—95 percent and entrainment by 60—90 percent.

5) Facilities located in a freshwater river or stream with a design intake flow 5 percent or less of mean annual flow must reduce impingement mortality by 80—95 percent.

6) Facilities located in a lake or reservoir must reduce impingement mortality by 80—95 percent and if they propose to increase their design intake flow they cannot disrupt the natural thermal stratification or turnover pattern.

EPA has also evaluated five regulatory alternatives that consist of CWIS technologies with different expected percent reductions in I&E. The five options that were evaluated in addition to Option 3 range from installing I&E controls at all facilities to installing dry cooling systems or cooling towers based on waterbody type, all the way to installing cooling towers at all facilities.

Under the proposed Phase II Rule, facilities have four compliance alternatives. First, they can demonstrate they already meet the new standards and thus no action is required. Second, they can select and implement new CWIS technologies that would bring the facility into compliance. A third option is to request a site-specific assessment of the BTA for minimizing I&E. This option is relevant if the costs of compliance are significantly greater than those considered by EPA during development of the rule, or significantly greater than the environmental benefits of compliance. A fourth option is to implement restoration measures that would maintain the levels of fish in the waterbody comparable to levels that would be sustained with the improved CWIS technologies.

EPA has conducted a benefit-cost analysis (BCA) of the proposed rule and five regulatory alternatives. They chose eight case study areas:

-Delaware Estuary Watershed Study
-Tampa Bay Watershed Study
-Ohio River Watershed Study
-San Francisco Bay/Delta
-New England Estuary (Mount Hope Bay)
-New England Coast
-Great Lakes
-Large River Tributary to Great Lakes.

EPA estimates benefits for each of the case study areas and then extrapolates to the national level. Recreational fishing, commercial fishing, forage species, and nonuse benefits are the major benefit categories.<FN1> The methods employed to estimate the benefits include Benefits Transfer, Random Utility Models (RUMs), Habitat Replacement Cost (HRC), and Societal Revealed Preference (SRP).<FN2> EPA estimates the total benefits of the proposed rule (Option 3) to be $735 million. Their estimate of the costs is $283 million for a net benefit of $452 million. Option 3 is selected as the preferred regulatory option because it has the highest net benefits of all the alternatives evaluated.

1.2 Major Concerns with EPA's Benefit-Cost Analysis

This report comments on EPA's economic benefits analysis of the proposed Phase II rule. The methods EPA employs to estimate the benefits of the regulatory options contain serious flaws and inconsistencies. There are many instances where the methods are not consistent with the EPA Guidelines for Preparing Economic Analysis (EPA Guidelines) (U.S. EPA 2000). Nor is EPA's application consistent with the OMB guidelines for conducting regulatory impact analyses<FN3>.

Additionally, the EPA benefits transfer application routinely violates both the similarity and soundness criteria used to evaluate the appropriateness of a transfer. The Agency's choice of the studies to represent the case study areas reflects many bad economic judgments. Moreover, EPA's failure to account for the appropriate timing of future benefits leads to significant overstatement. The commercial fishing benefits estimation methods use assumptions that are without economic foundation, leading to a substantial overstatement of benefits. The nonuse benefit estimates are calculated using a rule of thumb method that is based on studies conducted more than 20 years ago and are inappropriately transferred to the CWIS application. The Agency's rule of thumb fails to account for any of the recent studies that have raised serious concerns about the reliability of nonuse value estimates. EPA's method of extrapolating benefits to the national level systematically biases estimates upwards. Finally, the valuation methods referred to as Habitat Replacement Cost and Societal Revealed Preference confuse the fundamental concepts of benefits and costs, invalidating them for use in a benefit-cost analysis.

In preparing this report, we have reviewed the documentation and data provided by EPA. As we note in several places, our review has been limited by the lack of documentation of EPA's analysis and the format and timing of the data provided by the Agency. This has limited our ability to perform alternative calculations particularly of the recreation benefits estimates. Although we have been able to evaluate some of the significant issues in the benefits analysis, we are not sure that all fundamental flaws have been discovered because of the lack of clear documentation provided by the Agency. The sections below summarize the major problems with EPA's benefit estimate methods and provide some alternative benefit calculations to the extent that was possible.

1.2.1 Habitat Replacement Cost Benefit and Societal Revealed Preference Estimates Are Without Economic Foundation.

EPA's Habitat Replacement Cost (HRC) method and the Societal Revealed preference method are inherently flawed. Both methods use costs of one type or another as a substitute for benefit estimates. This assumption that benefits equal costs is fundamentally flawed. Consumer surplus, not cost, is the basic measuring concept for estimating benefits. There is no justification for using costs as a proxy for benefits in the economics literature nor is this approach consistent with EPA's Guidelines for Preparing Economic Analysis. EPA provides various rationales for using these non-economic methods to measure benefits. In this report, we refute each of the purported rationales for these approaches. In several instances, the rationales are inconsistent with EPA's own benefits analysis for the proposed Phase II rule.

1.2.2 Commercial Fishing Benefits Are Significantly Overstated Because of Suspect Empirical Analysis.

The methods EPA uses to calculate the benefits of increased commercial dockside landings are suspect. Areas of particular concern include incorrect specification of benefit timing and inappropriate benefit transfer. EPA's benefit timing assumptions ignore the time from implementing the CWIS investments to the time that fish mature sufficiently to be caught for commercial purposes. Any potential benefits accruing to commercial anglers will begin some time in the future and should be discounted appropriately. EPA's Guidelines clearly state that, "present consumption is valued differently from future consumption" (p. 34). In addition, only some surviving age 1 equivalents are caught in their first year of adulthood. Others in this cohort are partially harvested each year of their remaining expected lifetime.

The magnitude of incorrectly specifying this time profile on benefit estimates depends upon the appropriate discount rate, which is 7 percent for commercial fishing. The effect of time-lag to adulthood and partial benefit realization on net present value also is species dependent. However, EPA's analysis recognizes that more valuable fish such as striped bass and black drum take the longest to reach adulthood and live the longest. Thus, the appropriate discounting has a greater effect on the benefits from the most valuable species. Completely accounting for the effects of benefit timing and discounting is beyond the scope of this review. However, assuming a five-year lag to benefit accrual and harvesting of an entire cohort in its first year of adulthood produces an 11.9 percent reduction in EPA's benefit calculations.<FN4> Table 1.1 details the effects of appropriate adjustments to commercial fishing benefits on overall benefits estimates.

Table 1.1: Adjustments to EPA National Benefits
[See hard copy for table]

Moreover, the assumptions and studies used by EPA to obtain societal benefits estimates arising from short-run analyses to a long-run situation is improper. In a short-run analysis, commercial anglers can only change the amount of labor, fuel, or other variable inputs. In the long run, anglers can purchase new boats or make other capital improvements. More importantly, the longer the time period, the more likely that new entrants will be attracted by economic profits or larger producer surpluses. Thus, economic theory dictates that long run producer surplus and thus benefits to commercial angling should be zero. EPA provides no alternative theoretical explanation for the basic theory not to hold, nor does the Agency provide any empirical evidence required by its Guidelines to support this adjusted transfer. Thus, EPA's assumption that commercial fisherman will receive long-run profits ranging from 40—70 percent of increased dockside value is unwarranted. Removing the effect of these incorrect assumptions results in the 4.8 percent reduction in EPA's total benefits estimates depicted in Table 1.1.

EPA's multimarket producer surplus estimates hypothesize that long run increases in producer surplus also accrue to related fish markets. Here again, EPA inappropriately transfers a 4.5 benefit multiplier from a short-run study. The existence of long run producer surplus in any open market is an anomaly. According to a study cited by EPA, striped bass wholesalers receive markups of between "10 and 20 percent of the price paid to fisherman" (Norton, Smith, and Strand 1983). Prices are determined not by wholesalers, but by supply and demand situations at the Fulton Fish Market. Clearly, this is a description of a competitive industry with market participants receiving only normal market returns. Removing these inappropriate benefits from EPA's calculations results in a 36.6 percent reduction in EPA's total benefits estimates. Thus, the inappropriate inclusion of commercial fishing benefits leads to a combined overstatement of benefits of 41.4 percent.

1.2.3 Recreational Fishing Benefit Estimates Are Overstated and Based on Inadequate Methodologies.

EPA estimates recreational fishing benefits using benefits transfer and RUM analysis. Major areas of concern with EPA's recreational fishing benefit analysis include inaccurate characterization of the timing of benefits<FN5>, incorrect specification of random utility models, and improper selection of studies for benefits transfer. In the context of 316(b) regulations, random utility models provide the best opportunity for correctly valuing increased catch hypothesized to result from I&E reductions. These models are the most widely used method for valuing recreational fishing. The models assume that a fishing site is a bundle of features such as accessibility, aesthetics, relative fishing success, and distances from anglers' homes. The RUM models also assume that anglers choose fishing sites that will maximize their satisfaction or utility. By observing the choices angler make, and the distances they are willing to travel, it is possible to measure the value of increasing a single feature of a recreation site, such as improved fish catch, which would be associated with the 316(b) regulations.

However, EPA's analysis as presented, is unsuitable for this purpose. In particular, with the random utility approach, the specification of opportunity cost of time and the estimation technique employed are key features of the model. EPA's random utility analysis contains several errors in these areas that invalidate their results. In particular, departures from standard random utility methods in terms of sampling methodology, calculation of implicit trip costs, and participation modeling lead to inflated benefit estimates many times those found in typical RUM studies. Because EPA's RUM-based per fish valuation numbers arise from nonstandard techniques and appear greatly inflated, we conclude that they are inappropriate for the current application. Relying solely on benefits transfer numbers reduces overall benefits estimates by 8.4 percent as shown in Table 1.1. Furthermore, Table 1.1 shows that the combined effect of adjusting for the timing of benefits and relying only on benefits transfer numbers reduces EPA's benefits estimates by 9.5 percent.

For benefits transfer, EPA focuses on comparing the physical characteristics of the study areas to each case study site. Studies chosen for the transfer are based on waterbody type, geographic location, and relevant species of fish. However, there are other aspects in which the studies used are not similar. These include the comparability of affected populations and the nature of the effects being valued in the study.

Furthermore, EPA selects recreational fishing studies to use that are not scientifically sound in terms of the response rate and estimation techniques, thereby violating the soundness criterion for benefits transfer. Moreover, the dated nature of some of the studies results in estimation methodologies that are no longer consistent with the best practices in the economics profession. In violating the similarity and soundness principles of the benefits transfer method, EPA produces recreational fishing estimates that are upwardly biased. Correctly implemented original random utility studies or performing a detailed meta-analysis<FN6> of existing recreation valuation studies would provide the best opportunity for measuring the recreational benefits hypothesized to arise from 316(b) regulations.

1.2.4 The Conceptual and Empirical Bases of the Nonuse Benefit Estimates Are Flawed.

There is considerable agreement that some people hold nonuse values, also referred to as existence or passive-use values, for some resources. Whether nonuse benefits should be included in a benefit-cost analysis is more controversial (Madariaga and McConnell 1987) and (Hausman 1993). Citing difficulties with contingent valuation (CV), EPA employs a benefits transfer approach for nonuse valuation. They cite Fisher and Raucher (1984) as well as Freeman and Sharma (1977) in stating that nonuse values should conform to a simple 50 percent (of use values) "rule of thumb." According to this approach, the theoretical existence of positive nonuse values justifies an approximation. The 50-percent rule of thumb approximation is based on an average of resources for which both use and nonuse values have been calculated.

However, EPA makes no effort to investigate the similarity of these situations to CWIS improvements. For example, because nonuse values do not depend on direct contact, concepts such as uniqueness, awareness, and the motives people may have for nonuse values are important factors in their determination. A cursory investigation indicates that the marginal improvements to fisheries being studied here are not likely to be unique or be something that creates substantial awareness. In addition, EPA's argument that nonuse values result from existence and bequest motivations is unconvincing. EPA provides little data or results to support effects that are not captured in use values. For this regulation, we conclude that nonuse values are not zero, but are likely to be negligible. Table 1.1 includes nonuse values that are 10 percent of the combined use values, which reduces the EPA benefits estimates by 8.6 percent.

1.2.5 The Aggregation of Benefits to the National Level Uses Improper Statistical Methods Resulting in Biased Estimates.

EPA developed an extrapolation method to estimate national benefits from the proposed Phase II Rule and five regulatory alternatives. National baseline losses from I&E are estimated by extrapolating data from the facilities in the five case study areas to 539 in-scope facilities. Only a subset of these facilities is included in the actual aggregation, further limiting the size of the sample for estimating aggregate national benefits.

Moreover, several fundamental flaws in the EPA extrapolation methodology render the results unreliable. One of the biggest problems is the manner in which EPA chooses the case study facilities. They do not select a random sample of facilities for the case studies, which introduces a systematic bias to their results. EPA's grouping of the case study facilities into five waterbody types does not allow for variability of habitat, fish populations, and resulting I&E risk within a waterbody category. The habitat and respective I&E risk of the selected facility is applied to all in-scope facilities in that waterbody type resulting in biased benefit estimates.

Additionally, EPA introduces a systematic bias into their results by computing estimated fish lost per million gallons per day (MGD) based on flow indices. Estimates are developed for each waterbody type based on an arbitrary selection of a facility within that type. The fish populations present near that particular facility will determine the magnitude of the estimates. These fish loss estimates are then applied to all facilities within that waterbody type regardless of the nearby fish populations. Calculating a weighted average by waterbody type reveals the extent of bias in these calculations. Although not all data are available, our preliminary calculations suggest that flaws in EPA's aggregation methods overstate benefits by more than 12 percent. See Heimbuch (2002) for a more detailed explanation of EPA's procedure.

Finally, EPA's method of computing angling indices for each facility results in an overestimate of angling days due to their lack of consideration of substitute fishing sites. Overestimating angling days leads to an overestimate of benefits. Again, EPA bases extrapolations on estimations of recreational catch from only one facility per waterbody type. Lack of information limits our ability to quantify the extent of this bias. However, a cursory examination indicates that the degree of bias is similar to that found in EPA's flow index extrapolation method. Heimbuch (2002) contains a more thorough critique.

1.3 Maximum Net Benefit criterion

EPA also has requested comments on possible criteria for evaluating regulatory options. The maximum net benefit criterion is the only criterion that is consistent with the basic economic principle of efficiency. In its most basic form, benefit-cost analysis (BCA) seeks to find the technological alternative or other social investment that provides the most benefit for the smallest possible cost, thereby maximizing the net benefit (benefit - cost) of the improvement.<FN7> Thus BCA is a framework for determining which alternative will enhance economic efficiency the most. Efficiency addresses two broad considerations:

-In a world of limited natural, human, and financial resources, it is desirable to achieve any given goal at the least possible cost.

-When faced with multiple goals, we should allocate our scarce resources among these goals so as to achieve the greatest total benefit for any given expenditure of scarce resources.

Maximum net benefit is the preferred economic criterion for evaluating the efficiency of decisions.<FN8> It is the only criterion that identifies the alternative that will yield the highest potential gain in efficiency. That is, the alternative that will yield the largest gain in benefits to society. Maximum net benefit is preferred to maximizing the benefit cost ratio because it reflects the scale of alternative projects. For example, a project could have a high benefit-cost ratio but not produce the maximum net benefits simply because it is a low-cost alternative that produces relatively large benefits.

However, another project could involve higher costs, but produce larger total benefits and subsequently have a higher net benefit.

The maximum net benefit criterion has several important strengths and is especially well-suited to address the regulatory matters related to the 316(b) regulations. In particular, the criteria, when it is implemented as part of a BCA, organizes important information about the large number of potential CWIS investments in a logical form that allows for trade-offs and relates directly to a rule for identifying BTA. It also systematically incorporates considerations of uncertainty about both costs and benefits. Comparisons about uncertain benefits and costs are based on expected outcomes. Clearly, because of a lack of information or the limits of available methodologies, it may not be possible to accurately monetize all possible benefit or cost categories. In such cases, the BCA will qualitatively describe the benefits and costs in question. In cases where monetized benefits fall short of costs, decision makers may decide whether or not the likely value of identified, nonmonetized net benefits is large enough to justify the investment.<FN9> Thus, BCA is sufficiently flexible to address both monetized and non-monetized benefits.

BCA critics assert that such emphasis on human-use values neglects the value of ecological services. However, accurately measured human-use values incorporate values for ecological services. These ecological services provide benefits to humans even if they are not consumed directly by humans. For example, food-chain services provided by benthic organisms are analogous to factor inputs in production processes. These organisms derive their values from the value of the outputs that they produce, which are quantified by using nonmarket valuation techniques. Moreover, such benefits can be quantified and included in the analysis, even if they cannot be reliably monetized.

In addition, the criticism that BCA is overused or that subjective, non-monetary factors are neglected in public policy decisions are unfounded. Both OMB and EPA have issued guidance that requires careful accounting of uncertain and unquantified values and outlines established methods of doing so.

However, evaluating nonmonetized net benefits should not be confused with a wholly disproportionate cost test, which would mandate CWIS investments whose measured costs exceed measured benefits by a substantial margin. Such a test is arbitrary and tends to overcompensate for uncertainty. The net effect would be to waste scarce public and private resources. The wholly disproportionate approach seems motivated by the unjustified assumption that measured benefits are consistently and significantly understated relative to costs. In the context of CWIS, both costs and benefits include components that are difficult to measure and thus involve some degree of uncertainty. BCA of CWIS alternatives should incorporate OMB and EPA guidance on accounting for uncertainty and risk in both expected cost and expected benefit calculations.

Finally, some might argue that BCA is expensive and an unnecessarily complicated exercise. Economists have developed the benefits transfer approach as a cost-effective way to implement the framework. This approach uses the available data and models developed in the professional literature as a way to control the costs of the analysis. Nevertheless, the transfer is performed using sound economic principles that and is based on the maximum net benefit criterion. Additionally, the transfer can be tailored to meet the needs of a particular situation. In simple cases, the transfer is likely to be straightforward. More complicated cases may involve a mixture of targeted data collection and analysis, but this is still less expensive than a full-scale original study. Even those studies may be warranted in cases where the potential investment costs are sizeable and there is substantial uncertainty. Appendix A summarizes how the benefits transfer approach can be implemented cost-effectively.

1.4 Summary

EPA's analysis of the benefits presumed to arise from 316(b) regulations are predicated upon growth in commercial and recreational fish catch due to decreased juvenile mortality. EPA also accounts for nonuse benefits in their calculations, and includes some value for forage fish as well. As shown in Table 1.1, correcting only some of the more obvious flaws in EPA's benefits analysis reduces the aggregate benefits estimates from approximately $735 million dollars to $42 million dollars, or by 94 percent. Thus, EPA's benefits estimates are more than 16 times higher than the adjusted estimates discussed in this report. This level of overstatement indicates the gross inaccuracies in EPA's economic analysis. If more complete information had been provided and more time allowed, we are confident that even these revised estimates overstate the potential benefits associated with these 316(b) Phase II regulations.

The most significant reductions, slightly more than 40 percent, result from eliminating the dramatic overstatement of the commercial fishing benefits, especially the highly dubious benefits that purportedly would arise in secondary markets for fish. The highly competitive nature of such markets makes such benefits illogical and unlikely to ever occur. The second most significant reduction (almost 23 percent) occurs when the habitat replacement cost estimates are replaced by estimates based on economic principles. As we have indicated in our comments, there is no economic justification for EPA's use of this method.

Additionally, EPA's methods for aggregating benefits contribute at least another 12 percentage points to the overstatement. This results from a combination of serious sampling errors and other flaws that further weaken the fragile underpinnings of EPA's analysis.

Finally, recreation benefits and nonuse benefits contribute about 18 percentage points to the overstatement. However, these benefits are not adjusted for the inaccurate quantities that are contained in EPA's methodologies. Thus, EPA's benefits analysis contains many fundamental flaws that could easily have been avoided with more careful economic and statistical analysis. The combination of these errors yields benefits estimates that are more than 16 times higher than the estimates that result from correcting some of the more serious analytical flaws.

This report provides the rationale for our conclusion that EPA's benefit estimation is unsound and not reliable. Section 2 presents a detailed discussion of the major concerns with EPA's BCA incorporating examples from their case studies. Appendix A describes the benefit transfer framework and how to conduct a benefits transfer using sound economic principles. Appendix B discusses the habitat replacement cost method. Appendix C presents a summary of the recent literature on recreational fishing that EPA could have considered in their benefits transfer.

2. DETAILED DISCUSSION: MAJOR CONCERNS WITH EPA'S BENEFITS ANALYSIS

2.1 Commercial Fishing Benefit Estimates

EPA's benefits analysis assumes that a reduction of l&E improves commercial fishing through an increase in adult fish catch. This expected increase is derived through the biological assessment detailed in Chapter A5. More specifically, EPA calculates catch increases by "estimating the number of fish (and species associated pounds) of commercial species reaching harvest age, and then increasing landings in accordance with species- and location-specific fishery mortality rates." Here, species-and location-specific mortality rates are the percent of a given fish stock that fishery experts believe is harvested. The hypothesized increase in catch is directly valued through multiplication of the anticipated increase in species-specific pounds of fish landed by a ten-year average of each species' market value. This treatment produces the expected dockside value of one year's anticipated increase in catch. Finally, EPA converts the change in dockside value to a change in societal benefits by transferring values from previous studies. Studies cited include Huppert (1990); Rettig and McCarl (1985); Cleland and Bishop (1984); Bishop, personal communication (2002); Holt and Bishop (2002); and Norton et al. (1983).

The methods EPA uses to calculate the benefits of increased dockside landings are highly suspect. Actual estimates are flawed to the point of compromising their usefulness. Particularly questionable is EPA's apparent assumption of an immediate relationship between expenditures on CWIS technology and benefits due to increased commercial landings. According to the EPA's Guidelines (p. 36), many EPA policies are characterized by large early investments leading to benefits that begin sometime in the future and accrue over a long period of time. Time to implement new CWIS technologies and fish maturation requirements mean that this is an appropriate description of cost and benefit scheduling under the proposed Phase II Rule.

In addition, not all surviving age-i equivalents are caught in their first year of adulthood. Rather, this cohort is partially caught each year of their remaining expected lifetime. Thus, if the current analysis is to be in agreement with EPA Guidelines, the time profile of benefits arising from I&E reductions should be characterized appropriately. EPA's failure to appropriately schedule benefits leads to incorrect discounting and a significant overstatement of potential benefits from CWIS technology.

EPA also uses inappropriate assumptions and studies in their benefits transfer. In particular, EPA adopts the approach of scaling benefits from transfer studies to make them appropriate for the current situation. EPA Guidelines (p. 87) advise that, "judgments of this type should be based on economic theory, empirical evidence, and experience." In this case, EPA scales estimates arising from short-run analyses to a long-run situation. Economic theory dictates that these situations are vastly different. Not surprisingly, EPA offers no support for this ad hoc transformation. In fact, such a transformation is without foundation. Scaling estimates in this manner leads to a dramatic overstatement of benefits.

2.1.1 Inappropriate Characterization of Benefit Timing

EPA's failure to appropriately characterize the time profile of benefits leads to significant overstatement of benefits. EPA Guidelines (p. 34) for BCA clearly state that, "present consumption is valued differently from future consumption." However, EPA never considers the timing of benefits in their analysis. The magnitude of this omission depends upon species-specific benefit scheduling and the discount rate that is applied. Thus, while both recreational and commercial benefits should be discounted, the effect of discounting on present value is greater for commercial fishing.<FN10> Figure 2.1.1 demonstrates appropriate discounting and increased yield accrual for a single year on increased commercial Weakfish catch from the Delaware Estuary Case Study.

Figure 2.1.1: Example of Timing of Commercial Benefits from Reducing I&E: Weakfish (Delaware Estuary Case Study)
[see hard copy for figure]

Figure 2.1.1 demonstrates that once EPA's 316(b) rule becomes final, facilities will take some time to install protective technology. At that point the technology begins saving eggs and larvae. An egg or larvae takes about a year to become an age 1 equivalent, and another species-dependent time span to be a harvestable adult. At this point, some, but not all fish can be caught each year until the remainder of their life expectancy. EPA assumes that eggs and larvae are saved as soon as the rule becomes final, and that all benefits are realized immediately. The magnitude of this incorrect assumption depends on the lag between cost incurrence and technology readiness for all species. This number is not immediately available; however, more comprehensive and expensive remedies will generally take longer to implement.

Additionally, the influence of inappropriate benefit scheduling on net present value is species dependent. However, EPA's document recognizes that more valuable fish such as striped bass and black drum take the longest to reach adulthood and live the longest. The long lag to adulthood means all benefits accruing from harvest of these species will be subject to the stronger discounting. Long lifespan means that increased yield in these species will be spread over a longer period of time. This dilution of benefits further magnifies the impact of discounting. These are important factors reducing benefit estimates in commercial fishing. Thus, EPA's omission of appropriate discounting leads to a significant overstatement of benefits.

2.1.2 Producer Surplus to Primary Markets

After calculating the total yearly change in dockside value, EPA converts this number to a change in societal benefits. Specifically, changes in producer and societal surplus are obtained by transferring values from previous studies. EPA cites Huppert (1990) and Rettig and McCarl (1985) in estimating that producer surplus in commercial fishing ranges from 50-90 percent of market value. EPA attributes the very high marginal profit rate implied by these numbers to "very high fixed costs relative to variable costs" in the commercial fishing industry. The high end of the cited producer surplus values (90 percent) assumes that additonal fish are brought in nearly costlessly and sold at 9 times (90 percent divided by 10 percent) over variable costs. These studies assume that there is no additional capital expenditure associated with the increase in catch. This assumption may be appropriate for the short-run marginal imporvements considered in these studies. However, as we have previously demonstrated, catch improvements attributable to CWIS technology are predicated upon a yearly increase in fish stock. EPA hypothesizes that this larger stock will yield a stream of benefits over a period of many years. According to EPA Guidelines (p 87), the extent of change in transfer studies and the case being analyzed should be similar. The studies EPA employs are short-run. They do not consider the probability of new entrants to the marketplace. The extent of change that takes place in a long-run situation as compared to a short-run situation is markedly different. Therefore, transferring values from these studies is inappropriate.

EPA recognizes that there are stark differences between the studies cited and its analysis. In particular, the 90 percent estimate implies that "supply is relatively inelastic and demand is relatively unaffected by changes in supply." EPA believes that 90 percent producer surplus is suitable in the short term when effort and prices do not change. However, Huppert (1990) clearly states that his study "emphasizes issues of benefits estimation at any given time, but giving (sic) short shrift to complications associated with the dynamics process." Rettig and McCarl (1985) recognize that "common-properly resource theory, positie net benefits are reflected in increased profit, entry leads to decreased profit and net benefit." So, both studies cited explicitly state that they are short-run analyses. In addition, they recognize the fundamental dissimilarity between short and long run economic situations. However, rather than conducting primary research or transferring values from appropriate studies, EPA transfers values across very dissimilar situations. Recognizing that the study conditions are not alike, EPA simply scales the 50-90 percent producer surplus estimates to 40-70 percent.<FN11> This conversion is entirely without foundation. As shown in the references cited by EPA, and consistent with economic theory, Rettig and McCarl state, "if there were no new impediments to entry, net benefits in thelong run would tend toward zero."

Even if EPA uses appropriate transfer studies, according to Rettig and McCarl (1985), in the long run producer surplus tends toward zero as long as there is open access fishing. The tendency for economic profits, that is, producer surplus, to reach zero in the long run is a well known foundation of microeconomic theory (Mansfield 1988). However, the elimination of profits through competition depends upon an absence of market restrictions. In an open access fishery, new entrants are expected as long as the price of anticipated catch exceeds the cost of entry. The entry of new suppliers tends to reduce the stock of fish raising the cost of catching fish for all participants. Suppliers will continue to enter as long as the expected profits are above the normal rate of return for this class of investment. Entry ceases when the price and average cost of fish are equated at the industry level and producer surplus is eliminated.

It may be theoretically possible to produce profits that are greater than zero if market restrictions exist. However, nowhere does EPA mention the importance of or even consider the existence of such restrictions. At a minimum, an analysis predicting long-run producer surplus should consider commercial fishing restrictions. A complete analysis of fishery markets and restrictions for every coastal state is beyond the scope of this review. However, a cursory investigation conducted by TER provides some insight. Table 2.1.1 describes commercial fishing restrictions by state for four relevant commercial species based on publicly available information.

Table 2.1.1 demonstrates that open access is the norm for most relevant species and markets. Thus, once all adjustments are made, markets reach equilibrium and there is no producer surplus.<FN12> For this reason, it is generally incorrect to associate changes in fish stock with long-run changes in producer surplus. However, EPA bases the remainder of its analysis on the premise that long-run producer surplus associated with CWIS technology is 40—70 percent of market value.

Table 2.1.1: Commercial Fishing Restrictions for Coastal States
[see hard copy for table]

2.1.3 Producer Surplus to Secondary Markets

EPA contends that total benefits may accrue not only to the commercial fishing sector, but also to processors and retailers. Therefore, total surplus estimates should include benefits in these secondary markets. However, rather than conducting an appropriate general equilibrium analysis or transferring values from one (for example, see Thurman and Easly 1992), EPA again transfers values inappropriately. They state that producer surplus is about 22 percent of “total surplus accruing to watermen, retailers and consumers combined.” This “multi-market” estimate derives from citations of Bishop, personal communication (2002); Holt and Bishop (2002); and Norton et al. (1983). Here again, EPA inappropriately transfers short-run values to a long-run analysis. For example, Holt and Bishop specifically state that “in the empirical application we concern ourselves with the estimation of short-run demands for fish landed in the U.S. Great Lakes.” Nevertheless, EPA uses these two studies to support total benefits estimates that are 4.5 (1/0.22) times the producer surplus expected to accrue to commercial anglers.

The discussion above clearly demonstrates that long-run producer surplus is not a relevant concept for commercial fisherman in most U.S. markets. Thus, multiplying the calculated commercial fishing producer surplus values by any factor can only serve to compound existing errors. In addition, the absence of fixed production factors or legal entry restrictions in processing and retailing markets casts severe doubt on the existence of long-run economic profit in secondary markets. Fish processing and retailing in the U.S. are both relatively atomistic industries with tens of thousands of market participants. The competitive nature of these markets invalidates the existence of long-run producer surplus in fish processing and retailing. Therefore, EPA’s 4.5 multiplier is invalid as well.

2.1.4 Conclusion

EPA makes significant errors in calculating the expected benefits to commercial fishing arising from a reduction in I&E rates. Their analysis fails to correctly characterize benefit timing, resulting in inappropriate discounting and overstatement of potential benefits. In addition, the nature of fisheries markets highlights the long-run nature of this situation. In a competitive, atomistic market such as commercial fishing, equilibrium prices associated with higher fish quantities are reached quite rapidly. The existence of large auction outlets, such as the Fulton Fish Market, further facilitates rapid price transition.

EPA's analysis ignores basic benefits transfer methodologies in transferring values arising from studies of short-run phenomena to a long-run situation. To compensate, EPA scales expected benefits. However, they provide no rationale for the scaling factor employed. According to economic theory, new entrants will dilute profit until all participants earn a normal rate of return. The likelihood of long-run producer surplus accruing to commercial anglers depends heavily upon market entry restrictions. However, the analysis provides no evidence that entry conditions have been researched. Because such information has apparently not been considered, it is impossible to give any credence to EPA's commercial fishing producer surplus estimates.

A similar argument applies to estimation of producer surplus accruing tc watermen, processors, retailers, and restaurants. EPA's analysis provides no rationale supporting the existence of long-run producer surplus in these markets. The implication of this omission is that EPA's calculation of producer surplus in secondary markets is simply wrong. The appropriate value should be zero. In fact, the only likely long-run benefactors of CWIS technology are consumers, and even here the likely gains would be modest given the nature of the anticipated regulatory effects.

All other things equal, lower fish prices would presumably benefit consumers. Unfortunately, the only long-run concept relevant to this analysis, consumer surplus, is barely considered by EPA. Taken separately, each fundamental error in applying discounting, benefits transfer methodology, and basic economic theory gravely undermines the credibility of this work. Together, the methods employed are so erroneous that it is impossible to credibly identify any long-run societal benefits from commercial fishing from CWIS technology using this effort.

2.2 Recreational Fishing Benefit Estimates

This section summarizes our comments on EPA's recreational fishing benefits from reducing l&E. Our comments focus on the benefits from the case studies for the Delaware Estuary and Tampa Bay. These two case studies figure prominently in EPA's benefits analysis and are representative of the deficiencies throughout the analysis. Time constraints limited the opportunity to comment on the other case studies that attempted to use the appropriate economic methodologies. <FN13> Finally, this section discusses EPA's inappropriate characterization of the timing of benefit estimates.

2.2.1 Benefits Transfer Approach

EPA transfers values from recreational fishing studies that estimate the WTP for increases in catch and converts these values to "1 fish per trip" estimates in 2000 dollars. The EPA Guidelines (p. 59) provide the following important standards for transferring values:

Existing value estimates, for example, are often subject to large uncertainty bounds due to measurement error, model uncertainty, and the inherent variability of individual preferences. When drawing from these studies—and when using quantitative estimates of any kind— analysts should carefully assess the quality of the data and should clearly state the reasons for their analytical choices.

Despite this, EPA does not include an assessment of the quality of the data in any of their case studies. EPA simply lists each of the studies used. EPA chooses each of the studies used in the transfer because they report values for the relevant species of fish in the case study area. However, simply selecting studies on the basis of geographic area and fish species does not fulfill the requirements for benefits transfer as discussed in Appendix A. The next two sections critique the studies EPA uses for their benefits transfer on the basis of similarity and soundness.

Similarity

In addition to the criteria presented in Appendix A for similarity, the EPA Guidelines (p. 87) recommend the following for applicability (similarity) of the studies used in a benefits transfer:

-the basic commodities must be essentially equivalent
-the baseline and extent of the change should be similar
-the affected populations should be similar.

However, EPA focused on only selecting studies that were similar to the case study areas on the basis of:

-Geographic area
-Waterbody type
-Fish species

For example, for the Tampa Bay case study, the studies used (McConnell and Strand 1994 and Milon et al. 1994) were marine fish studies in Florida. For the Delaware Estuary case study, the studies used were marine studies that included sites from Florida to New York State. The San Francisco Bay/Delta case study used a study of the San Francisco Bay (Huppert 1989). EPA focused on comparing the physical characteristics from the studies transferred to each case study area. However, there were other aspects of the similarity criterion in which the studies used were not similar, such as those recommended in Appendix A.2.1 and by EPA's Guidelines.

According to Norton et al. (1983), used in the Delaware Estuary case study, their report is basically a snapshot of the recreational fishing industry "as it existed during 1979 through 1980. Changes have occurred in the industry since 1980, especially in response to changes in legislation." Since the study was conducted, there have been bag limits on the number of striped bass caught in the State of Delaware (2 per day). Furthermore, studies using data prior to 1990 may no longer be suitable because the affected angling populations may be different and the travel time and costs would be different in the because of increased congestion and new roads. For these reasons, Table 2.2.1 illustrates studies used in the Tampa Bay, the Delaware Estuary, and the San Francisco Bay/Delta case studies that are not applicable.

Table 2.2.1: Studies Using Data Prior to 1990

[see hard copy for table]

Furthermore, catch improvements transferred are not comparable, thereby biasing estimates. For example, the Norton et al. (1983) study is not similar to the situation considered in the Delaware Estuary case study (Delaware and New Jersey). One important difference is in relative catch improvements. The numbers transferred value a catch rate increase of 1 striped bass per trip for the mid-Atlantic (New York, New Jersey, and Delaware). According to the Norton, et al. (1983) study, 76 percent of all striped bass landings are in New York State. New York average catch rate (fish per trip) was 0.68 as compared to 0.07 for New Jersey, and 0.33 for Delaware. The average catch rate for the mid-Atlantic was 0.48. Hence, transferring the numbers for the mid-Atlantic for an additional striped bass is an overestimate (due to the high New York State average) and is not suitable because the basic commodities, average catch rates, are not essentially equivalent.

In addition, the studies EPA employs do not measure a 1 fish per trip catch increase. The studies are not measuring an increase in catch rate of 1 fish per trip but other catch measures. For example, McConnell and Strand (1994) reports a “two-month value per angler for a half fish catch increase per trip.”<FN14> Agnello (1989) reports values for “consumer surplus for a 20-percent increase in catch rate for all fish.”<FN15> Huppert (1989) reports, “willingness to pay (WTP) for a doubling of catch rate” and “WTP to avoid a 50-percent decrease in catch rate.”<FN16> EPA manipulates the numbers using simple mathematics to convert the values to 1 fish per trip numbers. However, for this transformation to be applicable, the value of fish must be linear, which is inconsistent with basic economic principles. in particular, the law of diminishing marginal utility says that as anglers catch more fish, the additional utility or benefit from catching an additional fish will decline (Mansfield 1988). Once again, the basic commodities are not “essentially equivalent” as required by the EPA Guidelines.

Another concern is that EPA uses the average values of all fish species to estimate the recreational value per fish for species that are not valued in the literature. However, value per fish is dependent on the species and studies tend to focus on more popular/valuable fish. For example, small gamefish is \$2.30 and king mackerel is \$5.53 (according to Table D4-2 from the proposed rule). The basic commodities (fish species) are not essentially equivalent. For this reason, values are biased upward.

Finally, EPA has not considered the effect of bag limits and fish consumption advisories in their analysis. In the San Francisco Bay/Delta case study, Huppert (1989) estimates the lower bound WTP for a 100-percent increase in catch. With an estimated 1.36 striped bass caught per trip, the catch rates would have to increase to 2.72 per trip. There is currently a two-fish bag limit on striped bass fishing in the San Francisco Bay/Delta estuary. The WTP estimates for increases in catch exceed the bag limits in this case study area. EPA does not consider the similarity in fish quality with this study either. There is a fish consumption advisory on striped bass in the estuary and no assessment is made to determine whether or not the value of a fish with consumption advisories is the same as the WTP values transferred from Huppert’s (1989) study.

Soundness

EPA selects recreational fishing studies to use in their benefits transfer that are not scientifically sound. Important factors EPA does not consider include response rates and sampling protocols. The response rate is the percentage of respondents that complete the survey. A sampling protocol includes the target population definition, sample selection methodology, and sample size. Studies of particular concern are discussed below.

The Milon et al. (1994) study used in the Tampa Bay case study is a mail CV<FN17> survey conducted in Florida. The study evaluates the economic value to anglers of marginal changes in management of certain near-shore marine species. Factors undermining the credibility of the study include: (1) it uses hypothetical situations and not actual behavior,<FN18> (2) the response rate was 53.8 percent (below the 70 percent recommended by NOAA), and (3) there were many zero bids (zero dollar values ranged from 60 percent for redfish average catch changes to 95 percent for mullet bag limit changes).<FN19> In addition, the McConnell and Strand (1994) study employed in the Delaware Estuary and Tampa Bay case studies uses sequential estimation to calculate their welfare values, which understates the variance in the estimated values as explained in Section 2.2.2.

The Huppert (1989) study used in the San Francisco Bay/Delta case study estimates WTP using an average of values from a CV model and a travel cost model (TCM). The data consisted of a phone survey of central California residents followed by a mail survey of angling households contacted. This study had an overall survey response rate of 38.3 percent, which is well below the 70 percent recommended by NOAA. The CV questions used hypothetical situations and not actual behavior, further undermining the credibility of the study. The response rate was also very uneven among levels of avidity. The response rate was 24 percent for anglers not fishing in the past 2 months and 72 percent for anglers fishing more than twice in the past 2 months. This avidity bias causes the WTP estimates to be biased and potentially overstated.

The Agnello (1989) study used in the Delaware Estuary case study employs a single-site TCM in the analysis. The TCM recognizes that exclusive of entrance fees, recreators at a particular site pay an implicit price for using a site's services through the travel and time costs associated with visiting that site. The EPA Guidelines (p. 74) indicate that TCMs are "limited, however, in their ability to model the recreationist's choice among competing sites." When there are numerous close substitutes available for a given site, WTP for small changes in natural resource services can be much less than if there are few alternatives available. Hence, the more sites to select from, the smaller the impact a change at one site will have on a recreator's utility. Since there are substitute sites in the case study areas, neglecting the role of substitutes will overstate consumer surplus and therefore benefits of CWIS investments. For these reasons, the Agnello (1989) study is not a sound study for use in the benefits transfer for estimating the value of recreational anglers catching additional fish.

As can be seen in this section, EPA uses many studies that are not similar or scientifically sound in their recreational benefits estimations, thereby biasing their results. EPA needs to select studies more carefully on the basis of similarity and soundness. Appendix C summarizes some of the recent literature on recreational fishing that EPA could have considered in their benefits transfer at a reasonable cost.

Furthermore, EPA never evaluates, quantifies, or discusses uncertainty in their analysis, which makes their benefits transfer incomplete. See Appendix A.3 for a detailed discussion on the role of uncertainty in benefits transfer. This discussion describes the impacts of uncertainty and how to account for uncertainty in a benefits transfer. EPA also fails to document their necessary assumptions and analyze the quality of the data in each transfer study as recommended by their Guidelines. For these reasons, EPA's recreational fishing benefit estimates from their benefits transfer analyses are biased and invalid.

[comment text continued in 316bEFR.041.452]

Footnotes

1 In this report, we focus our attention on the habitat replacement cost estimates that relate to forage fish.

2 Although EPA used the SAP method in the San Francisco Bay/Delta case study, the Agency did not use this case study in the national extrapolation of benefits.

3 Economic Analysis of Federal Regulations under Executive Order 12866. See www.whitehouse.gov/omb/inforegMaguide.html

4 This conservative assumption employs a 7 percent discount rate and does not spread benefit accrual over the life cycle of a fish cohort.

5 Corrections to benefit timing and discounting in recreational benefits analysis are similar to commercial corrections but less influential (2.3%) due to a lower (3% versus 7%) discount rate.

6 Meta-analysis is the statistical synthesis of a large number of similar studies.

7 An early definition states that BCA is a “technique that measures impacts in dollars or other quantified values and that also provides systematic recognition of unquantifiable values and significant qualitative impacts” (Liroff 1982). More recently, Arrow et al. (1996) provide eight principles on the appropriate use of BCA.

8 See Stavins (2002) for further discussion of this criterion.

9 Where substantial risks are involved, decision makers may be able to quantify the monetary value of the risks and include it as a cost associated with that alternative. This approach is the way financial markets absorb information about investments with varying risks.

10 We use a 7-percent discount rate to approximate cost of capital in commercial fishing. For recreational fishing we use the 3-percent social discount as specified by OMB.

11 EPA's calculation of producer surplus accruing to commercial fisherman consists of simply multiplying the expected value of increased landings by 0.4 for a lower bound and 0.7 for an upper bound.

12 Documents cited by EPA describe the nature of fish markets. Norton et al. (1983) specifically recognize that the atomistic and competitive nature of the industry constrains markups to 10% to 15% over costs.

13 In addition to the Delaware Estuary and Tampa Bay case studies, we include comments for the San Francisco Bay/Delta case study in this section only.

14 EPA converted this value by using the average number of saltwater trips from the 1996 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation (1.5 trips in 2 months) and dividing it by 1.5 (per trip value) and then multiplying it by 2 (per fish value).

15 EPA justified using the values from this study by first estimating the average catch rate was 4.95 fish per trip and therefore, a 20 percent increase in catch would be equivalent to 1 fish.

16 EPA justified using the values from this study by first estimating that anglers took 6.2 trips per year and catch 1.36 fish per trip. They converted this to fish per year and divided this into the WTP estimates to estimate WTP per fish. The lower bound was estimated using the WTP of having a 100-percent increase in catch and the upper bound used the WTP of avoiding a 50-percent reduction in catch.

17 The contingent valuation (CV) method for estimating the value of natural resource services involves a direct survey of individuals to elicit their WTP for different levels of services. Concerns about the reliability of CV estimates of nonuse

values prompted the National Oceanic and Atmospheric Administration (NOAA) to commission a blue-ribbon panel to study CV results and make recommendations about the role of CV in measuring nonuse damages. Although the panel concluded that CV may provide a starting point for considering total values in a damage assessment, the panel also concluded that no cv study to date had produced reliable estimates of total values (58 Fed. Reg. 4613).

18 Economists prefer preference data based on actual behavior rather than responses to hypothetical situations. With CV, the question format can influence respondents.

19 Zero bids may be protest bids (made by respondents who reject the ground rules of the CV study for one or more reasons that may include skepticism of the policy being described or the ability of the government to implement the policy) and hence, may bias your results.

EPA Response

The comment states that "the methods EPA employs to estimate the benefits of the regulatory options contain serious flaws and inconsistencies," and that "there are many instances where the methods are not consistent with the EPA Guidelines." EPA does not agree. EPA's approach to economic analysis of the final Section 316(b) Phase II rule is consistent with principles outlined in the EPA's Guidelines for Preparing Economic Analyses, United States EPA (EPA 240-R-00-003) (DCN #6-1931). Moreover, EPA's Guidelines expressly state that they "do not provide a rigid blueprint or a 'cook-book' for all policy assessments ... [and that t]he most productive and illuminating approaches for particular situations will depend on a variety of case-specific factors and will require professional judgment to apply." Id. at p. 2. The Guidelines also recognize that the choices made on how to approach the economic analysis issues in a given situation will necessarily be influenced by factors such as the nature of the issues present, the relevant statutory requirements, the availability of data, the cost and time needed to obtain data, and the need for expedition in taking regulatory actions. Id. at pp. 3, 5 (n. 2), 59, 64. Therefore, EPA's Guidelines for Preparing Economic Analysis are not legally binding and, in fact, allow EPA to use the most up to date approaches to benefit estimation, if applicable.

EPA has changed and improved many of the methods used to estimate benefits for the final Phase II 316b rule. Therefore, a number of the points made in this comment are no longer relevant. Nevertheless, specific concerns regarding EPA's approach to economic analysis of the Section 316(b) Phase II regulation are discussed below.

1. The Aggregation of Benefits to the National Level Uses Improper Statistical Methods Resulting in Biased Estimates

EPA has greatly expanded its analysis since the case studies were presented at proposal. EPA's final analysis evaluates many more facilities (a total of 46) and extrapolates I&E estimates within regions rather than across a waterbody type nationwide. Seven regions are evaluated—5 coastal regions (North Atlantic, Mid-Atlantic, South Atlantic, Gulf of Mexico, and California); the Great Lakes region; and the Inland region. I&E data from multiple facilities in each region were used to develop each regional estimate. In some cases, all of the facilities with I&E data in a region were evaluated (e.g., California). Given that the goal of EPA's analysis was to develop estimates of impacts and benefits at the national scale, EPA believes that this regional approach provided a reasonable basis for extrapolation.

For EPA's response to comments on the extrapolation method used at proposal, please see the response to comment #316bEFR.041.041.

Please see response to Comment 316bEFR.072.055 for a discussion of the size and representativeness of the sample of facilities used in EPA's analysis for the final rule.

2. Commercial Fishing Benefits

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment 316EFR.005.029.

3. Recreational Fishing Benefits

For EPA's Response to comments on the methods used to estimate recreational fishing benefits for the proposed Phase II rule, please see the response to comment 316EFR.075.504.

EPA agrees that random utility models (RUMs) "provide the best opportunity for correctly valuing increased catch." For the final Phase II 316b analysis, EPA has reduced its reliance on benefit transfer to estimate recreational fishing benefits. In the recreational fishing analysis, benefit transfer is used for the inland region, and benefit function transfer is used for the North Atlantic region. EPA has estimated RUM models for all other coastal regions (Mid-Atlantic, South Atlantic, Gulf of Mexico, and California), and for the Great Lakes region. Therefore, the comments on benefit transfer presented here are no longer relevant.

EPA does follow standard and generally accepted practices for sampling methodology, calculation of trip costs, and participation modeling. Please see responses to comments #316bEFR.041.452 and #316bEFR.072.058 for details regarding EPA's application of RUM modeling.

4. Discounting of Future Benefits

EPA has included species-specific discounting of future benefits in its final rule analysis, as recommended in this comment. This discounting takes into account both the lag in installation of the technology, and the lag in growth of fish to harvestable size.

5. Habitat Replacement Cost Benefit and Societal Revealed Preference Approaches

The habitat-based replacement cost (HRC) and societal revealed preference (SRP) methods are not used in the cost benefit analysis for the final Section 316(b) Phase II rule. While the Agency agrees that the HRC is cost of replacement and not benefits, the Agency believes that understanding what it would cost residents in an area to replace CWIS losses is a very useful tool in the regulatory process and also informs decisions on the use of restoration. The HRC like the HEA is a process that requires the analyst to systematically evaluate the losses caused by a CWIS, quantify them, and then consider the steps that would be necessary to replace these individuals and species. The species by species consideration of losses, even if not monetized, is a useful tool in considering the environmental effect of CWIS losses. or EPA's response to comments on the HRC method, please see response to comment # 316bEFR.005.035. For additional information on the HRC, please see the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003). For EPA's response to comments on the SRP method, please see response to comment #316bEFR.005.006.

6. Non-use Benefits

EPA agrees that “nonuse values are not zero,” but does not agree that nonuse values are negligible. As stated in the NODA, EPA attempted to include non-use benefits categories for the final Section 316(b) Phase II rule analysis. As stated in the NODA, the rule-of-thumb approach to estimating non-use is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. Given the unavoidable uncertainties in estimating non-use benefits at the national level, the Agency presented a qualitative assessment of the benefits of the environmental protections at issue in the final 316(b) benefit cost analysis.

EPA has responded to concerns regarding the Agency’s non-use valuation methods presented in the NODA in responses to a number of comments. For EPA’s benefit transfer approach, please see EPA’s response to comment #316b.EFR.307.061 regarding using habitat values to estimate values for fish; comment #316bEFR.304.002 regarding the soundness of value estimates used for non-use benefit transfer; comment 316bEFR.304.004 regarding comparisons of population demographics between the study region and policy region; comment 316bEFR303.020 regarding the definition of users vs. nonusers; and comment 316bEFR.303.021 regarding the allocation of values for various wetland services. For EPA’s meta-analysis please see EPA’s responses to comments #316bEFR.338.044 regarding meta-analysis in general; comment #316bEFR.338.046 regarding the appropriateness of the studies selected, comparison of baseline and extent of change, and comparison of affected populations; and comment #316bEFR.338.047 regarding sensitivity analysis in EPA’s meta-analysis. For EPA’s response to comments regarding the break-even analysis, please see response to comment #316bEFR.306.106.

7. Use of the Maximum Net Benefit Criterion

The comment suggests that the best way to evaluate the regulation is to use the maximum net benefit criterion. The comment points out that, using this criterion, it may be difficult to monetize all benefits and costs, and that it is appropriate and necessary to qualitatively or otherwise describe benefits and costs that cannot be monetized.

For the 316(b) Phase II regulation, the Agency was not able monetize benefits for 98.2% of the age 1 equivalent losses of all commercial, recreational, and forage species. (The percentages by region are as follows: California 95.2%, North Atlantic 99.0%, Mid Atlantic 98.4%, South Atlantic 98.1%, Gulf of Mexico 95.8%, Great Lakes 99.8%, and Inland 99.9%.) This means that the benefit analysis represents the benefits associated with less than 2% of the total age 1 equivalents lost due to impingement and entrainment by cooling water intake structures (CWISs)." EPA’s Guidelines for Preparing Economic Analyses recommend that benefits be considered from a qualitative perspective when developing monetized estimates is not feasible. The Agency believes that it adequately considered the benefits of the environmental protections at issue in the final 316(b) rule and carefully developed a qualitative assessment of ecological benefits stemming from the final 316(b) regulation. See responses to comment #316bEFR.206.047 regarding further detail on limitations in EPA’s benefits analysis.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

8. Considering Bag Limits and Fish Consumption Advisories

The comment suggests that EPA should consider the effects of bag limits and fish consumption advisories (FCA) in the recreational fishing benefits analysis. EPA was unable to do so because data are not available indicating the effects, if any, of these factors on values for increased catch rates. It is likely that such effects vary widely and are dependent on various factors, such as region, anglers' preferences, the level of bag limits, etc. For example, some anglers practice mainly catch and release, in which case a bag limit or consumption advisory would have no effect on their value for recreational fishing. Other anglers may fish for subsistence reasons, in which case, they may value species with higher bag limits and without consumption advisories more than species with bag limits and advisories. There is an endless variety of possible scenarios, so that such factors would be quite difficult to quantify without extensive survey data. The overall effect of the bag limits and FCA on the estimated benefits of the 316(b) rule is likely to be insignificant.

9. Evaluating Uncertainty of Benefit Estimates

Regarding uncertainty, EPA provides a discussion of uncertainty in I&E estimates in the context of its analysis in Chapter A6 of Part A of the Regional Study Document for the final rule. EPA notes that the lack of confidence intervals for EPA's I&E estimates reflects the lack of information in facility documents on the variance in facility estimates of I&E. In many cases only 1 or 2 years of annual estimates are presented. Moreover, given the complexity of EPA's analysis, involving 46 facilities, dozens of species and hundreds of life history values, characterizing uncertainty would be a large undertaking in and of itself. For example, Chapter A6 provides an example Monte Carlo analysis exploring uncertainty associated with foregone yield estimates. The example illustrates the high level of effort involved to conduct such an analysis for only one type of loss (entrainment) for one metric (foregone yield) for one species at one facility.

EPA also carefully evaluated and discussed uncertainty of its benefit estimates. For example, see the uncertainty and limitation section in Chapter A11 and Chapter 4 in Parts B through H in the regional study document prepared for the analysis for the final Phase II rule (DCN # 6-0003). The Agency, however, points out it is not always feasible to quantify uncertainty due to data limitations. When feasible, the Agency used state-of-the-art approaches, such as the Krinsky and Robb simulation method, to quantify uncertainty (see Chapter A12, Non-use Meta-Analysis Methodology, in the regional study document for detail, DCN # 6-0003).

[comment continued from 316bEFR.041.451]

2.2.2 Random Utility Analysis

Overview of Method

Random utility models (RUMs) were initially developed to analyze transportation-mode choices (McFadden 1974). More recently, they have been applied to recreation-site choices (Schuhmann 1998). The random utility approach posits that the benefit an individual receives from a given activity is observable with a degree of uncertainty. However, actual choices are based upon the expected utility that an individual associates with a particular choice (McFadden 1973). The probability that a person chooses to recreate at a particular site is based upon the expected utilities of all sites within the recreator's choice set.

Thus, the RUM does not predict the actual number of trips that an individual will take to a recreation site. Rather, a RUM estimates the probability that an individual will choose to visit a given recreation site. This probability depends on the characteristics of that site, the characteristics of available substitutes, and the travel costs to all the sites in a recreator's choice set. The better the characteristics of a site, the higher the probability that an individual will choose that site, and thus the higher the value of that site will be. With the focus on site characteristics, RUMs can be used to estimate the value of a marginal change in a single attribute at a single site. For this reason, RUMs are well suited for the type of analysis usually required for regulatory analysis. Although standard protocols for applying RUMs to recreation site choice are still evolving, Federal agencies have approved their use for valuing natural resources. (See U.S. Environmental Protection Administration, 2000, and National Oceanic and Atmospheric Administration, 1996 [61 Fed. Reg. § 439—510]). In the context of 316(b) regulations, random utility analysis presents the best opportunity for correctly valuing increased catch hypothesized to result from I&E reductions. However, EPA's analysis as presented is unsuitable for this purpose. In particular, with the random utility approach, the specification of opportunity cost and the estimation technique employed are key features of the model. EPA's random utility analysis contains several errors that invalidate their results.

Data

The data needs for a RUM are much more extensive than the data needs for the traditional travel-cost models. Typically for a RUM, respondents keep a log of their recreation trips, noting the location of each trip. They also provide personal information that may influence their recreation decisions, such as age, gender, and whether they own a boat. RUMs also require data on site-quality characteristics, not only for the recreation site being studied, but also for all relevant substitute sites. In addition, researchers need to know the round-trip travel costs from each recreator's origin to all potential recreation sites.

The data collection phase of an original RUM study can be time-consuming and costly. Rather than conducting an original study, EPA chooses to employ “Marine Recreational Fishery Statistics Survey (MRFSS) combined with the 1994 Add-on MRFSS Economic Survey” for their random utility analysis. There are several problems with EPA’s presentation of these results that make interpreting them difficult. Areas of particular difficulty include the following: programs were originally provided in PDF (not editable) format, editable programs were provided late, programs are not well documented, the link between random utility model output and benefit calculation is unclear, benefit calculation spreadsheets have unreadable “CBI” cells, and the link between benefit calculations and values listed in EPA’s report is unclear.

Despite these difficulties, TEA has replicated EPA’s random utility dataset and RUM output for the Delaware Estuary case study. This replication indicates that EPA’s construction of the random utility data set will result in overstatement of benefits. Important issues include, but are not limited to:

-Employing unweighted intercept data
-Incorrectly calculating trip costs.

EPA incorrectly utilizes the MRFSS intercept data for benefits estimation, which leads to inflated benefits estimates. Intercept surveys select respondents at specific recreation sites rather than at their residences. The major problem with this type of data for benefits estimation is that unweighted intercept data are not descriptive of the general population of anglers (McFadden 1981). Over-representation of avid anglers occurs because the probability of surveying an angler is related to the number of trips the angler takes. Thus, those individuals who presumably value an activity most highly are disproportionately represented. In the case of MRFSS data, a random digit telephone survey provides initial trip information. However, this information is combined with the 1994 Add-on MRFSS Economic Survey. While EPA documentation is vague on this point, it appears that economic information is derived from an intercept survey add-on. Thus, while angling activity may be fairly represented, valuation estimates are influenced by avidity bias.

In addition, responses of anglers typically exhibit recall bias. Recall bias is the well known tendency of recreators to overstate the number of trips they take (Westat Inc. 1989). Furthermore, the upward bias in benefits estimates caused by intercept sampling is compounded by anglers’ tendency to overstate their level of fishing activity. MRFSS attempts to minimize this problem by limiting sampling to two-month trip recall windows. However, daily trip logs are preferable. Some attempt at adjustment for this form of bias would be appropriate.

TER’s investigation of EPA’s programs for setting up their RUM data indicates additional problems.<FN20> An important area is in the specification of trip costs. EPA uses two variables (tripcst and timecst) to quantify the costs associated with a fishing trip. The following excerpt demonstrates that costs associated with a particular trip are heavily dependent upon respondent wages and whether or not respondents reported that they lost wages due to the trip. Boldfaced text is TEA interpretation of EPA SAS code.

467 if lost_nc=1 then do; (If respondent says Income was lost)

468 tripcst = (0.29*ds*2) + ((wage*(ds/40))*2);
(Cost of trip is $0.29 per mile + wage x hours)

469 timecst =0; (lime cost is $0)
470 end; (Stop)
471 else do; (If respondent says income was not lost)
472 tripcst = (0.29*ds*2); (Cost of trip is $0.29 per mile)
473 timecst = (ds/40)*2; (Time cost is travel hours)
474 end; (Stop)

Estimation of the opportunity cost of time is a controversial issue in economics. The approach generally taken in the literature is to specify opportunity cost as one-third of the wage rate (McConnell and Strand 1981). EPA's approach assigns the full wage rate to all respondents reporting lost wages. Their travel costs are lost wages plus $0.29 per mile in traveling expenses. Travel costs for those who did not report losing income are $0.29 per mile. Thus, trip costs are heavily dependent upon the validity of responses to the question about lost wages and to the estimation of the wage rate. According to EPA's data summary for Delaware Bay/Atlantic Coast anglers, "forty-seven percent of the anglers indicated that they had flexible time when setting their work schedule." This number includes fully employed, partially employed, students, homemakers, and retired individuals. It is unclear what question of the 1994 Add-on MRFSS Economic Survey provides justification for EPA assigning respondents to the "lost wages" category. Possibilities taken from the survey include:

26. Can you choose to work more or fewer hours per week?

28. Did you forgo any wages by taking this trip?

29. About how much money could you have earned if you hadn't taken this trip?

Again, precisely interpreting the approach taken is difficult. However, EPA's trip cost estimation technique focuses on wages lost due to travel time. For this reason, Question 28 from the 1994 Add-on MRFSS Economic Survey (which focuses on wages) is apparently the variable used to identify trip costs. This approach assumes that anyone losing wages lost the full pretax value of his or her average wage rate. This is an extremely generous allowance for the opportunity cost of time, leading to inflated value estimates.

The importance of wage approximations appears in additional EPA calculations. Because respondents are typically reluctant to report income, EPA estimates missing wages as a function of state, sex, age, employment status, and boat ownership. In every case, EPA employs assumptions leading to high wage estimates. For example, line 392 reads:
392 if unempl=. then unempl=0;

If the survey respondent does not describe unemployment status, he or she is considered fully employed. Line 435 reads:

435 if unempl=1 or retired=1 or home_mk=1 then wage=5.15;

Thus, minimum wages are assigned to people who are not working. Lines 389 and 390 do not include the homemakers and retirees considered in line 435, meaning that these respondents are considered full-time employees. In addition, people who work part time and report losing income are assumed to lose the full value of their estimated wage rate.

389 if student=1 or unempl=1 or partime=1 then fulltime=0;

390 else fultime=1;

Because of the difficulties in reconciling EPA's results, it is impossible to precisely state the effect of these factors. However, it is clear that all of these factors lead to high trip-cost estimates. EPA's approach of assigning full wage rates for those reporting any lost wages also leads to inflated trip costs. The costs associated with taking a fishing trip form the basis for quantifying benefits associated with an improvement in trip quality. Thus, eliminating these cost inflationary factors will necessarily lower the value of positive trip attributes such as increased catch.

Analysis

RUMs can be used to estimate both the distribution of trips among sites with various characteristics and the total number of trips across all sites in a given time period. The total number of trips taken in a given time can be modeled as a function of demographic characteristics, flexibility of time of the recreator, weather-related factors, and a measure of the attractiveness or utility of the set of choices available to recreators. This attractiveness index is estimated using site-choice data. Each recreator has a bundle of recreation sites from which to choose because time and budget constraints limit the number of sites that are available. As a result, the number of trips a person chooses to make in a given period of time is affected by the quality of the set of choices available. For example, a person living within 20 miles of 10 relatively unattractive sites has a less appealing set of recreation opportunities and therefore is likely to make fewer trips than a person who lives within 10 miles of 20 attractive recreation sites. EPA evaluates the effect of increased site attractiveness on overall visitation in a three-step process. First, the Agency evaluates the baseline utility for the set of relevant sites. Then EPA calculates overall expected utility using increased catch rates hypothesized to arise from I&E reductions. Finally, the Agency specifies the number of trips taken per year as a function of overall expected utility and a number of demographic variables.

Correctly specified, the RUM recognizes that there are several levels at which people make decisions, and the RUM explicitly models choice among available alternatives at each level. Thus, the researcher must make basic judgments about how to model the structure of the decision process. As the RUM becomes more widely used for natural resource valuation, the effects of alternative modeling strategies will be more clearly identified. However, EPA's technique of modeling trips in a sequential manner is incorrect. Current random utility participation models invariably model the decision to recreate and the selection of recreation site simultaneously (Morey 1999). Thus, EPA's method of estimating increased participation is flawed. Modeling trips sequentially in this manner guarantees increased participation and value estimates because it does not consider time limitations that can preclude such trips. Neither does this method recognize that the value of an additional trip is its marginal benefit when other opportunities are considered.

The RUM is the preferred method for valuing gains in recreational catch, such as those anticipated to arise from 316(b) regulations. However, EPA's programming and modeling is unclear, leading to difficulties in interpreting results. An analysis of programs and models reveals non-standard approaches to sampling, trip-cost specification, and participation modeling. Moreover, EPA's per-fish valuation numbers are many times those found in published literature (Schuhmann 1998). We presume that inappropriate specification underlies these results. For this reason, we cannot recommend using EPA's random utility estimates in their current form. In the absence of primary research, or at a minimum, more transparent benefits estimation, we recommend transferring values from appropriate random utility studies found in the economics literature.

2.2.3 Inappropriate Characterization of Benefit Timing

Similar to the commercial fishing benefit estimates, EPA fails to discount the recreational benefits appropriately in their analysis. The rate selected for discounting also impacts ultimate benefit estimates. Figure 2.2.1 demonstrates appropriate discounting and increased yield accrual for a single year of increased recreational Silver Perch catch from the Tampa Bay Case Study.<FN21>

As stated previously, the influence of inappropriate benefit timing on net present value is species dependent. For species with a long lifespan, such as black drum, which can live as an adult for 50 to 60 years, the total benefits accruing to recreational anglers from catching these species will be subject to stronger discounting. For such species, this dilution of benefits further magnifies the impact of discounting. These are additional important factors that reduce benefit estimates for recreational fishing. Thus, EPA's omission of appropriate discounting leads to a significant overstatement of recreational benefits.

Figure 2.2.1: Example of Timing of Recreational Benefits from Reducing I&E: Silver Perch (Tampa Bay Case study)
[see hard copy for figure]

2.2.4 Conclusion

The studies EPA chose for the benefits transfer are based on waterbody type, geographic location, and relevant species of fish. EPA focuses on comparing the physical characteristics of the study areas to each case study site. However, there are other aspects in which the studies used are not similar. These include the comparability of affected populations and basic commodities. Furthermore, EPA selects recreational fishing studies to use that are not scientifically sound in terms of the response rate and estimation techniques, thereby violating the soundness criterion for benefits transfer. EPA should select better studies to use in their analysis in terms of similarity and soundness. In violating the similarity and soundness principles of the benefits transfer method, EPA produces recreational fishing estimates that are biased.

When conducting a benefits transfer, competent analysts carefully document necessary assumptions and the sensitivity of estimates to these judgments. EPA fails to state their reasons for choosing a particular study, thereby transferring the assumptions and flaws of the methodology used in the original study.<FN22> In addition, EPA never evaluates, quantifies, or discusses uncertainty in their analysis, which makes their benefits transfer incomplete and their estimates incorrect.

In conducting their RUM analyses, EPA employ unweighted intercept data and incorrectly calculate trip costs. Unweighted data is not descriptive of the general population of anglers due to the over-representation of avid anglers and possible recall bias. In addition, avid anglers tend to overstate their level of activity, leading to an upward bias in recreational benefits. EPA's trip costs are high because of the use of the full wage for individuals reporting any lost wages instead of the general one-third of the wage rate approach. Finally, EPA's fails to characterize the timing of recreational benefits appropriately in their analysis, thereby inflating their estimates. For all the reasons presented in this section, EPA's recreational benefits are biased, overstated, and flawed.

2.3 Nonuse Benefit Estimates

Nonuse values do not require visiting or using a resource (Krutilla 1967). There is considerable agreement that some people hold these values, also referred to as existence or passive-use values, for some resources. Whether such values should be included in a benefit-cost analysis is more controversial (Madariaga and McConnell 1987; Hausman 1993). A major source of the controversy is the inability to externally validate the estimates with methods that do not rely exclusively on hypothetical responses.

Measuring nonuse values through revealed market behavior is not feasible because no behavior is required to experience a nonuse value (Freeman 1993). For this reason, economists have developed hypothetical valuation methods. Currently, CV is the most widely used technique for measuring nonuse values.<FN23> In the CV approach, respondents are asked hypothetical valuation questions in a survey setting. Theoretically, responses are a direct measure of compensating surplus. In practice, answers are often complicated by hypothetical bias.<FN24> Thus, responses do not accurately reveal preferences. Responses are biased upward, in some cases leading to dramatic overstatement of actual values (Hausman 1993). In general, bias undermines the validity and reliability of nonuse value estimates. As a result of these serious measurement problems, it is unclear what the magnitudes of true nonuse values actually are.<FN25>

Citing difficulties with CV, EPA employs a benefits transfer approach for nonuse valuation. While EPA states that difficulties with CV present difficulties with primary research, they base benefits transfer estimates on research using that very technique. Research conducted since Fisher and Raucher (1984) has indicated the lack of reliability of CV (Hausman 1993). Specifically, they cite Fisher and Raucher (1984) in stating that nonuse values should conform to a simple 50 percent (of use values) "rule of thumb." According to this approach, the theoretical existence of positive nonuse values justifies an approximation. The 50-percent approximation of use values is based on an average of resources for which both use and nonuse values have been calculated. For further support, EPA cites Sutherland and Walsh (1985) and Sanders et al. (1990) in implying that nonuse values for angling improvements may actually be greater than 50 percent of the corresponding use value.

In applying this rule, EPA recognizes its weaknesses. Specific drawbacks emphasized by EPA include (1) the dated nature of the supporting literature; (2) differences between the current situation and study subjects; and (3) problems in applying results consistently across different nonuse valuation scenarios. However, instead of explicitly considering these factors, EPA simply acknowledges them and states that they will apply the 50-percent rule until they are able to "revisit the body of literature." The value of applying the 50-percent rule to the current situation depends heavily on the factors EPA mentions. However, the study contains no systematic comparison of theoretically important resource characteristics across studies. At a minimum, EPA's stated intention to revisit relevant literature should include such a comparison.

A review of Fisher and Raucher (1984) employed by EPA indicates that this study focuses solely on the nonuse benefits associated with intrinsic benefits of water quality improvements. Applying the

Fisher and Raucher (1984) findings to nonuse values of marginal changes in catch rate is an extension far beyond that supported by this study. Applying a ratio that values water quality, a nonconsumptive good, to changes in catch rate, a consumptive good, does not comply with EPA Guidelines. As mentioned earlier in Section 2.2.1, the EPA Guidelines (p. 87) recommend using studies in which the basic commodities are essentially equivalent and where the baseline and the extent of change are similar.

Water-quality improvements are in no way similar to marginal changes in catch rates, and, therefore, cannot be considered “essentially equivalent” commodities. Naturally, different commodities cannot have similar baselines or changes. The extent of change for water-quality improvements, such as improved aesthetics, is qualitative with a high level of awareness to a presumably large group of nonusers. The extent of change for marginal changes in catch rates is quantitative with limited levels of awareness to some anglers who could be categorized as nonusers. Another important factor to consider is whether the nonuse-to-use ratios cited in the Fisher and Raucher (1984) study use total benefits as valued by respondents or net benefits (consumer surplus). It is more appropriate to use net benefits that account for associated costs, as this is a true measure of consumer surplus and could affect the nonuse-to-use ratios. Fisher and Raucher (1984) do not indicate what components comprise the use and nonuse values reported in their paper.

The type of in-depth investigation proposed by EPA should consider the theoretical components of nonuse value and their importance in the current situation. In particular, because nonuse values do not depend on direct use of the resource, concepts such as uniqueness, awareness, and value motivation are important factors in their determination. Each of these factors is discussed below.

2.3.1 Uniqueness and Awareness of the Valued Resource

A classic example of a resource often believed to have significant nonuse values is the Grand Canyon (Carson 1991). People may hold positive values for the existence of the Grand Canyon, even if they never plan to visit it. As with use values, we expect that characteristics of the Grand Canyon influence its value, however the traits that matter may be different. Instead of particular physical details, the significance of the resource as determined by its uniqueness and a high level of awareness is more important.

For the mere existence of a resource to have value to people, it must be in some way unique. The Grand Canyon evokes nonuse value in people because it is one-of-a-kind and could not be replaced if damaged. Arguably, there are very few, if any, resources in the world that are a meaningful substitute for the Grand Canyon. This uniqueness and irreplaceability make it valuable for people that never go there. By comparison, resources lacking these qualities should have relatively lower nonuse values.

Even if a resource is unique, it cannot provide nonuse value to a person who is totally unaware of its existence. In the Grand Canyon example, many people in the western United States have considerable awareness and knowledge of the Grand Canyon because information is readily available. Awareness is likely to decrease as distance from the resource increases, even for a prominent resource like the Grand Canyon. For other, less significant resources, awareness is likely to diminish much faster as distance increases (Johnson et at. 2001).

A brief analysis of important nonuse value factors indicates that 50 percent of use values is probably an excessive estimate for CWIS improvements. Awareness and uniqueness are important factors that do not apply to catch improvements from CWIS technology. A healthy marine fishery is a significant and relatively unique resource. Awareness of the presence or absence of such a fishery should be reasonably high, especially for those who live nearby. However, the use component of this study reveals that a healthy fishery is not what should be valued. EPA's recreational benefits analysis values marginal improvements in catch; therefore, nonuse values must be based upon marginal improvements. The nonuse values for marginal improvements in catch rates are quite different than the nonuse values people hold for the presence of a viable fishery. Similarly, awareness of marginal improvements in catch rates is likely to be insignificant for non-anglers. Desvousges et at. (1993) discuss the additional empirical burdens that arise in trying to measure nonuse values that are associated with marginal changes in natural resources. This complication adds further concern as to the appropriateness of using a broad average to value marginal changes in natural resources.

2.3.2 Motivations for Holding Nonuse Values

Consideration of the motivations underlying nonuse value should be part of the analysis. EPA's study states that nonuse values typically embrace "the concepts of existence (stewardship) and bequest (intergenerational equity)." However, EPA makes no effort to consider the applicability of these concepts to the proposed rule. This requires careful consideration of both the improvement being valued by users of the resource and the impact of that value realization on nonusers. To generate use benefits, EPA values catch improvements for current anglers. These catch improvements are both realized by and valued by current anglers. Because EPA's study does not restrict recreational angler benefits to catch-and-release fishing, it is reasonable to conclude that at least some catch improvements are harvested. This fact severs the link between use and nonuse values, undermining the validity of the 50-percent rule for this situation. The nonrenewable nature of use benefits realized by recreational anglers significantly diminishes the likelihood of both existence and bequest motivations for nonuse values. Use of the resource reduces the stock of fish, which is purportedly increased through reduced I&E impacts. Once these benefits have been realized, they are no longer available to others. Thus, in this instance, nonuse valuation predicated upon existence or bequest motivations seems at odds with the presence of recreation use values.

2.3.3 Conclusion

Resources such as fish may have nonuse values, and in some cases these values could be significant. It also is likely that the use values are not capturing all the benefits associated with the 316(b) regulations as there could be some effects on the food chain or other ecological considerations. Of course, EPA has not provided any information to support the presence of such benefits, other than to assert their existence. If EPA were concerned that these values could be significant for these regulations, a prudent course would have been to conduct a properly designed study to evaluate their potential significance. Instead, they have chosen to rely on a convenient rule of thumb that was developed more than 20 years ago and is based on studies that value considerably different changes in environmental quality than the likely effects of the 316(b) regulations.

It is our conclusion that EPA's approach to nonuse values is inconsistent with both sound theory and good empirical practices. In particular, economic theory implies that nonuse values are most important for unique resources with high awareness levels. An entire stock of marine fish could certainly be considered significant. However, it is important to recognize that the potential benefits under consideration are not a consequence of a large discrete change such as the complete loss of a fishery, the improvement in water quality at a waterbody, or the Grand Canyon. Rather, it is a very marginal change to a significant resource, fish, and some poorly defined other effects on the ecosystem. This recognition is crucial because it undermines the validity of EPA's 50-percent rule. Furthermore, from a theoretical perspective, EPA has not addressed the potential inconsistency between its use benefits, which result from the extraction of resources from the ecosystem and nonuse benefits, which often are purported to arise from knowing that fish are present in the ecosystem. This weakens EPA's claim that nonuse values for CWIS technology improvements arise from existence and bequest motivations. Thus, there could perhaps be some motive for valuing the potential effects on the ecosystem beyond fish, but the Agency has not provided a sufficient theoretical or empirical rationale for such benefits. Clearly, such vague connections do not justify EPA's method of deriving nonuse values as 50 percent of use values. While such an approach may be expedient, it is inconsistent with good economic practices. Based on our review of the available information provided by EPA and the current economic literature on nonuse values, we conclude that if such values were relevant for the 316(b) regulations, their empirical magnitude would be quite modest and certainly less than 50 percent of use values.

2.4 Aggregation of Benefits to the National Level

EPA developed an extrapolation method to estimate the national benefits of the proposed Phase II Rule. EPA posits extrapolating data from the eight case study areas to the national level. There are 23 power plants represented by the eight case study areas and no indication that EPA randomly selected these plants. Furthermore, EPA uses only five of these eight case study areas for their extrapolation to the national level. Of these five case studies that represent 19 facilities, three use economic methods<FN26> and two employ the habitat replacement cost method. EPA estimates there are 539 power plants affected by this proposed rule. The case studies are chosen on a convenience-sampling basis with considerations given to data availability.

EPA's use of a convenience sample rather than a scientifically drawn random sample of the case study facilities produces biased results. Convenience samples consist of partial lists of sample members, which is inconsistent with good sampling practices. Random sampling methods are well established protocols for aggregating from a sample to a population based on scientific sampling principles. EPA's Guidelines recognizes the appropriateness of using random samples. Random samples also can be stratified, or grouped, if some types of facilities, or sizes of facilities, or locations of facilities are of greater importance than others. There is no scientific justification for using convenience sampling.

An evaluation of the geographic distribution of the facilities shown in Table 2.4.1 below shows that the Northeast region is over-represented by almost 50 percent. There is no case study example in the Southwest region even though 10 percent of the affected facilities are located here. There is only one case study representing 2 facilities for the entire west coast and there are none located in twenty-five states between Ohio and California. In addition, there is evidence that the EPA sample is biased towards larger facilities. A comparison of the facilities' net generation (as a proxy for size) reveals that the mean of the case study facilities is twice as large as the mean of all in-scope facilities<FN27>. For these reasons, the sampling method EPA employs in selecting the case study facilities is not a random sample and is therefore not representative of the population, resulting in biased estimates. It is possible that the sample is non-representative based on other criteria in addition to geography and plant size (existing CWIS technology, waterbody fish populations, etc.). This would introduce a systematic bias to their results as well. Attempts to secure this data from the EPA were unsuccessful, preventing further evaluation of this issue.

Table 2.4.1: Geographic Distribution of Affected Facilities vs. Case Study Facilities
[see hard copy for table]

EPA employs two methods in aggregating the data to the national level: the Flow Index and the Angler Index. In order to account for the unique characteristics inherent to different types of waterbodies, EPA groups the facilities into five categories prior to indexing: (1) Freshwater, (2) Estuary—Non-Gulf, (3) Estuary—Gulf, (4) Great Lake, and (5) Ocean. For these groupings, EPA assigns Flow and Angler Index weights and extrapolates the baseline losses for all facilities. By grouping the facilities by these five waterbody types, EPA is contending that there is no variability in I&E risk within each of the waterbody types. This is not the case as each waterbody has different species and populations of fish that are at different life cycle stages. For example, the 29 facilities in the freshwater category are extrapolated to 393 facilities. All 29 of these facilities are located on the Ohio River. This applies the I&E risk of the Ohio River to more than 70 percent of the facilities used to develop the national benefit estimates. EPA's grouping of the facilities into general waterbody categories disregards habitat variability and biases the benefit estimates.

The Flow Index relates facilities by the I&E stress they place on their environment. This stress is measured by the millions of gallons per day (MGD) used in the operational flow of the facility's cooling systems. EPA establishes a facility's weighting in the Flow Index based on their operational flow as a percentage share of the total operational flow of all facilities in the same waterbody category. Next, they apply the Flow Index to the baseline losses of the reference facility for that grouping. EPA then sums the total losses for each waterbody type to generate the national baseline losses for all facilities. (See Heimbuch [2002] for a discussion on the mechanics of EPA's Flow Index Method of Extrapolation and concerns about this method.)

EPA uses baseline loss data from selected case study facilities as reference values for the extrapolation. Then they select what they refer to as the "best estimates" which are the "set of extrapolation values the Agency believes are the most reflective of the baseline loss scenarios for each waterbody type." An estimate of fish lost per MGD is developed for each waterbody type based on an arbitrary selection of a facility with that particular waterbody type. This estimate will be correlated with the fish populations present near the plant that was selected: those with the highest fish populations will have the highest fish lost per MGD estimates. EPA then applies this estimate to all facilities within that waterbody type regardless of the fish populations present near the plant. If EPA selects facilities located near large fish populations, I&E estimates will be overstated. An examination of the case study facilities selected for the extrapolation supports this assertion.

Table 2.4.2 illustrates that EPA I&E estimates are overstated because they have selected the facilities with the highest fish lost per MGD within each waterbody type to serve as their reference value.<FN28> For example, EPA chose Salem as the reference facility for the Estuary (Non-Gulf) category. As Table 2.4.2 illustrates, Salem's fish lost (expressed as Year 1 Equivalents) per MGD is 50 to 200 times higher than the other Estuary (Non-Gulf) facilities for which EPA has l&E data. Another example is EPA's use of the Pilgrim facility as the reference value for the Ocean category. Pilgrim has fish lost per MGD values almost four times higher than the other Ocean facility, Seabrook. EPA has sufficient I&E risk data by facility to calculate an average fish lost per MGD across each waterbody type. However, EPA selected only one reference facility per waterbody category—and this analysis suggests they chose the one with the highest fish lost per MGD—thereby producing inflated national benefits estimates. Heimbuch (2002) discusses in more detail EPA's improper use of reference facilities for national extrapolation.

Table 2.4.2: A Comparison of Fish Lost per MGD Across Case Study Facilities by Waterbody Type
[see hard copy for table]

EPA uses the Angler Index to assign a relative "value" to each affected fishery and uses this value to assign a weight to each facility. The Index uses angling activity (measured in Angling Days [AD]) within 120 miles of the facility as a measure of the demand for the affected fisheries. The Angler Index for each facility is divided into two categories—rural and urban AD. EPA calculates the total AD for each facility as a percentage share of the total AD for each waterbody category—thus establishing each facility's weighting in the Angler Index. Finally, they apply the Angler Index to the baseline losses of the reference facility. In estimating the number of angling days by facility, EPA's analysis does not consider the availability of substitute fishing sites. This creates a problem of multiple counting of angling days. In the freshwater category, EPA makes an adjustment for this by treating the 29 Ohio facilities as one facility. They do not make an adjustment for the possibility of an angler choosing a substitute site in any of the other waterbody categories. This approach results in an overestimate of angling days and an overestimate of benefits. See Heimbuch (2002) for a more detailed description of EPA's Angling Index Method of Extrapolation.

2.5 Habitat Replacement Cost Benefit Estimates

EPA introduces the habitat replacement cost (HRC) method for valuing losses of aquatic resources that result from I&E of organisms by a CWIS. EPA argues that HRC can be used to value a broad range of ecological and human service losses associated with 316(b) regulations. They argue that it can both be viewed as a substitute for and a complement to conventional valuation methods because it provides a full valuation of species associated with l&E losses. EPA argues that conventional benefits methods can omit important ecological and public services.

EPA uses the HRC method for the Brayton Point, Pilgrim, and JR Whiting case studies. The estimates are extrapolated from the case studies to the Ocean and Great Lakes aggregate benefits categories. Generally, the Agency uses a four-step process to determine the cost of replacement habitat to provide sufficient offsets for the I&E losses associated with the facility. The process involves quantifying losses, identifying habitat requirements and alternatives that would offset losses, and estimating the cost of the associated habitats. EPA performs this analysis for specific species, assuming that each species represents a biological service. Costs are estimated as annualized unit costs of implementing the various measures.

EPA conveniently overlooks one fundamental flaw associated with using the HRC to measure benefits: it measures costs not benefits. There is no economic rationale for confusing these two different concepts: benefits are associated with people's willingness to pay to have certain products or services while costs are the opportunity costs of the forgone resources used to produce that product or service. There is no reason to expect that costs would be a good proxy for benefits. They may be higher, lower, or the same but that will depend on the unique circumstances of each situation. Thus, there is no basis in economic theory or practice for using replacement costs to approximate benefits. Such an approach is inconsistent with EPA's own Guidelines and contradicts concepts based on hundreds of years of development.

EPA argues that because recreational fishing benefit valuation studies only focus on certain desirable game fish, they do not reflect the benefits from protecting forage fish. (See All-i.) This conclusion is erroneous in that economics recognizes that one can choose to evaluate the consequences of a regulatory action in either the input market, which would correspond to the forage fish, or at the output market, which would be recreational fishing. (See Carlson 1988, and Just, Hueth, and Schmitz 1982). Since changes in the number of forage fish, either positively or negatively, would affect the game fish, it is possible to measure the value of changes in forage fish through their effects on recreational fishing.

In addition, EPA argues that HRC addresses a broad range of ecological and human services that are either undervalued or ignored by conventional valuation approaches. However, EPA's own benefit calculations contradict this view. In particular, EPA includes benefits for nonuse values in their assessment of the 316(b) regulations. (While we disagree with the magnitude of these benefits, we do not disagree with the notion that some benefits beyond use values may be generated by the regulation.) Presumably, these nonuse benefits are intended to reflect values that go beyond direct use values. As we note in our discussion of nonuse values, EPA provides very little documentation on the linkages that are expected between the regulations and nonuse values. This lack of documentation makes it hard to know exactly whether the nonuse values do indeed reflect the benefits that would accrue from protecting fish other than game fish. Thus, if our interpretation of the nonuse value component is correct, then EPA has already addressed the benefits for protecting forage fish with the inclusion of nonuse values, and to contend that HRC is needed, is not substantiated.

EPA suggests that I&E losses may affect services that include human uses such as diving, birding, or boating. (See A11-2.) The difficulty that EPA fails to overcome is to substantiate any linkage between I&E and these activities. EPA's Guidelines discusses the need to establish baseline conditions and to describe exactly how the regulations would change such conditions. (See page 21.) In order for benefits to occur, boaters would have to experience an increase in satisfaction from their boating activities because there are more forage fish or game fish in the relevant areas. The basis for such a linkage seems tenuous at best. Diving and birding also would seem to have at most a marginal impact. Other features such as accessibility would dominate the choices made by these recreators relative to the marginal changes in fish species that would likely accompany the reduction of I&E. Thus, EPA's motivations for including HRC are without economic foundation and are not supported by the purported rationales.

2.6 Societal Revealed Preference Benefit Estimates

EPA employs a method they refer to as Societal Revealed Preference (SRP) to determine the economic value of I&E of special status fish. Special status fish are those fish that are classified as threatened and endangered (T&E). In the San Francisco Bay/Delta estuary, there are eight species of T&E fish that inhabit the waters near two power plants: the Pittsburgh and Contra Costa power plants. The SRP method is used to determine society's value of a T&E fish. The estimated number of T&E fish lost to I&E is then multiplied by this estimated value to determine the total value of lost T&E fish.

EPA contends that a CV study would be the best way to estimate society's value of a T&E fish, or society's willingness to pay. An alternative method was developed due to the cost and time needed to conduct a CV study. The actual amount of money society dedicates to restoring and preserving T&E species was used as a proxy for society's revealed preference value of protecting T&E species. This decision is completely inconsistent with sound economic principles. There is no valid rationale for such an approach within the economic literature, or other regulatory guidance. Moreover, it is not supported in EPA's own Guidelines, which only considers approaches that are based on the principles of consumer sovereignty such as willingness to pay.

Additionally, the Societal Revealed Preference approach leads to nonsensical results. For example, suppose you have two programs, each of which protects the same number of fish equally well. Suppose also that Program 1 costs half as much to administer and implement as Program 2. Under this approach, if an agency chose to implement Program 2, it would be justified in doing so, because the benefits would automatically equal the costs. This result would occur despite the fact that another program could deliver the same results for half the cost. Thus, a higher cost program does not necessarily yield values that are higher than a low cost program. EPA violates basic common sense in confusing costs and benefits. Costs are based on the opportunities forgone and benefits are based on users willingness to pay to have a product, service, or even a government program.

EPA's SRP approach also requires the implicit assumptions that regulatory or management agencies always provide exactly what consumers would have wished and exactly in the correct amounts. There is considerable literature on the factors that can affect a regulatory agency's choice of specific programs (McFadden 1975 and Spence 1975, for example). While the CALFED Bay-Delta Ecosystem Restoration Program Plan (ERPP) program may well be a model of efficiency, there is considerable reason to think that specific programs will be influenced by many factors ranging from the scientific disciplines of the program administrators to their perceptions of the relative importance of certain species or geographic areas. There is little reason to think that these factors will result in decisions that conform to the willingness to pay principle.

Additionally, it is useful to not confuse SRP with the averting behavior approach, which uses the costs of actions that individuals take to reduce their exposure to some form of pollution as a lower bound estimate of benefits. (See Smith and Desvousges, 1986 and EPA's Guidelines). Two fundamental differences separate the averting behavior and SAP approaches. First, in the averting behavior approach, individuals are making decisions that maximize their own personal welfare. In the SAP approach, we have government agencies making decisions based on some unknown utility maximization process. Secondly, in the averting behavior approach, it is possible to directly link the expenditures to the specific harm being avoided. In SRP, the costs are not linked to specific actions but include fixed costs that are unrelated to protecting threatened and endangered species.

Finally, EPA rationale that it was impractical to conduct a CV study is of limited foundation. For example, if such benefits were likely to be significant, then EPA would have had sufficient time to conduct the study since they started addressing these regulations in one form or another in the early 1990's. Moreover, EPA could have chosen to undertake a benefits transfer, as they have done on the recreation benefits. At a minimum, benefits transfers are based on the correct theoretical foundations and can be evaluated for the sensitivity of their results to key assumptions or data limitations. Clearly, this is not the case with the SAP approach. As we show in our Appendix A, benefits transfer also is both time and cost effective. Thus, the SRP approach should be rejected as being without economic foundation and unjustified based on any of the other rationales that EPA purports to justify the method.

EPA compounds the problem of using a completely inappropriate method for measuring benefits by the many logical inconsistencies in its implementation of the SAP methodology. Specifically, EPA identified the cost of the CALFED Bay-Delta ERPP to protect T&E species as one of the components of society's value of restoring and preserving T&E species in the San Francisco Bay/Delta estuary. However, The CALFED program protects more T&E species than those located near the Pittsburg and Contra Costa power plants. There is no adjustment to reflect only those costs incurred to protect the eight species of T&E fish near the power plants. Moreover, there are eleven program elements that address several goals in addition to restoring and preserving T&E species. The ratio of costs allocated to restoring and preserving T&E species are arbitrarily determined across program elements potentially overstating the cost estimates as well.

Another component of EPA's estimate of society's value of restoring and preserving T&E species in the San Francisco Bay/Delta estuary is the opportunity cost of foregone water used. The estuary provides over 50% of California's supply of freshwater and there are restrictions on withdrawals due to various endangered species acts. The amount of water restricted is based solely on a regulatory policy and not on society's willingness to forego consumption to preserve T&E fish.

EPA's methodology for developing these cost estimates involves arbitrary assumptions and adjustments. Specifically, EPA estimates water reductions of 40 to 60 percent from supply restrictions. They also estimate a baseline of 7 million-acre feet that represents unrestricted water use. However, EPA provides no supporting documents to substantiate the reasonableness of the baseline. The EPA's source of this information is from personal communications with the California Division of Water Resources and the Central Valley Project. These communications are not documented nor are they substantiated with other sources. EPA further estimates the value of water through a series of undocumented transformations. This exercise concludes with a series of calculations of per-fish values that are illogical and undocumented. Given the vagueness and lack of documentation of the assumptions throughout this analysis, the validity and reasonableness of the estimated value of foregone water used is highly questionable.

Footnotes

20 The following text refers to the program Coastal Restricted Choice Sets III.sas.

21 The discount rate applied is the 3 percent recommended by OMB for social discounting.

22 In order to evaluate a study's soundness, the study must be well-documented. In some cases, studies cannot be used in benefits transfer simply because not enough information is available to properly evaluate it.

23 Recently, there has been some research into using stated preference (SP) surveys to measure nonuse values. While more complex than CV, SP still requires respondents to value unfamiliar, hypothetical commodities. As a result, SP is as subject to similar problems with hypothetical bias as CV.

24 Hypothetical bias is the potential error that results from not confronting an individual with a real situation. CV responses and SP responses likely reflect hypothetical bias.

25 See for example, Freeman's (1993) discussion of the difficulties associated with disentangling the use and nonuse

components of total value.

26 The economic methods are benefits transfer and random utility analysis.

27 Due to data restrictions, this analysis examines 396 of the 539 in-scope facilities, including 11 of the original 23 case study facilities

28 Due to insufficient data provided by EPA, we are unable to analyze the three other waterbody types in a similar manner.

EPA Response

The commenter states that random utility analysis presents the best opportunity for correctly valuing increased recreational catch resulting from reduced impingement and entrainment. The commenter, however, identifies several methodological flaws in EPA's analysis. From the commenter's point of view, these flaws completely invalidate EPA's results. Each of the commenter's arguments is addressed below.

EPA agrees that "In the context of 316(b) regulations, random utility analysis presents the best opportunity for correctly valuing increased catch hypothesized to result from I&E reductions." However, EPA does not agree with the commenter that EPA's RUM approach is invalid. It appears that the commenter did not properly understand EPA's analysis, the NMFS data used, and how NMFS' surveys are conducted and adjusted.

1. Use of the Intercept Data

EPA does use intercept data in the site choice model. Most RUM studies use intercept data to evaluate site choices. EPA uses data from the National Marine Fisheries Service (NMFS) Marine Recreational Fishing Statistics Survey. NMFS has very carefully designed its sampling strategy to capture the most representative sample of anglers possible, and they have been conducting and refining their surveys for many years, resulting in one of the best surveys available for recreational activities. The NMFS Data Manual, Chapter 1, Survey Methodology (http://www.st.nmfs.gov/st1/recreational/pubs/data_users/index.html) discusses data collection and sampling procedures (DCN #6-3189). Two independent surveys are conducted: a telephone survey of households, and an intercept survey of anglers at fishing access sites. Data on fishing trips in the previous two months is collected in the telephone survey. Information on actual catch is collected in the intercept surveys. Economic information is collected in an add-on to the intercept survey. According to NMFS: "Data from the two independent surveys are combined to produce estimates of total participation, effort and catch. Survey sampling and estimate generation is stratified by subregion, state, fishing mode..., fishing area, and bimonthly wave." For the intercept surveys, sampling is allocated between months of a wave (a two-month period, e.g. July - August) according to proportion of fishing pressure in each month. Survey sampling sites are randomly selected from all access sites, weighted by expected fishing activity. Sampling is also distributed among weekdays, weekends and holidays.

It is not necessarily true that the data provide estimates of values for changes in catch rates that are biased upwards. First, NMFS sampling strategies, described above, are designed to minimize such bias. Second, while it is likely that more avid anglers are more likely to be intercepted, it is not clear from economic theory that more avid anglers have higher values for increases in catch rates than less avid anglers. In fact, it is possible that the opposite could be true. A more avid angler might also be more skilled and therefore already have a higher catch rate than a less avid angler. Thus, the value of a marginal change for the more avid/more skilled angler would be lower than that for a less avid/less skilled angler, if diminishing marginal utility of catch rates holds.

EPA estimates total benefits by multiplying estimated values per day for changes in catch rates by the total number of fishing days in each region, as estimated by NMFS. NMFS refers to this estimate as "total fishing effort." Fishing effort is defined by NMFS as "the estimated number of fishing trips taken by individual anglers." This is estimated for each state, mode, and wave. Data are adjusted for outliers when estimating fishing effort, by reducing the number of trips for any household reporting more than the 95th percentile for the five-year distribution of trips to the 95th percentile. This generally reduces total fishing effort estimates by 15-20 percent. Estimates of fishing participation ("the number of participants in recreational fishing activities") are derived from intercept data and effort estimates. "The estimation procedure accounts for varying levels of reported fishing avidity...The probability of selection in the intercept survey is higher for a person who fishes frequently than for a person who seldom fishes. NMFS corrects differences in probability of selection by using the reciprocal of the mean number of trips each intercepted angler reported having taken in the previous 12 months." None of the NMFS studies, including the Hicks et al. study that several commenters recommend for benefit transfer, include further corrections for avidity bias.

In summary, EPA believes that NMFS has adequately corrected for sampling bias through long-established and tested survey and statistical methods. The NMFS data collection methods and estimates of fishing effort (number of trips) and total catch have been carefully designed, tested and adjusted in order to minimize bias as completely as possible. Because of the rigorous level of NMFS' statistical methods, EPA believes that sampling bias is minimized to the greatest degree possible.

2. Incorrect Estimation of Trip Costs

The comment indicates that the commenter did not properly understand EPA's analysis related to inclusion of wage rates in the RUM model. EPA follows generally-accepted RUM procedures for estimating the opportunity cost of time. In regions where data were available on angler income, EPA included income for anglers who reported that they lost income by taking the fishing trip, and who reported their income. However, in all of these cases, only a minor fraction of anglers in the RUM data set provided information on household income. For example, in the mid-Atlantic region, only 191 respondents reported losing income and reported income (or had income estimated using other data), and thus were assigned a value for income in the model; 11,911 anglers either did not lose income, did not report income, or were not assigned an estimated income, and thus were not assigned an income in the model. For these anglers, opportunity cost of time was measured only in terms of time spent driving, without a dollar value assigned to that time. Because only 191 of over 12,000 anglers were even assigned an opportunity cost of time, any changes in the opportunity cost of time in the model would have a minuscule affect on value estimates. Similarly, in the Gulf region model, 181 respondents were assigned an opportunity cost of time, while 10,081 respondents were not. It is most likely that including income for all anglers, at 1/3 the wage rate, would have increased benefit estimates. Thus, EPA's approach is conservative.

In some regions, NMFS did not collect income data. For these regions, EPA estimated income for each angler using the median household income by zip code from the U.S. Census. Opportunity cost of time was estimated as 1/3 of the household wage (household income divided by 2080 hours), as recommended in the comment.

In summary, EPA does not believe that the Agency's analysis incorrectly calculates opportunity cost of time in the RUM models. If anything, EPA's measure of opportunity cost of time would result in downward bias in estimates for regions where income was reported for extremely small numbers of respondents. For regions where income was estimated using median household income from the U.S. census, it is impossible to determine the direction of bias, if any, without having a way to compare the median income of anglers to the median income of all households in the region. EPA has followed standard, generally-accepted methods of RUM modeling, and there is no clear evidence of upward bias in per-day estimates.

3. Use of Incorrect Modeling Procedures

The commenter argues that sequential modeling of trips used in the proposed rule analysis is incorrect. EPA disagrees. A number of different approaches to modeling fishing participation appear in the published literature, including the Poisson trip model used in EPA's analysis and the repeated logit model that allows building the participation decision directly in the RUM (Morey et al.,1999). EPA believes that its Poisson trip model is adequate and valid for the purposes of the 316b analysis, because the trip model is used only to estimate the percent change in total trips when catch rates change, not the absolute number of trips. As described above, EPA uses NMFS' estimates of total fishing effort (fishing days) to estimate total values. The percent change in catch rates predicted by EPA's Poisson trip model is applied to NMFS total effort to predict the change in trips with increased catch rates. In most cases this percent change is quite small, so EPA does not believe that applying more complicated trip estimation methods would provide enough of a difference in the estimates to justify the additional effort in terms of programming required.

There is no general consensus among economists as to whether "modeling of trips in a sequential manner is incorrect." All of the NMFS studies, based on the initial study of McConnell and Strand (1994)(DCN #6-3174), use sequential estimation. From McConnell and Strand: "The random utility model departs from the standard framework by considering decisions on a particular choice occasion. It does not incorporate features to evaluate the angler's behavior over a longer period of time. ... We model the angler as first choosing the mode and target species and then, conditioned on this choice, choosing the site. These decisions can be separated because of the structure of the utility function (pp. 69-70)." "In applying random utility models to recreation systems, we model the decision per choice occasion and this leads to an additional limitation of the model. Because our discrete choice model explains decisions among discrete alternatives, it is structured so that each trip is a mutually exclusive event. From a practical standpoint, this simple model is satisfactory, because the direction of bias is known and likely to be small for most applications. ... Conceptual advances are illustrated by Parsons and Kealy (1994)(DCN #6-3257) and by Morey (1994) (DCN #6-3258), who have recently made progress in developing models to handle the quantity and distribution of trips (p. 71)." "The welfare estimates that are calculated are per choice occasion. ...if the change in circumstances is great enough to induce substantial changes in the number of trips taken, then the welfare measure will underestimate the effect of an improvement in circumstances and overestimate the effect of a decline. ... To compare the estimates derived from a constant trip assumption, we develop a model of the demand for trips as a function of the inclusive value, among other variables. This model, which is satisfactory in most pragmatic aspects, converts the unit of analysis from representative trips to individuals and hence requires estimates of the number of anglers for aggregation (p. 72)."

Parsons, Jakus, and Tomasi (1999)(DCN #6-3198) compare welfare estimates from four methods of linking site choice RUM models to seasonal trip (participation) models, using a single data set and applying each method to their data. The four methods compared in this study include: Morey et al. (MRW), Hausman et al. (HLM), Parsons and Kealy (PK), and Feather et al. (FHT) Although they "are ostensibly developed from different theories, we find that they are nearly the same mathematically." HLM estimate trips using a Poisson-based count model, with a price index based on the inclusive value as an explanatory variable to explain the number of trips. MRW use a repeated logit model to build the participation decision (i.e., go/don't go fishing choice) directly into the RUM. However, both relate the number of trips during the season to the inclusive value index. "Econometrically, they differ only in their treatment of the data-generating process (functional form and error distribution) selected for the estimation..." Parsons, et al. estimate a new model, using a demand function specified as in MRW, but applying HLM's welfare analysis, and find that the results are the same. "That is, analyzing the MRW empirical form using HLM theory and welfare analysis gives us the same welfare measure as using MRW theory and welfare analysis. The 'stories' told by the theorists to motivate their models are different, but they are equivalent mathematically when a common functional form is used." The same results hold when the HLM demand model is analyzed using MRW theory and welfare estimation. "With the exception of differences in functional form in their empirical analysis then, the MRW and HLM models are equivalent." All four models are estimated using FIML (Full Information Maximum Likelihood) with site and trip models estimated simultaneously. All (HLM, FHT, and PK) but MRW used Poisson count models similar to those used in EPA's analysis; MRW used nested logit.

4. EPA Results Are Not Comparable to Those Found in Published Literature.

The comment suggests that EPA's per-fish valuation numbers are "many times those found in published literature." However, EPA found that the Agency's per-fish numbers were for the most part comparable to estimates in the published literature. See Chapter 4 in Sections B through H of the Regional Study Report (DCN # 6-0003). The comment refers to an article by Schuhmann (1998). Table 11 of Schuhmann gives "Mean Compensating Variation for a 25% Increase in Expected Catch: Boat Mode" He does not give a value per fish, so that comparing EPA's estimated values to those from Schuhmann is not straightforward.

5. Inappropriate Characterization of Benefit Timing

In response to public comments received on the proposed rule analysis, EPA incorporated timing of benefits in its analysis of recreational use benefits of the final 316(b) rule. See Section XII.D.2 of the 316 (b) rule preamble for detail.

The HRC method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see comment #316bEFR.005.035.

General/Benefit Transfer

APPENDIX A: BENEFITS TRANSFER APPROACH

Benefit-cost analysis (BCA) provides the basic framework for comparing benefits and costs of technologies available for minimizing AEI of CWIS. Benefits transfer employs fundamental and cost-effective methods for interpreting, summarizing and integrating available information into a new policy context. EPA utilizes the benefits transfer approach to estimate the benefits from reducing I&E at existing large power plants. This section highlights the appropriate steps involved in performing a benefits transfer using sound economic principles and discusses how EPA's methodology is flawed.

A.1 Benefits Transfer Method

The benefits transfer method provides an economical way to conduct research when a full-fledged study is not practical or necessary. This method applies results from a previous study to a new policy context, occasionally with adjustments. The benefits transfer approach economizes on the time and expense of primary data collection and developing new estimates.<FN29> However, the benefits transfer method still requires careful analysis and use of information. Benefits transfer methods require the use of basic microeconomic and econometric tools, as well as careful judgment and creativity.

Figure A.1.1 illustrates the five basic steps involved when performing benefits transfer. The figure orders the steps to show the conceptual relationship between them, although in practice these steps may be performed in a different order or simultaneously.

The three types of benefits-transfer approaches are the basic benefits transfer, benefits function transfer, and meta-analysis. In the basic benefits transfer, the researcher selects the best available study from a range of studies that use other valuation techniques (i.e., CV, travel-cost method, or RUM) and simply transfers the average value from that study to the new site. EPA employs the basic benefits transfer approach in their estimation. For example, EPA selects the McConnell and Strand (1994) marine fishing study and transfers their value for small gamefish in Florida to the Tampa Bay case study.

Figure A.1.1: Five Steps for Performing Benefits Transfer
[see hard copy for figure]

There are several advantages to using the benefits transfer method. The first and foremost advantage is cost-effectiveness. Although there are certainly costs associated with the benefits-transfer method, it is the least costly method for valuing natural resource services due to the utilization of existing studies and data. As the EPA states in their Guidelines, original studies and data are costly and time-consuming, and benefits transfer can reduce the resources required to evaluate the benefits and costs of a proposed policy. This advantage is particularly important in light of the demands of the regulatory process. Benefits transfer can be used as a "scoping" technique to identify where more analysis is necessary and where it is unproductive. Furthermore while the benefits transfer process is both logical and thorough, it is also flexible. A benefits transfer can evolve over time as additional or better quality information becomes available.

Estimates using the benefits-transfer method obviously are not as accurate as results from carefully conducted original studies because the benefits-transfer method does not use estimates for the specific study site. Instead, the researcher is constrained by the availability of appropriate original studies. The original studies used for transfer purposes generally are not designed for the transfer application, and finding suitable studies can be difficult. As Brookshire and Neill (1992) comment, the transfer can be no more reliable than the original estimates upon which it is based and can only magnify the uncertainty surrounding the original estimates. To ensure acceptable results, transfer analysis must identify a transfer study that is both suitable for the specific transfer and scientifically sound.

Such assumptions introduce subjectivity and uncertainty into the analysis. Competent benefit-cost analysts carefully document necessary assumptions and the sensitivity of estimates to such judgments. This documentation provides decision makers with full information about the sources and nature of uncertainties and allows them to evaluate the potential consequences of uncertainties in making their decisions. This view is a reminder that BCA provides decision-making tools, not decision-making rules.

A.2 Selecting a Study for Benefits Transfer: Similarity and Soundness

The benefits transfer process described above hinges on the selection of appropriate studies to use in the transfer. Evaluating original studies for use in a benefits-transfer context relies on two key criteria: similarity and soundness. <FN30> If either of these assumptions is not met, then using that study for a transfer can result in biased estimates.

A.2.1 Similarity

The first criterion requires the evaluation of the similarity of the original study for answering the questions posed in the transfer study. In order to determine the similarity of the original study for transfer, the researcher can compare many different aspects of the study. For example, the physical characteristics of a resource will affect its value. Attributes such as size, water quality, accessibility, and amenities all factor into the value of a site and should, therefore, be as similar as possible between the original study site and the transfer site. In addition, the services provided by the site are important. For water resources, these services may include boating, fishing, swimming, shoreline hiking, and water skiing. Resources that support more services are more likely to have higher values, so services should be comparable across the original study site and the transfer site.

The number and quality of available substitute sites will also affect the value that people place on a site. A change in quality at a site with many substitutes will result in a smaller change in value than for a site that is relatively unique. As an illustrative example, consider two extremes. Site A is a small lake in the middle of an area with 30 other identical lakes. Site B is a lake in an area with no other flat-water recreational opportunities. A decrease in quality at Site A will have a much smaller effect on users than a similar decrease in quality at Site B because Site A users can easily substitute another site. Therefore, a researcher should not transfer a value for a unique resource with few substitutes to a resource that has many available substitutes because the transfer value will overstate the benefits of improving the latter resource.

The characteristics of the users of a resource can also affect the value of that resource. Because consumers have different preferences, some consumers may value certain features of a resource differently than others will. Socioeconomic characteristics, along with a budget constraint, help explain individual preferences for particular resource services, which affects demand. For instance, age may determine whether an individual uses a natural resource for specific recreational purposes. Similarly, income may affect individuals' value for the services of a natural resource. Transfer values may be adjusted to reflect differences in characteristics between the transfer site and the injured site. However, these adjustments should have some empirical justification. In the past, many researchers have made adjustments based on ad hoc professional judgments. Decisions based on the analysts' discretion increase the potential for adjustment errors.

A.2.2 Soundness

The second criterion of the benefits-transfer approach requires that the study being transferred is scientifically sound. Several economists (Smith 1992; Brookshire 1992; Desvousges, Naughton, and Parsons 1992; McConnell 1992; and Boyle and Bergstrom 1992) recommend reviewing existing studies for their scientific soundness because existing studies have varying levels of quality. Because the benefits-transfer approach involves transferring the value for a different site from a previous study and applying it to a new site, the analyst also transfers the assumptions and flaws of the methodology in the previous study.<FN31> Three important components of scientific soundness are sampling protocols, response rates, and estimation technique.

The sampling protocol includes the definition of the target population, sample selection methodology, and sample size. The sample should be randomly drawn and should reflect the target population. Also, the target population should be empirically determined and documented. An adequate sample size is necessary to obtain reliable estimates (Lansing and Morgan 1971; Backstrom and Hursch-Cesar 1981). Studies need to demonstrate that the sample size is adequate to estimate the valuation models with sufficient precision. Failures in the sampling protocol can bias the results of the original study.

Response rate is the second important aspect of scientific soundness. To minimize the potential for nonresponse bias, analysts should select benefits-transfer studies that have a high response rate. Nonresponse bias refers to the bias that may result from failing to include the values of nonrespondents. The concern is that nonrespondents are somehow different from respondents, and those differences are not reflected in the study results. Because nonrespondents are a part of the relevant population, study results may not be representative when response rates are low. While no definite guidelines exist for response rates, NOAA has recommended a 70-percent response rate as the threshold for environmental valuation studies (59 Fed. Reg. 1183 [1994]). <FN 32>

The third component of scientific soundness is that the existing study should use valid and accepted estimation techniques. The results must be robust and consistent with basic economic principles of demand and utility theory. Values should not be transferred from studies lacking these general qualities because the weaknesses will be transferred to the benefit-cost analysis for the site.

Economists generally prefer preference data based on actual behavior rather than responses to hypothetical situations. For example, in the case of recreational fishing benefits, RUMs are the best technique for estimating consumer surplus for improvements in fish catch. If no acceptable RUM results are available, then a high-quality SP or CV study may be the next best alternative for obtaining reasonably good estimates of consumer surplus for recreational fishing. <FN 33> Nevertheless, an SP or CV study produces hypothetical use values, not use values based on actual behavior or market transactions. Consequently, use values from even a high-quality CV study should be calibrated whenever possible using information on actual behavior or market transactions, as recommended in the NOAA proposed NRDA regulations (59 Fed. Rag. 1983 [1994]). <FN 34>

EPA focuses on comparing the physical characteristics of the studies to each case study in their benefits transfer. However, there are other areas in which the studies used are not similar, such as those listed above. Furthermore, EPA selects studies to use in their benefits transfer that are not scientifically sound in terms of the response rate and estimation techniques, thereby violating the soundness criterion for benefits transfer. EPA should select better studies to use in their analysis and should take more care in analyzing those studies in terms of similarity and soundness. Hence, EPA's benefit estimates are biased.

A.3 Role of Uncertainty in Benefits Transfer

EPA fails to evaluate, quantify, or discuss uncertainty in their benefits transfer analysis. This section discusses uncertainty in benefits transfers in terms of:

-the impacts of uncertainty
-how to account for uncertainty.

In statistical analysis, the term uncertainty refers to the statistical reliability of estimates. It means that a range of likely results can be inferred from observed data, where some outcomes are more likely than others. While uncertainty is an inescapable aspect of quantitative analysis, that does not imply that results are inevitably vague or indeterminate. Instead, benefit estimates are most useful to decision makers when the causes of uncertainty are clearly identified and quantified.

A.3.1 Impacts of Uncertainty

Although uncertainty is intrinsic in all forms of empirical analysis, it is a particular concern in transfer studies. Benefits transfer requires the creative use of limited information. Thus, professional judgment and simplifying assumptions necessarily play a central role. Any such transfer study must be regarded as incomplete if it lacks a careful evaluation, quantification, and discussion of uncertainty. Quantifying uncertainty can help clarify the effects of various forms of uncertainty and help decision makers interpret and use transfer estimates appropriately.

A.3.2 Accounting for Uncertainty In Benefits Transfer

While sources of uncertainty can be classified and often assessed, they cannot be eliminated entirely. To reflect the inherent uncertainty in a benefits transfer study, analysts should carefully track and quantify the uncertainty in their analysis. The results can then be presented as the most likely range of effects and thus help decision makers to interpret and use the analysis appropriately.

Statistical models use the attributes of a sample to infer information about the attributes of the group as a whole. This information generally takes the form of coefficients estimated to show the relationship between a dependent variable (such as the number of fishing trips taken) and explanatory variables (such as distance to a fishing site). The estimated coefficient represents the estimate that is most likely to be true, given the data used. For example, suppose a simple travel-cost model estimates the following relationship between distance and number of per-capita trips:<FN35>

Number of per-capita trips = 10—0.2 * (distance to the site)

The estimate in this example is the coefficient —0.2. It is the most likely value of the true relationship between distance and per-capita trips, based on available data. Thus, in this simple example, we expect that people living five miles from the site will take, on average, nine trips (10— (0.2 x 5 miles)) to the site.

In addition to the estimated coefficient, models also estimate a standard error for that coefficient, which indicates how precise or "noisy" the estimate is. Using that standard error, analysts can calculate a confidence interval around the coefficient estimate that reflects the variability of the observed response relative to the variability of the explanatory variables. A confidence interval is the range of values within which some percentage—say 90 percent—of repeated studies would fall. Viewed in another way, a 90-percent confidence interval provides a range in which the true value would fall with 90-percent certainty. In this simplified example, the coefficient estimate is normally distributed with mean —0.2 and standard error 0.09. In this case, the 90-percent confidence interval for the coefficient would range from —0.05 to —0.35, implying that there is a 90-percent chance the actual relationship between distance and number of per-capita trips falls into that range.<FN36>

A.3.3 Using Monte Carlo Simulations In Benefits Transfer

Monte Carlo simulations provide a more rigorous approach to measuring uncertainty when using estimates derived from a number of parameters and values. A Monte Carlo simulation draws a large number of random samples from each of the underlying distributions of values and then calculates the corresponding combined values for each draw.<FN37> For example, in the Delaware case study, EPA uses estimates from more than one study to derive their 1 fish/trip values for species of small game fish and bottom fish. EPA transfers the uncertainties about the applicability of the estimates as well as the statistical uncertainty from the original studies to these values. Using a Monte Carlo simulation in their analysis would have alleviated some of this uncertainty.

A.4 Using Sensitivity Analysis in Benefits Transfer

A sensitivity analysis evaluates the effect of assumptions and analytical decisions on transferred values. With this type of analysis, estimates are calculated under a variety of sets of assumptions to deduce the effect of each set of assumptions on the final value. In this way, a sensitivity analysis helps distinguish between important and unimportant assumptions and results in selecting a set of assumptions that are both plausible and conservative in a meaningful sense.

Performing sensitivity analyses has several additional benefits. Determining which assumptions have a large effect on the estimate helps to identify areas where additional effort in either obtaining further information or conducting additional analysis is likely to be relatively cost-effective. Thus, sensitivity analyses may indicate where limited analytical resources can best be allocated to produce the greatest improvement in the quality of the estimates. In addition, a sensitivity analysis can help distinguish between results that rely primarily on data and results that rely primarily on professional judgment. While “bad” data are not necessarily superior to good judgment, the analyst should make clear to what degree results depend on assumptions rather than empirical information.

Footnotes

29 See Desvousges, Johnson, and Banzhaf (1998) for a recent, comprehensive discussion of transfer methods for environmental policy analysis

30 National Oceanic and Atmospheric Administration’s (NOAA’s) proposed natural resource damage assessment (NRDA) regulations list three basic issues that federal trustees should consider when selecting transfer values:

-comparability of the users and the natural resource and/or service being valued
-comparability of the change in quality or quantity of the resources and/or services
-the quality of the studies being transferred (59 Fed. Reg. 1148[1994]).

NOAA also recommends several questions for researchers to ask with respect to these three basic issues, but does not elaborate on these issues. Thus, NOAA does not provide any specific criteria that federal trustees must follow when using the benefits-transfer approach. As noted in Smith (1992), such critena are needed to produce more reliable natural resource damage estimates

31 In order to evaluate a study’s soundness, the study must be well documented. In some cases, studies cannot be used in benefits transfer simply because not enough information is available to properly evaluate it.

32 There is no statistical criterion for determining the minimum acceptable response rate. Researchers must incorporate well known techniques for maximizing response rates in designing and administering the survey. Regrettably, growth in direct marketing has had a negative effect on the maximum achievable response rate in any given area. Even if contacts do not respond fully to the survey, collecting minimal information on demographic characteristics of refusals can help control for possible response bias in subsequent analysis.

33 While a high-quality CV study may produce reliable use-value estimates, CV does not produce reliable estimates of nonuse values (i.e., values that people may have for the mere existence of natural resources that they do not use). See our comments on NOAA’s proposed NRDA regulations for more details (Desvousges et al. 1994).

34 Calibration requires data that matches intentions with actual purchases. There are many such studies for recreation and many in the marketing literature. In particular cases, it may be possible to identify a study that is sufficiently similar to the problem under consideration to assist in adjusting for hypothetical bias.

35 The example here has been dramatically oversimplified to assist in the explanation of statistical concepts. It does not reflect an actual model.

36 The 90-percent confidence interval for a normally distributed variable is calculated as the mean ± (1.645 x standard error). In this example, the confidence interval would be (—0.2) ± (1.645 x 0.09).

37 See Fishman (1996) and Halton (1970) for an introduction to Monte Carlo techniques. Most commercial statistical software packages include procedures that can be adapted for Monte Carlo analysis. In addition, spreadsheet programs such as Excel can perform random draws on normal distributions for simple Monte Carlo simulations.

38 The proposal discusses and dismisses hatchery-based offset in Chapter A-11 of the Facilities Benefits Case Studies document. Yet the method as proposed cannot avoid “hatchery-style restoration” because of the focus on individual species, rather than whole-ecosystem services.

39 Likely the majority of cases, as pointed out on page 17192 if of the Federal Register notice, Vol. 67, No. 68, April 9, 2002

40 In practice, it would likely be difficult or impossible to measure the specific restoration-site related increase in production. This is due to inherent natural variability, not to measurement weaknesses. This is another strong argument for

compliance by habitat provision, not by (scientifically noncredible and nonmeasurable) production of particular species.

EPA Response

This comment focuses on EPA's use of benefit transfer for the proposed rule analysis.
For the final Phase II 316b analysis, EPA has reduced its reliance on benefit transfer to estimate recreational fishing benefits. In addition, EPA no longer uses case studies of individual facilities. Instead, EPA has estimated regional models. For the recreational fishing analysis, benefit transfer is used for the inland region, and benefit function transfer is used for the North Atlantic region. EPA has estimated RUM models for all other coastal regions (Mid-Atlantic, South Atlantic, Gulf of Mexico, and California), and for the Great Lakes region. Where benefit transfer is used, EPA has followed generally accepted procedures, and has carefully applied benefit transfer methods.

For detail on the benefits transfer approach used at proposal, see response to comment #316bEFR.075.504.

For the North Atlantic region, EPA's benefit transfer uses the benefit function from the Hicks, et al., study recommended by several of those who commented as the most appropriate study for benefit transfer for the North Atlantic region. By using benefit function transfer, EPA was able to make appropriate adjustments to Hicks' model, to estimate values for relevant changes in catch rates. This benefit function transfer follows accepted methods and was performed carefully to provide the best available estimates of values for changes in catch rates for the North Atlantic region.

For the Inland region, EPA did a benefit transfer using values from several studies. EPA generally followed its Guidelines for Preparing Economic Analyses for benefits transfer (BT) in developing a benefits transfer approach for the Inland region. The steps were followed as recommended in the Guidelines when using BT: (1) describe the policy case; (2) identify existing, relevant studies; (3) review available studies for quality and applicability; (4) transfer the benefit estimates; and (5) address uncertainty. Further information on the methods EPA used to estimate recreational fishing benefits for the Inland region is provided in the regional study document prepared for the analysis for the final Phase II rule. See Chapter H4: Recreational Fishing (DCN #6-0003).

EPA agrees with the commenter that it is necessary to evaluate uncertainty in benefits transfer analysis. The Agency, however, disagrees that it failed to evaluate uncertainty. EPA carefully evaluated and discussed uncertainty in the uncertainty and limitation section in the recreational fishing benefits chapters. See the regional study document prepared for the analysis for the final Phase II rule (DCN #6-0003). The Agency, however, points out it is not always feasible to quantify uncertainty due to data limitation. When feasible, the Agency used the state-of-the-art approaches such as the Krinsky and Robb simulation method to quantify uncertainty (see Chapter A12, Non-use Meta-Analysis Methodology, in the regional study document for detail, DCN #6-0003).

Use of Replacement Costs (HRC and hatchery-based)

APPENDIX B: RESTORATION AND MITIGATION CONSIDERATIONS

Facilities may decide to undertake mitigation actions to offset the potential losses from I&E. The HRC can be used to help determine the appropriate scale of the mitigation options. However, it is important to not confuse this mitigation scaling with measuring the benefits of the mitigation. As noted in this report, appropriate economic measures of benefits require that they be based on the willingness-to-pay principle.

Conceptually, HRC is based on sound scientific principles and could play an important role in evaluating mitigation opportunities. It is also useful to consider HRC as part of larger regulatory programs such as Integrated Coastal Management (ICM) and Integrated Watershed Management (IWM). ICM is:

a process by which rational decisions are made concerning the conservation and sustainable use of coastal and ocean resources and space. The process is designed to overcome the fragmentation inherent in single-sector management approaches … ICM is grounded in the concept that the management of coastal and ocean resources and space should be as fully integrated as are the interconnected ecosystems making up the coastal and ocean realms … if a degraded coastal habitat affects the attainment of fisheries management goals, management of that habitat should be within the ambit of an integrated coastal management process (Cicin-Sain and Knecht 1998).

Similarly, IWM is:

...trans-media environmental management—management using the "ecosystem" concept… born of experience showing that single-medium or single-source management was not successful… (Heathcote 1998).

Although the HRC method in concept is useful for evaluating mitigation measures on a site-specific basis, the method in practice, as presented by EPA in the 316(b) proposal, is intensely flawed. Specific areas of concern are enumerated and discussed below.

1. The proposed rule should clarify that HRC would only be appropriate as a mitigation approach. In addition, it should clarify the revised objectives. As proposed, the objectives and compliance standards are vague and contradictory.

The proposal (as described in Section VII of the proposal published in the Federal Register) implies that restoration to offset losses would have the objectives of maintaining "fish and shellfish at a level comparable to that which you would achieve were you to implement the requirements of Section 125.94" and maintaining "biotic community structure and function" at a level "comparable or substantially similar to that which would be achieved through Section 125.94(b) or (c)." The proposal does not define "fish and shellfish," "biotic community structure and function," or "comparable or substantially similar." Elsewhere (in the Summary of Alternative Regulatory Options), the proposal seems to define “maintaining fish and shellfish” as “demonstration of comparable performance for species of concern.” The latter application (species-by-species offset valuation of restoration methods) is applied in the case studies provided with the proposal.

It is important to understand that individual species and biotic community structure and function are quite separate and distinct aspects of the ecosystem. Populations of individual species are highly variable in space and time, while ecosystem structure and function are higher-level properties and tend to be more stable (Odum 1983).

Restoration is not a meaningful concept if the objective is to replace or maintain precise species-by-species equality in a waterbody. To do this would simply mean that the exact number of individuals of each species and life stage lost via the CWIS would need to be replaced. In this case, restoration is an effective option only if the habitat required to “produce” the desired specific number of individuals of the desired particular species is known and can be provided. For most aquatic organisms and nearly all fish species, habitat is not so specific, nor can the productive capacity of habitat be known so specifically.

However, from an ecological perspective it may be more important to maintain the biological processes of the waterbody than the particular species relationships. For example, many, if not most, predatory fish species are willing to feed on a wide array of forage fish species as long as sufficient nutrition is provided by the forage base (Ryder and Kerr 1978, Gerking 1994). If the major impact of a particular CWIS is on the forage base of the waterbody, restoration options that would produce sufficient forage to offset the losses (without regard to species composition) would have high ecological value and should be encouraged in the rule.

The most effective way for the proposal to accommodate these ecological realities would be to clarify and specify restoration option objectives. In cases where CWIS effects are of concern because of individual species losses, the rule should specify that restoration options (and associated monitoring requirements) would focus on those species with the attendant technical needs for habitat-specific “production” and demonstration of same (acknowledging that for many species restoration other than individual replacement [as by hatchery] is difficult or impossible given the present state-of-the-science) <FN38> In cases where CWIS effects are of concern at the level of trophic interactions, <FN39> the rule should encourage restoration with monitoring requirements that specify appropriate, trophic-level (vs. individual species) demonstration thresholds. It is in the latter case that restoration alternatives are particularly applicable, both for their ecological usefulness and for their effectiveness in evaluating mitigation.

2. The proposed rule should be made consistent with the technical foundations of the HRC Method. As proposed, the language of the rule is highly inconsistent with the scientific basis of the HRC. This inconsistency makes it impossible to apply the HRC for compliance purposes.

The proposal (Section VII of the Federal Register notice) specifies the maintenance of “fish and shellfish” as a goal. Elsewhere (for example, on page 17190 of the Federal Register notice), the rule seems to equate “fish and shellfish” with particular species. On page 17190, bullet-point descriptions of CWIS impacts refer to “...aquatic species present...,” “...ages and life stages of aquatic species...,” “...species’ exposure...,” and (in two places) “...impacted species...” This equation of “fish and shellfish” with I&E losses is carried to the HRC methodology, which establishes that the restoration area be scaled specifically to species and loss levels associated with I&E.

This narrow focus on I&E is incompatible with the ecosystem approach on which the HRC must be based if it is to be implemented successfully. First, the ecosystem production capacity of particular habitats for particular species is known only within very broad bounds, and not known at all for many coastal and estuarine species. Second, the enormous year-to-year variability in populations and year classes of many species of fish and shellfish, and the high experimental uncertainty associated with monitoring, make it highly unlikely that a one-to-one production-to-loss goal could be established at a level beyond several orders of magnitude. Finally, whole-ecosystem restoration can provide the potential for individual species production, and indeed the likelihood that over the long term (on the order of decades), production will occur at specified levels. But it is well beyond the present capabilities of human beings to manage whole ecosystems or entire habitats to produce specific species in specific numbers. Indeed, the U.S. Fish and Wildlife Service now recognizes this in their endangered species management. The Service recognizes the need for:

… a transition from reactive species-by-species management to the generally more productive ecosystem approach… (FWS 2002)

Because habitat productivity of specific species in the pool of I&E fish cannot be known precisely or controlled with any certainty, the HRC method should not be applied as if it were possible to do so. Rather, the HRC method should be applied so as to generate the ecosystem potential to produce sufficient fish (of particular species) or sufficient resource services (for example, of a particular trophic level) to offset losses.

This application of the HRC methodology would lead to very different mitigation decisions. These thresholds would be characteristics of the restored habitat and NOT attempted measures of species production. With this shift in the mitigation concept, the HRC could be a useful tool for managing l&E in an integrated fashion, compatible with coastal and fresh water ecosystems.

3. Habitat restoration should be the focus of HRC in mitigation.

Chapter A11 of the Existing Facilities Benefits Case Studies (“A11” or “Chapter A11”) presents a brief sketch of how the HRC method is to be applied. The most fundamental step is at A11-2.l, “Quantify I&E Losses by Species.” The remaining steps of the method (and the restoration cost itself) are all scaled to the I&E loss values. The habitat to be restored is scaled specifically to produce the precise number of individuals lost per species per year (A11-2.6), and the total restoration is to be scaled precisely to offset losses of all I&E species (A11-2.6, paragraph 2).

Consider what would happen if a restoration project were to succeed in producing specifically, on an annual basis, the number of individuals of a species necessary to assume offset for I&E. The local subpopulation of that species would grow by the difference. The increased subpopulation would contribute proportionally to the I&E pool, yielding higher estimates of restoration required. Each increment of restoration would be followed by an incremental increase in losses, leading to an increase in necessary restoration, ad infinitum.<FN40>

No rational environmental manager of a regulated facility would adopt such a method, and no facility could in theory comply over the long term. This fundamental flaw in the HRC should be corrected before the method is proposed further.

4. The application of HRC in the case studies errors in these methods lead to grossly inflated offset cost estimates and should be corrected.

The Brayton Point case study is presented as an example of a full-scale application of the HRC methodology. The severe (fatal) flaws from a biological perspective, not to mention the inappropriate theoretical foundations, revealed in this case study are:

-Abundance is proposed as a surrogate for production to estimate restoration habitat value (F5-5, Step 5, page F5-8). It is a well-known fact of ecology that abundance must always underestimate production by a large amount. This is simply an artifact of energy flow, the foundation for all life, and the biological interactions by which organisms live. Measures of standing stock cannot be used to estimate production, as annual stock-recruitment relationships are highly variable in fisheries (Sissenwine 1984). The standing stock cannot effectively be used to account for the density-dependent and —independent variables that control compensation in fish stocks. As such, it will underestimate or create an erroneous estimate of production. Therefore, applying standing stock in the way it is describe here would assure that costs estimated by this method always grossly overestimate restoration requirements, because habitat productivity will always be grossly overestimated. The proposal should be revised to reflect this scientific reality, and possibly incorporate the potential to relate productivity to standing stock using factors developed in the technical literature or with site-specific data. The erroneous assumption specified here as “necessary given the limited amount of quantitative data” (F5-5, Step 5, second paragraph) cannot be used in this context.

-Implementation costs as estimated here are too simplistic (and inflated) to be useful. The basic restoration cost is estimated from a proposal to replant seagrass in three tiny (16 square meters) parcels. It is inappropriate and counterproductive to scale up from this proposal (at $93,000) to a much larger project, and the other cost components in this example are similarly estimated poorly. Table F5-4 illustrates clearly the effect of this caricature approach to cost estimation. For example, for tautog (impinged and entrained at a rate of 30,000 age 1 equivalents per year), nearly $1,000,000,000 annualized costs are necessary to offset the losses. Ignoring discounting, and assuming 30 years of losses at 30,000 fish per year, 900,000 year-i equivalent tautog are lost. Dividing the $1,000,000,000 by 900,000 fish yields a cost of over $1,000 per individual year-i tautog! This value is so divorced from reality as to be ludicrous. This is particularly true since the HRC method as proposed specifically prohibits the party undertaking the restoration from claiming any explicit “credit” for non l&E species produced, or for ancillary ecosystem benefits arising from the restoration project. The method should be revised to more completely capture all the relevant effects of restoration projects and much more effectively estimate the costs.

-Relative time is not accounted for accurately in the offset comparison. Specifically, a successful habitat restoration provides ecosystem values essentially in perpetuity. The life span of a generating station is on the order of decades. Accurate comparison of restoration habitat gains (in perpetuity) vs. CWIS losses (over decades) would in all cases demonstrate clearly the usefulness of effective habitat restoration as a means of mitigation. This is in fact one of the central features of habitat restoration—it is forever. This ecological (and valuation) reality should be reflected in the relevant calculations. Once again to provide a simplistic example (i.e., without accounting for discounting), consider the 900,000 tautog lost over 30 years as assumed in the bullet immediately above. Under the reasonable assumption that CWIS losses then cease but artificial reef production continues (see Table F5-4), the size of the reef needed to offset 30 years of CWIS losses would shrink considerably, as would the restoration costs. The HRC method for cost comparison should be revised to accurately reflect the differential time scales for restoration (long-term, essentially perpetual) vs. station life (short-term and finite).

EPA Response

First, regarding the commenter's discussion of restoration in general, EPA concurs that restoration should consider ecological processes. EPA also believes that restoration, as a concept, can include species-by-species equality.

Under the final rule, EPA allows use of restoration measures to minimize or to help to minimize adverse environmental impacts deriving from impingement and entrainment of aquatic organisms.

The final rule does not require the use of any particular method during the development of restoration measures. See EPA's response to comment 316bEFR.312.006 for additional discussion.

Second, regarding the use of the habitat-based replacement cost (HRC) method specifically, EPA concurs with the commenter that the HRC method is based on sound scientific principles and has value as a restoration scaling tool. However, the HRC method is not a part of the 316b rule, as the commenter apparently assumes. For additional information on the HRC method, please see the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003).

EPA concurs that abundance and productivity are important ecological concepts in the context of the HRC method. In restoration scaling it is important to use similar methodologies to convert abundance to productivity in both the loss (impingement and entrainment) and gain (habitat production) calculations. The Brayton Point example presented at proposal converted both losses and gains to age 1 equivalents to account for these differences.

Regarding implementation costs, the commenter assumes that linear scaling of costs in an HRC analysis is inappropriate. The assumption would be valid if there were recognized "economies of scale" (i.e., the more the restoration, the cheaper it gets). However, in the Brayton Point example, SAV restoration, artificial reef emplacement, and fish passageways require materials that are expected to vary linearly with the scale of implementation.

The annualized cost estimate discussed by the commenter is an alternative representation of the cost so that restoration costs could be compared with annualized cost estimates of alternative technologies to reduce I&E. However, as noted in the document on the HRC method (DCN # 6-1003), accurate and complete measurement of annual variation in I&E losses is often unattainable, limiting the utility of annualizing HRC.

The commenter is correct that the HRC analyses presented at proposal take no account of potential production of non-I&E species or any ancillary benefits of restoration. However, there is nothing in the HRC method that eliminates consideration of these other benefits if desired for a particular restoration objective.

The commenter is correct that if production increases from restoration actions are realized in perpetuity, in each year when the facility is not in operation there would be an increase in fish production that is not offsetting any loss. As noted in the document on the HRC method (DCN # 6-1003), the required scale of implementation should equate the expected present value increase in I&E with the expected present value of I&E losses over the period that a plant is in operation. Unfortunately, in the case of the HRC analyses for the 316b Phase 2 proposal, the expected facility operating lifetimes were unknown.

Finally, EPA concurs with the commenter that relative time should be accounted for and discounting is necessary when using the HRC method.

General/Benefit Transfer

APPENDIX C: SUMMARY OF FISHING STUDIES

Table C.1: Summary of Fishing Studies
[see hard copy for table]

EPA Response

EPA noted this submission and took these studies into consideration in developing a benefits transfer approach for valuing recreational fishing benefits for the final 316(b) regulation.

EPA, however, has reduced its reliance on benefit transfer to estimate recreational fishing benefits for the final Phase II 316b analysis. For the recreational fishing analysis, benefit transfer is used for the inland region, and benefit function transfer is used for the North Atlantic region. EPA has estimated RUM models for all other coastal regions (Mid-Atlantic, South Atlantic, Gulf of Mexico, and California), and for the Great Lakes region. Where benefit transfer is used, EPA followed generally accepted procedures, and has carefully applied benefit transfer methods. Further information on the benefits transfer method EPA used to estimate recreational fishing benefits for the Inland region is provided in of the final Phase II Regional Study Document (DCN #6-0003). See Chapter H4: Recreational Fishing.

Extrapolation Methods

Review of the Biological Validity of EPA's Methods for Baseline Loss Estimates at Case Study Facilities and Extrapolation to National Estimates

Prepared for: Utility Water Act Group

Prepared by: K. J. Hartman, West Virginia University, Morgantown, WV

I. Introduction

This report reviews EPA's methodology for estimating case-study and baseline biological losses in its report entitled "Case Study Analysis for the Proposed Section 316(b) Phase II Existing Rule (CSA)." (DCN 4-0003). The objective of this review is to assess the validity of EPA's extrapolation methodology given what is known about factors that limit distribution of species (e.g., salinity, dissolved oxygen, water temperature, natural distribution), and to comment on the effect of identified errors on EPA's estimates of impingement and entrainment (I&E) and resulting national baseline losses. The primary documents examined as part of this review were Chapter C2 (Summary of Case Study Results) of EPA's Economic and Benefits Analysis for the Proposed Section 316(b) Phase II Existing Facility Rule (EBA), and Chapters B3, C3, D3, and H3 (Evaluation of I&E Data for the Delaware Estuary, Ohio River, Tampa Bay, and Great Lakes Case Study Facilities) of the CSA.

This review does not include 1) an assessment of the validity of the entrainment and impingement data EPA used, 2) an assessment of EPA's estimates of pounds lost to the fishery, age-i equivalents, and production foregone, or 3) an assessment of benefit transfer techniques applied by EPA. Assessments of the validity of EPA's assumptions regarding entrainment survival rate estimates, and the validity of EPA's random utility model estimates, habitat replacement cost estimates, and societal revealed preference estimates (which factor into EPA's national baseline estimates) also are beyond the scope of this review. Other reviewers of EPA's CSA and EBA reports are addressing the validity of these estimates, methods and assumptions.

The remainder of this report is organized into two main parts. Section II discusses the validity of extrapolations among case studies and in-scope facilities on the basis of distributional biology and habitat characteristics at the case study facilities relative to in-scope facilities on the same general water body type, as well as temporal issues raised by EPA's assumptions. Section III describes, for each case study, how EPA's methods and assumptions consistently overestimate biological losses, and thereby lead to erroneous national baseline estimates.

II. Biological Aspects of EPA's Methodology

EPA chose to conduct a case study that relies on extrapolations of impingement and entrainment from a handful of case study facilities to in-scope facilities within a waterbody type. EPA identified five general waterbody types (rivers and streams, lakes and reservoirs, the Great Lakes, oceans, and estuaries). From these five waterbody types EPA selected eight case studies from which they estimated impingement and entrainment and used these estimates to further estimate impingement and entrainment for all facilities with 50 million gallons per day (MGD) or greater within a waterbody type.

For example, EPA selected the Delaware Bay as a case study to represent non-Gulf estuaries (apparently a subset of the estuaries waterbody type). Within Delaware Bay EPA identified four power plants (Salem, Hope Creek, Edge Moor, and Deepwater) and a number of other facilities that use Delaware Bay for cooling water (see CSA, Figure B 1-2). EPA decided to use only impingement and entrainment estimates from the Salem plant for estimates in Delaware Bay. However, engineering improvements at Salem were not in operation at the other three plants so EPA recalculated impingement and entrainment at Salem assuming no entrainment survival and then applied these estimates to the other three facilities (in-scope facilities) based on impingement and entrainment per flow in MGD:

[see hard copy for equations]

Where I and E represent impingement and entrainment and MGD is plant flow for in-scope facilities i or Salem, respectively.

In a similar manner, EPA used I & E estimates from the J. R. Whiting Generating Station, located on Lake Erie, to extrapolate predicted I & E for all Great Lakes facilities. From a purely statistical point of view, such extrapolations might produce unbiased estimates of I & E losses at other facilities provided that the temporal, physical, and biological characteristics of data used in the case study facilities is representative and unbiased relative to the in-scope facilities to which the data are extrapolated.

The temporal, physical, and biological characteristics of relevance to the appropriateness of the extrapolation include the following questions:

-Do differences in life history patterns or density of organisms influence the applicability of extrapolations?

-Do the locations of plants within their systems (e.g., relative to the salt wedge, water depth, or sources of life stages susceptible to I&E {such as spawning and nursery areas}, etc.) significantly affect the applicability of extrapolations?

-Are there substantial differences in species assemblages and densities of organisms between the case study plant locations and the locations of other plants within a waterbody type?

-Have biotic communities changed greatly since the time when in-scope data were collected?

-Are the years in which case study data were collected representative of typical conditions for the case study plants and in-scope applications?

To examine these questions we will use specific case study examples and attempt to relate them to documented information that can provide a measure of the extent of the applicability of EPA's methodology for estimating nationwide I&E losses from the case studies.

A. Estuary — Non Gulf Waterbody Type.

Background information.

This waterbody type extrapolation was based on a single reference facility — Salem Generating Station (Salem) - and applied to all in-scope facilities except Salem, Brayton Point, Contra Costa and Pittsburgh facilities, for which EPA accounted separately. Although EPA had data from a small number of other estuary non-gulf plants - (Brayton Point, Pittsburgh, and Contra Costa), it apparently found all, but the Salem data lacking. Furthermore, EPA ignored the extensive databases available from the power plants on the Chesapeake Bay and Hudson River. EPA therefore chose to apply the I&E data from Salem to all in-scope facilities. Essentially, EPA selected Salem in mid-Delaware Bay to represent the non-gulf estuary portion of the estuary waterbody type.

Salem is located at RKM 80, downriver of all other in-scope facilities in the EPA's case study. EPA used impingement and entrainment data for Salem from 1978-95 and 1997-98 for their extrapolation baseline. According to EPA, data from other non-gulf estuary plants was sufficiently flawed to preclude its use in their estimates. EPA used I & E loss estimates from Salem to represent losses at Salem assuming plant-derived estimates of impingement survival, but no entrainment survival. However, EPA recalculated the plant estimates of impingement at Salem assuming no survival and applied these flow-adjusted estimates of I & E to other in-scope facilities within Delaware Bay. These other in-scope plants are located from RKM 96 to RM 128 and are all located upriver of Salem in lower salinity waters. The higher salinity water at Salem compared to the in-scope extrapolation plants means that species found at Salem in I & E may be more or less affected at other in-scope facilities purely on the basis of species-specific salinity preferences. This represents a serious source of error for the case study and for extrapolations to the non-gulf estuary plants within the estuary water body type. To apply Salem I&E numbers to any other facility without similar biological (e.g. species composition and density) and chemical (i.e., salinity) regimes is inappropriate.

Biological issues

Extrapolating Salem loss estimates to other in-scope facilities is a potentially serious error in application due to differences in both species distributions and densities across locations of in-scope facilities. Salem is located in the salinity transition zone and area of the turbidity maxima on the Delaware Estuary. Assuming no survival, most of the estimated impingement of fish (i.e., age-i equivalents) from the Salem plant, consist of bay anchovy (Anchoa mitchilli), followed by species such as white perch (Morone americana), blue crab (Callinectes sapidus), spot (Leiostomus xanthurus), and Atlantic croaker (Micropogonias undulatus) (CSA, Table B3-3). EPA's estimated entrainment at Salem assuming 100 percent through plant mortality consists mainly of bay anchovy (97%), followed by Atlantic croaker, weakfish (Cynoscion regalis), spot, white perch, and striped bass (Morone saxatilis) (CSA, Table B3-7). When these estimates are used in EPA's EBA, benefits are identified as greatest for spot, striped bass, Atlantic croaker, and weakfish. Most biological losses to which EPA ascribes economic value are generated from extrapolation of entrainment of early life stages (ELS) of these species to numbers of fish that might have later contributed to recreational or commercial fisheries. Thus, about five species represent most of EPA's estimated losses and economic costs associated with the Salem facility. Therefore, these five species (bay anchovy, spot, striped bass, croaker, and weakfish) will form the basis of this analysis of the representativeness of extrapolating Salem I & E estimates to other facilities given species-specific differences in distribution and density within the Delaware Estuary.

Water Quality Conditions Influencing Fish Distributions

Water quality or environmental factors such as salinity, temperature, and dissolved oxygen can combine to influence the distributions of fish and ELS within the estuary. Thus, the location of in-scope facilities relative to these conditions, and the conditions experienced at Salem, will influence the representativeness of extrapolations from Salem to other in-scope facilities. Among these factors, temperature and dissolved oxygen appear to be less of an influence in this system relative to other estuaries, due to the high degree of mixing that produces more homothermic conditions within the estuary and improvements in water quality resulting in minimum summer dissolved oxygen (D.O.) levels of generally above 5.0 mg/l (Marino et al. 1991).

As with many other estuaries, salinity differences within the Delaware Estuary influence the distribution and abundance of fish species at these sites and influence the accuracy of extrapolations (Monaco et al. 1992; Weisburg and Burton 1993; Able and Fahey 1998; Able et al. 2001). Information presented as part of Salem's permit renewal documentation depicts the salinity conditions in the Delaware Bay under high and low flow conditions (Figure 1). Near Artificial Island, salinity ranges from 1-2 ppt during high flow years to 10-15 ppt during low flow years. Most of the in-scope facilities are located upriver of Salem in areas of lower average salinity. Salinity range for these facilities is typically 0-2 ppt. As the following discussion shows, the density and distribution of key fish species vary with salinity, thus the potential applicability of I&E data generated at Salem to other in-scope facilities is questionable. Below we examine how species-specific differences in distributions may influence these extrapolations for several key species identified above.

Key Species:

Bay anchovy

Bay anchovy distributions in estuaries are closely linked to salinity distributions. In the Chesapeake Bay, highest egg densities were found in salinities of 13-15 ppt, with a second peak observed at 17-23 ppt (Houde & Zastrow 1991). Houde & Zastrow (1991) reported that egg viability may decline at saliities below 8 ppt, while juvenile anchovy were found to prefer salinity ranges of 9-30 ppt. These data suggest that anchovy life stages generally decline in abundance with declining salinity. In fact, PSEG's (1999) studies of anchovy egg and larval distributions in Delaware Bay verify that densities of ELS's and young anchovy are much higher down-bay from Salem and much less abundant upriver of Salem. These distributions suggest that extrapolation of Salem bay anchovy I & E to other in-scope facilities within Delaware Bay overemphasizes the impact that in-scope facilities have upon this species.

Atlantic Croaker

Atlantic croaker has shown widely varying abundances in Delaware Bay. No eggs were collected from Delaware River (PSEG 1984; PSEG 1999), which is in keeping with their life history of marine spawning and estuarine recruitment of larvae and very small juveniles (Homer and Mihursky 199 1). During 1979, no larvae were collected from RKM 0— 117, but in 1980, larvae were collected from

September to December. Larval maps for Delaware Bay in 1980 show larvae abundance sometimes higher or lower than Salem during October to November (Figures 4-9 to 4-il, PSEG 1984). The general larval distribution pattern suggests Salem is not representative of upriver conditions to which it is extrapolated.

Juvenile croaker was most abundant from RKM 0-80 during October 1980— January 1981. During 1979 (Figure 4-5, PSEG 1984) and 1980 (Figure 4-6, PSEG 1984) in Delaware Bay, age-0+ croakers were more abundant below RKM 80 and RKM 32, respectively. Thus, if the distributional patterns observed during 1979-80 are typical, age-0 croaker are likely less impacted upriver and more impacted downriver than at Salem. Given that there were no in-scope facilities downriver of Salem, extrapolations of Salem impingement data to other in-scope facilities within the Delaware would represent an overestimate of losses. Similar overestimates would be expected for other facilities in non-gulf estuaries when EPA applies the Salem-derived estuary values to plants located in lower salinity waters than Salem for extrapolation of waterbody type and nationwide estimates of losses.

Weakfish

Weakfish are found throughout the Delaware Bay estuary from RKM 0— 117 (PSEG 1999). However, larval and juvenile abundances appear to be higher near the case study location (Salem) than in the vicinity of the in-scope facilities up-bay, apparently related to salinity or some other factor (PSEG 1984). Thus, extrapolation of weakfish I&E data to the in-scope facilities (all up-bay of Salem) likely will represent an overestimate of the I&E losses to weakfish in those facilities.

From 1979 to 1982 larval data suggest that larval abundance is lower upriver of Salem than at Salem. In 1979, postlarvae were of similar abundance from RKM 48 to 117, but show up in high densities somewhat earlier in the year at RKM 48-97. Thus, Salem data may overestimate losses that do not occur upriver of Salem (shorter duration of peaks and lower peaks in density). In 1980, postlarvae were more abundant, and occurred for a longer period, south of RKM 80-97. Peak densities occurred in RKM 80-97, but dropped off to near zero north of RKM 80-97. These same trends were observed in 1981 and 1982 with no larvae north of the region from 80-97 RKM. Thus, it appears Salem entrainment estimates will overestimate losses to weakfish when extrapolated to in-scope facilities located from RKM 80-97 (see, Figures 4-113 to 4-116 in PSEG 1984).

Bottom trawl data for age-0+ weakfish also suggest that data extrapolation from Salem to facilities up-bay will overestimate potential impact to weakfish. Age-0+ weakfish catches differed very little across river regions in 1979 during trawl surveys (PSEG 1984). However, from 1980 to 1982, there were similar spatial and temporal patterns in catch of age-0+ weakfish in bottom trawls, and much higher catches, of weakfish in bottom trawis in RKM 0—80 than upriver. Thus, the preponderance of data suggest that during years of high I&E of weakfish, extrapolation of Salem's I & E data to the in-scope facilities (all up-bay of Salem) will represent an overestimate of potential weakfish losses due to lower density of weakfish near the other in-scope facilities within Delaware Bay.

Striped Bass

Most of EPA's estimated losses at Salem for striped bass appear to occur as entrainment so evaluation of the applicability of extrapolations based on distributions should focus on striped bass ELS. Distributions of young striped bass appear to be governed somewhat by salinity. Striped bass spawning takes place near the freshwater interface (Setzler-Hamilton and Hall 1991) and larval striped bass typically are found in low salinity waters (Setzler-Hamilton and Hall 1991), despite reports of higher larval survival at 10 ppt (Morgan et al. 1981). As with other key species for the non-gulf estuary case study, PSEG's (1984 and 1999) studies provide the best information on which to evaluate the distribution of striped bass relative to the case study and in-scope facilities for extrapolations.

Recent studies completed by PSEG (1999) suggest that the majority of striped bass spawning in the Delaware River occurs in areas upriver of Salem. PSEG's (1984) studies reveal that in 1979 larvae were found in May-June in RKM 80 to RKM 117 (Figure 4-5, PSEG 1999). Similar results were observed in 1980. A study of egg and larval striped bass densities suggests that during 1972-1978, early life stages of striped bass were generally more abundant in the regions upriver of Salem (Weisburg and Burton 1993). If this is the case, densities of striped bass larvae may be more abundant upriver of Salem and hence, extrapolation of striped bass estimates from Salem to the other in-scope facilities may result in additional errors in EPA's calculations.

Spot

Spot are reported to metamorphose to the juvenile stage and become demersal prior to recruitment to estuarine nursery areas (PSEG 1999). Within the estuary, early juveniles appear to favor shallow water with muddy bottoms and low salinity (Dawson 1958; PSEG 1999), while later juveniles appear to be distributed in lower stations with higher salinity (Rogers et al. 1984).

In EPA's estimates of age-i equivalent losses, most of the losses for spot are attributed to entrainment. Entrainment losses for spot are inflated by just a few years of data. During the 19-year data series, only four times did the annual estimate exceed the 19-year average of 22.6 million age-i equivalent spot. In 1980, 1982, 1989, and 1995 estimated entrainment exceeded the average levels, ranging from 25.9 to 183.3 million (CSA, Table B3-8). Obviously, most of the "average" entrainment losses estimated by EPA occurred during a relatively few periods. This high variability in estimated entrainment, its significant impact in extrapolations, and the great likelihood that site-specific factors strongly influence I&E for this species, suggests that accurate estimates of I&E losses for spot will require sitespecific estimates of I&E and not estimates based on flow extrapolation methodology. Failure to incorporate site-specific estimates of I&E losses for species with such variable abundance has resulted in a great amount of uncertainty in EPA's estimates for the species and case study.

Water body extrapolations

Due to the reliance of the non-gulf estuary extrapolations on data from Salem, and differences in salinity at estuarine plants throughout the East coast of the U.S., the EPA's estimates of losses for the non-gulf waterbody type are biased. Many of the issues related to applying Salem estimates to the other in-scope Delaware Bay plants that were located in lower average salinity, apply to other estuarine plants. For example, in Chesapeake Bay the Calvert Cliffs facility is located in a similar salinity regiment as at Salem (Cory and Nauman 1970). However, many other stations (such as Chalk Point, MD, etc.) are located near freshwater and hence may have lower expected losses for bay anchovy, weakfish, spot, and croaker based solely upon salinity-related distributional patterns for key species. In the Hudson River estuary, the Albany, Danskammer Point, Bowline, Lovett, Indian Point and Roseton plants are all generally found in freshwater and the 59th Street Plant is located in higher salinity water than is found at Salem (Cooper et al. 1988; Hutchinson 1988). Given the influence that salinity has on distribution patterns of some estuarine fishes (Monaco et al. 1992; Weisburg and Burton 1993; Able and Fahey 1998; Able et al. 2001), it is likely that application of loss estimates derived from Salem for the non-gulf waterbody type inflict serious bias when applied to other non-gulf estuaries along the U.S. Atlantic coast. Such bias is likely even greater in applying Salem estimates to estuarine facilities on the U.S. Pacific coast with grossly different species assemblages and productivity than the Atlantic estuaries.

B. Great Lakes Waterbody Type

Background information

For the Great Lakes waterbody type, EPA used I&E data from the J. R. Whiting facility, located in western Lake Erie, to represent all facilities in the Great Lakes. This method may produce accurate results if the I&E rates used from J. R. Whiting are representative of all -- or even most -- of the CWIS facilities within the Great Lakes waterbody type. However, available data on relative productivity and species compositional changes among the Great Lakes (discussed below) do not appear to concur with that assumption. Western Lake Erie is the most productive portion of the most productive system in the Great Lakes. As such, extrapolation of J. R. Whiting loss estimates to all other flows within the Great Lakes waterbody type will result in a serious overestimate of I & E losses in these systems.

Biological Issues

A comparison of productivity and species assemblages between the J. R. Whiting site and the sites of other Great Lakes facilities demonstrates why the Whiting extrapolation seriously overestimates Great Lakes I&E losses. First, western Lake Erie, where J. R. Whiting is located, is the area of highest biological productivity in the Great Lakes (Wallen & Botek 1984; Jude & Leach 1993). The high productivity of Lake Erie relative to the other lakes has been documented through primary production estimates (Jude & Leach 1993) as well as earlier estimates of possible I&E in the Great Lakes (Kelso & Milburn 1979).

Lake Erie is the most productive of the Great Lakes (5.0 mg/rn3 mean chlorophyll a), followed by Lake Ontario (3.8 mg/m3 mean chlorophyll a), Lake Michigan (2.1 mg/m3 mean chlorophyll a), Lake Huron and Lake Superior (1.0 mg/rn3 mean chlorophyll a) (Jude & Leach 1993). The ranking of Lake Erie as most productive of the lakes is mirrored in an earlier estimate of I&E for Great Lakes facilities. Kelso & Milburn (1979) reported that entrainment estimates were highest in Lake Erie (588 million or 68.7% of total) despite the fact that Erie represented only 20.6% of the electricity produced from power plants on the Great Lakes. One way of examining whether the use of J. R. Whiting is representative of I&E losses from other sites in the Great Lakes is to examine the estimated I&E from Kelso & Milburn (1979) relative to electrical generation (megawatt of electricity, or Mwe). Thus, I&E / Mwe provides an index of differences in I&E loss associated with lake-specific differences in fish communities and productivity.

Overall projected I & £ rates per electricity produced were highest in the Lake Erie estimates. The other four Great Lakes and the Detroit/St. Clair system all had similar or lower I&E contributions relative to their electrical generation (Table 1). J. R. Whiting is situated in the most productive part of the most productive Great Lake, and this fact is reflected in higher I & E values than found in other Great Lakes systems. Thus, use of the I&E data for J. R. Whiting to represent all facilities in the Great Lakes waterbody type necessarily will lead to elevated estimates of the impact and costs associated with CWIS in those systems.

[see hard copy for table]

In addition to differences in productivity and resulting differences in I&E among Great Lakes facilities, data reported by Kelso and Milburn (1979) indicate that larval species groupings differ substantially among the various Great Lakes and the Detroit River/ Lake St. Clair system. These differences in species groupings will result in differences in impingement and entrainment among the Great Lakes due to species-specific differences in life history, density, behavior, etc.

For example, differences in species groupings will also affect EPA's economic analysis because of differences in the value of species affected. In Lake Erie, most of the clupeid grouping is represented by gizzard shad (Dorosoma cepedianum), while in the other Great Lakes these groups are likely dominated by the non-native alewife (Alosa pseudoharengus). In EPA's economic analysis, alewife have no commercial value, while EPA values gizzard shad at $0. 15/lb. Gizzard shad represent the majority of costs estimated for J. R. Whiting. Further differences in the Great Lakes are illustrated in the Kelso and Milburn (1979) study. There, no cyprinids were reported entrained in Lake Ontario or Detroit/St. Clair, and no percids were entrained in Lake Ontario. However, smelt (Osmerus mordax) were the dominant grouping entrained in Lakes Erie and Huron (Figure 2). Although the magnitude and direction of economic changes that would result from differences in species affected among Great Lakes facilities are difficult to assess with the available information, it is clear that biological differences in species assemblages across Great Lakes locations will greatly diminish the accuracy of EPA's I&E estimates.

For the J. R. Whiting case study, EPA used entrainment data from a 1979 study, and impingement data based on averages of available data from 1981-82, 1987, and 1991. Significant changes have occurred in Lake Erie (and other Great Lakes systems) since 1979, and even since 1991, that may influence the validity of applying these I&E data to current conditions. Fish community composition and the abundance of key species has changed a great deal during this time. The USFWS — Sandusky Biological Station has used the catch per unit effort (CPUE, fish / hour) of age-0 fish during fall bottom trawis at their East Harbor station as an index of abundance and trends in age-0 fish abundance since about 1960. This same data can be used to evaluate the magnitude of changes in the juvenile fish community of Lake Erie between the timing of the J. R. Whiting data sets and present extrapolations by the EPA. A comparison of the five-year average CPUE's from a period spanning the J. R. Whiting entrainment data (1978 — 1982) and for a five-year average from the most recent data (1996-2001) suggests that the composition of juvenile fishes and their abundance has changed markedly between the timing of the I&E losses studies and present (Figures 3 and 4). Species that accounted for most of the I&E numbers and the majority of economic costs estimated by EPA included gizzard shad, emerald shiner (Notropis atherinoides), sunfish spp. (Lepomis spp.), and yellow perch (Perca fiavescens). Among these species, gizzard shad appear to have declined in abundance from 16% to 4% of catches (Figure 3) and its relative abundance is only 56% of 1978-82 (Figure 4). Emerald shiner appear to have increased from 34% to 63% of age-0 fishes in trawls and are 3.66 times more abundant than in 1978-82. Yellow perch are less abundant (75% relative abundance) than in 1978-82, and declined from 6% to 2% of catches. Sunfish spp. were not collected in research trawis and thus abundance could not be assessed. Of the nine most commonly collected species in these research trawis, six have declined in abundance in the recent period in comparison with the period when I&E data were collected (Figure 4).

These changes are believed to be related to changes in the Lake Erie food web that have resulted from nutrient abatement programs (Millard et al. 1996) and invasion of the ecosystem by no less than five new species of fish and zooplankton, and perhaps most importantly, zebra and quagga mussels (Gopalan et al. 1998). Declines in commonly collected fish species include recreational species such as white bass (Morone chrysops), yellow perch, and freshwater drum (Aplodinotus grunniens), and forage species such as alewife, gizzard shad, and spottail shiner (Notropis hudsonius). Walleye (Stizostedion vitreum) are about 40% more abundant than in 1978-82 and white perch, a marine invader, (Schaeffer and Margraf 1986) has increased 13-fold in recent years.

Although the J. R. Whiting I & E database may represent the best available information for EPA's I&E analysis for Great Lakes waterbodies, significant changes have occurred in composition and abundance in the 20 years since those data were collected. Such differences in abundance and species composition will influence current I & E values and cast serious doubt as to the validity of I & E loss estimates for the Great Lakes in-scope facilities and the extrapolation of these data to other facilities of this water body type.

Productivity in Lake Erie and all the Great Lakes has declined tremendously since nutrient abatement activities in the mid-l980's and the invasion of the lakes by zebra mussels (Dreissena polymorpha) in the late 1980's and 1990's. Declines in productivity and a shift from pelagic energy pathways to benthic pathways has necessarily altered the ecosystems and resulted in declines in fish production and community changes (Johannsson et al. 2000, Lowe and Pillsbury 1995, Millard et al. 1996). These drastic changes in productivity and community structure undoubtedly translate into lower numbers of ELS and young fish susceptible to I&E. Thus, observed declines in productivity and changes in the fish community of Lake Erie and the other lakes since the case study data were collected suggest EPA's present estimates for J. R. Whiting severely overestimate I&E losses for Great Lakes facilities.

C. Gulf Estuary Type Extrapolations

Background Information

In the Tampa Bay case study, EPA used data from Big Bend located on the eastern shore of Tampa bay near the lower Hilisborough Bay, upper middle Tampa Bay region, to extrapolate to three other in-scope plants in Tampa Bay. The three in-scope plants to which Big Bend I&E loss estimates were extrapolated are located in: mid-Tampa Bay on the western shore (Bartow plant), and in the upper Hillsborough Bay (Hooker's and Gannon Point plants).

D.O. levels are similar between Big Bend and the P.L. Bartow plants, but quite different between the Big Bend plant and the facilities in upper Hillsborough Bay. D.O. is low in upper Hillsborough Bay. Many estuarine species of fish and shellfish avoid areas of low D.O. (Chesney and Houde 1989; Pihl et al. 1991) and as a result, EPA's extrapolations of losses from Big Bend to F. J. Gannon and Hooker's Point may result in an overestimate of losses at these two facilities. These biases are compounded in national estimates because EPA used the Tampa Bay estimates to apply to all gulf-type estuary facilities. Thus, all I&E losses and the benefits estimated by EPA in their analysis are derived from a biased extrapolation of the I&E losses at a single facility.

Spatial maps of the D.O. in Tampa Bay suggest that the Big Bend plant and Bartow plant are located in an area of adequate D.O. levels for estuarine organisms. However, the Hooker's Point power plant and F. J. Gannon plant are located in areas of consistently low D.O. with periodic hypoxia (Figure 5). Because low D.O. has been shown to negatively affect the distribution of bay anchovy (Chesney and Houde 1989), spot, Atlantic croaker, and other aquatic organisms (Pihl et al. 1991), it is expected that lower numbers of organisms will be found in the vicinity of Hooker's Point and F. J. Gannon facilities due to low D.O. The impact of low D.O. at Hooker's Point and F. J. Gannon will be even greater for ELS of bay anchovy and black drum, which are even less tolerant of low D.O. than juveniles and adults. Because the ELS are more often involved in estimated losses (through entrainment), reduced D.O. levels at these two plants will result in I&E losses being very much overestimated through EPA's extrapolations from the Big Bend estimates (where water quality is better). The result of this bias in extrapolation is that the I&E losses for Hooker's Point and F. J. Gannon will be overestimated by using extrapolations from Big Bend. This will result in significant overestimates of the I&E losses for the Tampa Bay case study and for the national extrapolation for this waterbody type.

Examination of EPA's I&E loss and economic analysis for the Tampa Bay case study suggests that most of the estimated losses are derived from a few species including bay anchovy, black drum (Pogonias cromis), and stone crab (Me ippe mercenaria). Only very limited information on the density distributions of these species in Tampa Bay or the water quality patterns in the Bay are available. However, species life history information from other studies can be applied to evaluate the potential for errors in I & E loss extrapolations. Below we look at the potential effect of these errors for key Tampa Bay species.

Key Species:

Bay anchovy

Bay anchovy distributions in estuaries are closely linked to salinity distributions in many estuarine systems. In Chesapeake Bay, highest egg densities were found in salinities of 13-15 ppt with a second peak observed at 17-23 ppt (Houde & Zastrow 1991). Juvenile anchovy were found to prefer salinity ranges of 9-30 ppt. In the Little Manatee River, Florida juvenile and adult bay anchovy were found in lowest densities in freshwater and polyhaline waters (> 18 ppt) and highest densities were in 0.5 — 18.0 ppt. Similar distributions have been observed in the Hudson River for juveniles and adults (Hartman 1998). However, growing evidence suggests that larval bay anchovy may recruit to areas of freshwater or low salinity in estuaries from the Hudson River to Chesapeake Bay (Dovel 1981: Kimura et al. 2000; PSEG 1999; Schmidt 1992). Low D.O. levels can also limit bay anchovy distributions. Bay anchovy eggs and yolk sac fry do not tolerate D.O. <3.0 mg/l and are less abundant in waters < 5.0 mgi/l D.O. (Houde and Zastrow 1991).

In Tampa Bay it seems that salinity levels and low D.O. make extrapolations of I&E loss estimates from Big Bend to other in-scope facilities biased. Salinity levels are less favorable for bay anchovy near the Bartow facility than in the Big Bend and other facilities. As noted above, D.O. levels are commonly < 5.0 mg/l near Hooker's Point and F. J. Gannon, while salinity levels are generally higher (28-30 ppt) at Bartow than in the Hillsborough Bay region (26-28 ppt). Only very limited distributional data for bay anchovy are available for Tampa Bay to verify patterns (TBNEP 1992). Distributional data did not include upper Hillsborough Bay, but it is believed bay anchovy densities are lower there than in the vicinity of Big Bend due to reduced D.O. in upper Hil!sborough Bay. Distributional data suggest that bay anchovy are also more abundant near Big Bend than near Bartow. During spring and fall, anchovy (juvenile and adult) appear more abundant in trawls from mid-Hillsborough Bay (near Big Bend) than near Bartow (TBNEP 1992).

Thus, available data on water quality and species requirements, and limited distributional data, suggest that extrapolation of I&E losses from Big Bend to other in-scope facilities will represent an overestimate of actual losses at these facilities. This overestimate carries over into EPA's extrapolations to the case study and waterbody type extrapolations for the national baseline estimates.

Other species

Differences in water quality (D.O. and salinity) between the in-scope facilities in Hillsborough Bay and Old Tampa Bay may lead to other errors in extrapolations from Big Bend to other in-scope facilities. Although D.O. levels appear similar between Big Bend and Bartow, the generally higher salinity at Bartow may affect the abundance of other key species such as stone crab and black drum. However, little specific life history information regarding distributions relative to salinity for these species is reported in the literature. It is not possible to assess the validity of extrapolations from Big Bend to Bartow for the other key species due to a lack of species-specific information. However, it is apparent that circulatory and freshwater inflow patterns are substantially different between the Old Tampa Bay and lower Hillsborough Bay areas. Such differences are likely important in species abundance and distributions in Tampa Bay and introduce considerable uncertainty in the EPA's estimates of losses for the Gulf Estuary case study, especially since all extrapolations are based on a single plant (Big Bend).

D. The Ohio River Watershed Case Study Extrapolations.

Background information

In many ways, the quantity of data used by EPA in the Ohio River watershed case study is greater than that used in any of the other case studies. Unlike the estuary and Great Lakes waterbody type extrapolations, where data from individual plants were used to estimate losses for the case study or entire waterbody, EPA used data from nine facilities to estimate I & E losses along the Ohio River. Data from these nine facilities were then extrapolated to 20 other facilities. However, there are several serious flaws in the EPA's Ohio River case study. First, the data used are quite outdated, having been obtained from studies at plants during 1977-1979. Changes in fisheries abundance and composition and associated vulnerabilities to CWIS have occurred during the 25 years since some of these studies were conducted. In addition, two notable potential sources of extrapolation error occur in EPA's methodology. First, EPA used an average flow-adjusted I&E for three plants in the Markland Pool (W.C. Beckjord, Miami Fort, and Tanners Creek, RM 490, 494, and 560, respectively) to extrapolate to two other in-scope facilites within a 193 mile region from RM 260 to RM 453 for which no I&E loss estimates were available. Also, EPA used I&E loss data at Clifty Creek to estimate I&E losses for at least eight other in-scope facilities between RM 540 and RM 952.

Both of these extrapolations represent potentially serious errors and bias in EPA's methodology that, in light of species-specific distributional differences and plant-specific differences in I&E losses, leads to serious overestimates in EPA's loss estimates.

Biological issues

From the EPA's analysis it appears that several key species are responsible for most of the I & E losses attributed to CWIS facilities in the Ohio River case study. Summing the mean number of age-l equivalents estimated as impinged (Table C3-7) and entrained (Table C3-1 1) provides a means of determining which species have the highest estimated age-l equivalent losses (Table 2).

[see hard copy for table]

Based on EPA's estimated age-i equivalent losses (Table 2), most of the losses appear focused on six species. These species are: bluntnose minnow (Pimephales notatus), river carpsucker (Carpiodes carpio), gizzard shad, emerald shiner, sucker spp. (presumed Moxostoma spp., Catostomus spp.), and common carp (Cyprinus carpio). In addition, smallmouth bass (Micropterus dolomieu) represent an important recreational species with high economic value in EPA's analysis. Therefore, we will use these species as the basis for evaluating how two potential errors in EPA's methodology -- use of outdated data and distributional / extrapolation issues -- may affect the I & E estimates for in-scope facilities.

Key Species:

Bluntnose minnow

Patterns in estimated losses of bluntnose minnow suggest that most losses occur in the upper half of the river as entrainment (Figure 6). Estimated losses from the W. C. Beckjord plant (RM 453) through the Clifty Creek plant (RM 560) were negligible. EPA applied average I & E losses estimated for the three facilities in the Markland Pool to the in-scope facilities between Kyger Creek and W. C. Beckjord plants (the 193 mile data gap). Estimated entrainment of bluntnose minnow at Kyger Creek was higher than in facilities downriver. Therefore, the use of the average I & E from the Markland Pool facilities to fill in the data gap may represent an underestimate of bluntnose minnow losses for those facilities.

Recent changes in the Ohio River fish community suggest that the bluntnose minnow has declined in abundance since the time of I&E estimates in the Ohio River facilities (see page 25 and Figure 15). If bluntnose minnow have declined in abundance then it is likely that the EPA's estimates of losses for this species are much higher than is presently occurring in the Ohio River watershed. This erroneously high estimate of bluntnose minnow losses inflates EPA's estimate of losses for the case study and is compounded in EPA's nationwide extrapolation of this data for the waterbody type (lakes and rivers).

River carpsucker

Patterns in estimated losses of river carpsucker suggest that most losses occur in the middle portion of the river as entrainment (Figure 7). Highest estimated losses were between the Kyger Creek and Tanner's Creek facilities. As stated earlier, EPA applied average I & E losses estimated for the three facilities in the Markland Pool to the in-scope facilities between Kyger Creek and W. C. Beckjord plants (the 193 mile data gap). Estimated entrainment of river carpsucker at the Kyger Creek plant was higher than any other plant. Therefore, the use of the average I & E from the Markland Pool facilities to fill in the data gap between RM 260 and RM 453 may represent an underestimate of river carpsucker losses for those facilities.

Emerald shiner

Emerald shiners are a pelagic species found throughout the Ohio River (Trautman 1981). EPA's estimated I&E losses for emerald shiner show several orders of magnitude difference in I & E losses among facilities (Figure 10). The differences in emerald shiner I&E among the case-study facilities likely reflects differences in sites and plant designs because fisheries surveys show this species to be abundant throughout the river. Estimated losses of emerald shiner at the nine Ohio River case study facilities occurred mostly in the form of entrainment, although estimated impingement was significant at Miami Fort. Notably, the same pattern of highest I&E occurring at the Miami Fort plant occurred for another pelagic species—gizzard shad. This suggests that site- and plant-specific designs are important factors in I&E losses. In the absence of spatial patterns in abundance and in the presence of strong site- or plant- influence on I&E for emerald shiners, extrapolations from case-study plants to other in-scope facilities are prone to error. Without plant-specific I&E data for all plants within the in-scope area it is impossible to assess the accuracy of I&E for emerald shiner, but given the wide range in I&E rates for specific plants within the case studies, EPA's methodology could be very high or very low for this species.

Recent changes in the Ohio River fish community suggest that emerald shiner may have decreased in abundance since the time of I&E estimates in the Ohio River facilities (see Figure 15). During the time of the I&E studies, emerald shiner represented 51% of all fish collected in agency rotenone surveys of the Ohio River, but during 1999-2001, emerald shiner represented only 3% of all fish collected. If emerald shiner abundance has decreased, then it is likely that the EPA's estimates of losses for this species are higher than is presently occurring in the Ohio River watershed. These potential errors would be compounded in EPA's extrapolation of this data for the entire waterbody type (lakes and rivers).

Sucker spp.

The suite of sucker species inhabiting the Ohio River is quite diverse. However, EPA's grouping of this taxa as "sucker spp." eliminates the ability to evaluate individual species distributions and the role of these distributions on I & E extrapolations. It is not clear from EPA's documentation why these species were lumped together, although we speculate this may be due to taxonomic identification problems in the original I & E estimates.

Suckers have pelagic larvae that settle to the bottom and have a benthic lifestyle after metamorphosis into juveniles. This life history is borne out in the estimated I&E losses for the grouping. In looking at EPA's estimated I & E for sucker spp., it appears that impingement is minimal for this group (Figure 11). Most estimated losses are through entrainment, with peak losses at Clifty Creek and, to a lesser extent, at Phillip Sporn. Of primary importance to the extrapolations is the use of the Clifty Creek data to estimate losses along 412 river miles. There is no reason to believe that abundance or susceptibility of young suckers increases downriver in the Ohio, nor is there reason to believe that the high entrainment estimates of sucker spp. at Clifty Creek should continue downriver (Figure 11). Therefore, extrapolation of the Clifty Creek sucker spp. entrainment data over 412 river miles likely overestimates I&E losses for this species group.

Common carp

Carp is a non-native species introduced to the United States in the late 1800's. Carp is responsible for alterations of the aquatic habitat, such as increased turbidity, that may be responsible for declines in abundance of native species. Many fisheries resources agencies have sought to eliminate this species from their waters, but have met with limited success. Due to the very limited ecological or economic utility of carp in the Ohio River, it is difficult to consider any I & E losses to this species as a particular concern. Further, carp do not appear to be integral to aquatic food webs as forage for more desirable species. If EPA considered the negative impacts of carp to native species, it would likely negate any economic costs associated with I & E losses of carp to the Ohio River.

Smallmouth bass

Smallmouth bass are distributed throughout the length of the Ohio River (Trautman 1981). The smallmouth is considered a fish of streams and rivers with a preference for moving waters. Upper areas of pools (below dams) tend to have hydrologic characteristics more similar to un-impounded waters. However, smallmouth bass tend to spawn in near-shore areas of lower velocity water and the larvae and juveniles tend to inhabit these near shore nursery areas during much of the first year of life. It is during these stages (larvae and early juvenile) that smallmouth bass are likely to be most vulnerable to CWIS. EPA's estimates of I & E losses suggest that entrainment is the major source of loss for this species.

The distribution of estimated entrainment for smallmouth bass is not homogenous along the River (Figure 12). Thus, methods used for extrapolating data from case study facilities to in-scope facilities are critical to the accuracy of EPA's estimates. Most of the entrainment is estimated to occur at two facilities (W. C. Beckjord and Miami Fort) that are located at RM 452.9 and RM 490, all within the same pool (Figure 12). Entrainment at a third plant in the pool (Tanners Creek) was nil. EPA's methodology for extrapolation called for the data from the average of these three plants in the Markland Pool to be used to estimate I & E losses for in-scope facilities at Spurlock, Stuart, Killen, New Boston Coke, Zimmer, and East Bend facilities. Among these in-scope facilities, flow is substantial only at J. M. Stuart (773.3 MGD). J. M. Stuart is located at approximately RM 390 with the next closest facility upriver at RM 260. EPA chose to use the average I & E losses at three plants in the Markland Pool (RM 436-531.5) that had elevated entrainment rates of smallmouth (relative to all other plants in the detailed study) to apply to the Stuart plant. This methodology likely overestimates losses of smallmouth bass at the Stuart facility since all other case study facilities between RM 53.9 and 260 and between RM 494 and 560 had low rates of bass entrainment. A data gap of 193 miles exists between the Kyger Creek and W. C. Beckjord plants. Given this large gap, the extrapolation to Stuart cannot be considered appropriate. A better method would have been either to use an average value based on I & E losses from the two nearest up- and down-river plants to represent Stuart, or to include only areas with sufficient and proximal data in the in-scope analysis. Large spatial extrapolations where data are lacking (such as down river of Clifty Creek) should be avoided. Unless actual entrainment of smallmouth bass at J. M. Stuart is much higher than the rates estimated at 7 of the 9 in-scope facilities, then use of the Markland Pool averages to apply to the upriver Stuart facility will result in gross overestimation of the entrainment losses and benefits for the J. M. Stuart facility, and by extrapolation, to the Ohio River watershed. EPA's use of the Clifty Creek smallmouth bass impingement estimates to apply to the 400 miles of river and facilities downriver also biases case study loss estimates. Estimated impingement losses of smallmouth bass were highest of all in-scope plants at Clifty Creek. There is no reason to believe that impingement of smallmouth bass should remain as high downriver as it is at Clifty Creek. Therefore, EPA's use of Clifty Creek impingement losses for smallmouth bass to extrapolate to all downriver facilities likely results in a very high bias in smallmouth bass losses in the case study. The errors identified above will be compounded as the Ohio River case study is used to develop national extrapolations for the rivers and lakes waterbody type.

Freshwater drum

Freshwater drum is a common species in I & E estimates for the Ohio River. They are a common fish in agency lock rotenone samples in the Ohio River both during the time of the I&E studies and recently. Estimates of I & E losses as age-i equivalents (after standardizing for operational flows) show no longitudinal patterns in drum occurrence. However, one notable observation is the presence of a peak in both impingement and entrainment estimates at RM 490 for Miami Fort (Figure 13). This suggests that either the density of drum was much higher in that region during the study, or the site- and/or design of the facility makes it more likely to encounter drum. The result of this peak in I&E for freshwater drum is that estimates of losses over the data gap area will be overestimated. As noted before, EPA used the average I & E from W.J. Beckjord, Miami Fort, and Tanners Creek plants in extrapolating losses to the in-scope facilities between RM 260 and RM 453. The averages used for extrapolation are inflated by the inclusion of Miami Fort data. This is particularly true for impingement data. A better approach would have been to average several upriver and downriver facilities for application to the data gap region. EPA's present methodology will overestimate losses of freshwater drum in the data gap region. This overestimation will result in an overestimate of freshwater drum losses for the case study and in the national extrapolation based on the case study.

Validity of Extrapolations Based On Spatial and Temporal Changes in Fish Communities

EPA's extrapolation of I & E loss estimates in the case studies may be valid if the assumptions regarding extrapolations across regions and years are accurate. However, this does not appear to be the case. There is one Ohio River dataset available with which to assess the validity of EPA's assumptions regarding continuity of fish populations in areas of data gaps and EPA's assertion that fish abundance has increased since the time of the I & E studies and hence impact estimates are conservative. The Ohio River Sanitation Commission (ORSANCO), in cooperation with fisheries resource agencies, has conducted lock chamber rotenone surveys since the late 1950's. ORSANCO maintains a database of these data. Included in the data are numbers of fish by species from the series of lock and dam structures along the Ohio River. Such data can be used to consider whether juvenile and adult fish populations have changed considerably since the time when I & E studies that serve the basis of EPA's analysis were performed. These data can also be used to examine spatial patterns in abundance that may permit verification of the appropriateness of EPA's extrapolations for case study facilities down river of Clifty Creek and in the data gap area (RM 260 — 452.9) identified above.

All chambers are not sampled every year, but by looking at (1) sets of the data that correspond to the period of I & E estimates and (2) recent collections (1999) we can evaluate EPA's assumption. In lock rotenone surveys, carp were generally more abundant upstream than downstream and this pattern has existed since the earliest samples (Figure 14). In looking at the sections of the River where data extrapolations were made, the 1978-80 chamber data suggest that carp were relatively more abundant where I & E estimates were derived (upstream of RM 260, below RM 453, and extrapolations of RM 560 to downstream areas) than the areas where data were lacking. During the 1978-80 period of the case studies, and continuing in recent years (1999), abundance of carp as indexed by lock chamber surveys was higher in the case study areas than in the in-scope areas to which it was extrapolated. This suggests that EPA's estimates of I & E losses for carp are an overestimate due to inaccurate assumptions of distributions, abundance, and associated extrapolations. Although further data examination for other key species in the Ohio River study was not conducted, it is apparent that EPA's extrapolation methodology for regions without I & E estimates is flawed and likely results in overestimates of I & E losses in the case study for other species.

The lock chamber data suggest that changes in abundance and species composition have likely occurred over time, but among the key species the incidence and percentage of all fish collected has changed little. Gizzard shad still dominate the species composition by numbers across the river and other species such as bluntnose minnow, walleye, smallmouth bass, and sucker spp. are relatively minor components of the river community (Figure 15). In fact, bluntnose minnows were not reported as caught in the ORSANCO database in 1999. These data suggest that limited changes in species composition have occurred between the case study data collection for I & E and 1999. However, bluntnose minnow are much less abundant in the 1999-2001 agency rotenone surveys (0.002%) than at the time of the I&E studies (0.2% - 1977-79) Bluntnose minnow have been reported at only six sample sites and in low densities (N ~ 15 individuals per sample) in all samples since 1989. If bluntnose minnow have declined in abundance since the I & E estimates, then I & E losses associated with that species are likely overestimated in the EPA case study.

III. Summary of Identified Concerns

After examining and evaluating EPA's case studies in light of biological and temporal patterns in the abundance and distribution of aquatic species, it is apparent that in each case study examined, there are potential violations of extrapolation assumptions.

A. Salem

Extrapolations of data from Salem to represent all in-scope facilities for the Delaware Estuary case study will result in overestimates of I & E losses for the case study because of differences in organism distributions over the estuary, perhaps related to salinity. These differences in distribution for key species like bay anchovy, Atlantic croaker, and weakfish show that abundances up-estuary from Salem are lower than at Salem. As all other in-scope facilities are located up-estuary of Salem, differences in distributional density between Salem (where the I & E estimates were generated) and the other in-scope facilities will result in lower availability of these species for possible I & E. Thus, applying the higher I& E rates to the other in-scope facilities based on flow will overestimate the true impact of CWIS in the Delaware Estuary.

Salem's I&E estimates for spot further illustrate the uncertainty in EPA's estimates of losses. In the 19-year data series for Salem, the average entrainment loss of spot is derived largely from the influence of a few years of exceptional spot abundance and most occurred over 15 years ago (1980, 1982, 1985, and 1995). Thus, if EPA had used only more recent data it would produce a much lower estimate of losses for spot than the present approach. This high year-to-year variability in I&E points out the potential for poor estimates of losses that rely on dated or limited data as is commonly the case in EPA's methodology.

B. Great Lakes

For the Great Lakes waterbody type, EPA used I&E data from the J. R. Whiting facility to represent all facilities in the Great Lakes. Available data do not appear to concur with the assumption that the J. R. Whiting plant losses are typical of any other facility in the Great Lakes. The J. R. Whiting facility is located in the most productive section of the most productive of the Great Lakes. Hence, in the absence of differences in technology or design and assuming I & E is related to species abundance, extrapolations from Whiting to other facilities will necessarily be biased towards higher losses than a similar facility located in other areas with lower productivity. The magnitude of this bias will vary from facility to facility, but there is no doubt this is a serious error that results in an overestimate of I & E losses for this waterbody type.

Further, differences in species group assemblages across the Great Lakes and changes in abundance and composition of the fish community that have occurred between the time of I & E data collection and present, increase the bias towards higher I & E losses. Production of Lake Erie and the other Great Lakes has declined since the I & E studies and changes in abundance of most fish species examined should reduce I & E unless EPA's assumption that I & E is related to flow and abundance is inaccurate.

C. Tampa Bay

The Tampa Bay Watershed Case Study was more difficult to evaluate due to a relative paucity of data on the distribution of key species in the Bay and limited water quality information. However, the key feature in EPA's Tampa Bay extrapolation was the use of Big Bend I & E estimates for extrapolation to the Hooker's Point and Gannon facilities. Available data suggest that water quality is lower (low D.O.) for the upper Hilisborough Bay where these two in-scope facilities are located. These differences in habitat quality (low D.O.) will necessarily result in lower abundances of organisms near these facilities and this will equate to lower potential I & E. Thus, extrapolation to the Hooker's Point and Gannon plants from Big Bend estimates will result in elevated estimates of I & E for the Tampa Bay Watershed Case Study and the waterbody type.

D. Ohio River

The Ohio River Watershed Case Study extrapolations are also plagued by antiquated data, spatial gaps in data, and an ill-conceived extrapolation methodology. First, the data used by EPA were collected in 1977-1979. Many changes in fisheries abundance, composition, and associated vulnerabilities to CWIS have occurred during the 25 years since the I & E studies were conducted.

Additionally, I & E data were available only downriver to RM 560, yet EPA extrapolated the estimates from Clifty Creek downriver for 404 miles to the extent of the in-scope facilities (Joppa Steam Plant, RM 952). Thus, estimates from only one plant were expanded to over 40% of the length of the river. Any errors or bias in the Clifty Creek estimates are compounded by this heavy reliance upon Clifty Creek data and extrapolation over a large area. Species abundances change along the Ohio River, as suggested by the I & E estimates for the in-scope facilities (Figures 6, 7, 9-13). Hence, extrapolations of data from Clifty Creek to facilities down-river are invalid. Very high estimates of I & E at Clifty Creek for sucker spp. results in elevated estimates of loss of this species for the facilities in the 404 miles below Clifty Creek. Estimates of smallmouth bass I & E in the case study are also biased high due to a 193 RM data gap between Kyger Creek and W C Beckjord. In this case, instead of using an average of I & E that was weighted by distance from the closest upstream and downstream plants, EPA used a weighted average from three plants located downstream. Two of these three plants had the highest estimated losses of smallmouth bass --much higher than in the other seven facilities. The use of these data to estimate losses in the data gap zone results in biased high estimates of smallmouth bass losses for the case study. These high estimates then result in overestimates for in-scope plants on the Ohio River.

E. Conclusions

Although EPA was limited by the data available to estimate I & E losses in the case studies, in every case the Agency chose to use the highest possible impact scenario for extrapolation. This is true whether it be in selecting facilities for in-depth studies that appear to be at the apex of biological activity and productivity for each waterbody type, or when ignoring biological and distributional patterns that affect the validity of the extrapolations. However, EPA made no effort to place any reasonable bounds on the I&E loss estimates. In every case, they selected the approach that would generate the highest estimate of losses. In the scientific literature it is common practice to place bounds on model estimates at all stages so as to evaluate the uncertainty in the data and provide a reasonable bound that likely encompasses the true value. A better approach for EPA's methodology would be to use both liberal and conservative bounds for estimates made in generating numbers of organisms affected by CWIS.

In general, EPA's estimates of I&E losses has ignored the scientific literature, disregarded differential distribution, composition and density of fishes across systems within a waterbody type, and mixed data of different vintages. Each of these oversights or methodological errors leads to uncertainty or bias towards higher losses in EPA's estimates. As pointed out elsewhere, evidence exists in the scientific literature that compensation does occur in fish populations (Jensen 1981; Leggett 1977; Rose et al. 1999), yet EPA chose to ignore it. EPA's methodology also lacked consistency by mixing data of different vintages across the case studies. EPA's methodology should have used only recent data for all case studies, or used only datasets with long-term data series. Given the changes in productivity, species abundances, and species invasions that have occurred in many of the case study systems in the last 20 years, a long term dataset including recent years is preferable to that employed by EPA. Further, EPA ignored differences in productivity, species assemblages, and densities across systems or sites within a case study. This has resulted in a great deal of uncertainty in EPA's estimates.

EPA Response

This comment refers to the Case Study Document (DCN # 4-0003) presented at proposal, which was been revised considerably for EPA's final analysis. Specifically, extrapolation of I&E was done on a regional basis for the final rule (see Chapter A5 of the Regional Analysis Document, DCN # 6-0003, and response to Comment 316bEFR.041.041.

EPA appreciates the commenters concerns about potential difficulties when data are extrapolated. However, the examples provided by the commenter no longer apply to EPA's 316b analysis because EPA has greatly expanded its analysis since these case studies were presented at proposal by adding many additional facilities (a total of 46). Please see response to Comment 316bEFR.041.041 for information on the regional extrapolation for the final rule.

EPA agrees that temporal, physical, and biological characteristics can be important in determining I&E rates at particular facilities. EPA considered as many of these factors as possible for a national-scale analysis. For example, extrapolations were on a regional basis, with regions defined in terms of ecological similarities. EPA also considered technologies in place and adjusted old I&E data for any technology changes subsequent to data collection that may have led to a percentage reduction in I&E.

EPA notes that careful and accurate monitoring is necessary to develop accurate estimates of I&E rates at individual facilities. Most of the factors discussed by the commenter vary depending on the time of monitoring and waterbody conditions, including life history patterns, densities of aquatic organisms, and changing salinities and other waterbody conditions that vary seasonally and year-to-year.

Contrary to the commenter's assertion that only high-impact facilities were considered, EPA notes that the magnitude of losses varied widely at the facilities evaluated. Regarding the Great Lakes extrapolation, please see response to Comment 316bEFR.207.023.

Please see response to Comment 316bEFR.041.843 for a discussion of uncertainty and confidence intervals.

Proposed standards for lakes and reservoirs

Some Reservoirs Are Contrived Artificial Ecosystems

Many reservoirs in the Southwest illustrate several of the concepts discussed in UWAG's comments on the proposed Phase II § 316(b) rule — for example, the need to look closely at site conditions and the effect of nuisance species. For example, of the 212-plus "lakes" in Texas, only one, Caddo Lake, is natural. All other Texas lakes actually are manmade reservoirs constructed for single or multiple purposes, including potable water sources, flood control, recreation (boating, swimming, skiing, sports fisheries, etc.), and industrial use. Many of these reservoirs were constructed specifically to support the operation of power plants, in recognition of the important role recirculating cooling systems play in conserving water, compared to cooling towers.

In general, the power plant reservoirs are relatively shallow (less than 30 feet in depth on average), with gently sloping bottoms over a wide variety of substrates. The water volumes are controlled by either mechanical tainter gates or passive overflow structures, and the reservoirs are subject to significant annual pool level variation due to seasonal climatic conditions. Occasionally, there is some form of continuous flow-through to maintain downstream conditions, but retention times are very long, ranging from weeks to years.

A. Southwestern Reservoirs Are Affected by Fish Stocking and Exotic Nuisance Species

With no natural "lake" flora or fauna present, many Southwestern reservoirs support a combination of introduced lacustrine and adaptive riverine species. The fisheries of the publicly accessible reservoirs in Texas, for example, usually are stocked and managed by the Parks and Wildlife Department to support sports fishing, a major recreational industry in the State. The usual fish stocking regimes include predator species, strains and hybrids (largemouth bass, catfish, crappie, etc.), and prey species/hybrids, such as sunfish, minnows, and shads. Over time, and at various locations, the State also has introduced striped bass, redfish, carp, and other non-native species. Most of the stocked sport fish species, however, must be restocked periodically, regardless of cropping by CWIS, because of high fishing pressure, low naturalization, and the need to increase genetic diversity. For example, in 1998, the Texas Parks and Wildlife Department's Inland Fisheries Division stocked over eight million Florida-strain largemouth bass and over nine million fingerlings of other species.

With little natural seed bank and no managed vegetation stocking program in many reservoirs, the aquatic flora develops slowly and can result in unbalanced and/or low-diversity plant communities. So, for example, in recent years many Texas reservoirs have become increasingly impacted by exotic nuisance plants (water hyacinth, hydrilla, giant salvinia, eurasian water milfoil, etc.). These invasive plants often have a negative effect on the fisheries by altering the available nesting/spawning areas, influencing recruitment of certain species, and decreasing the depth of light penetration and the associated dissolved oxygen levels. Heavy infestations also can alter species distribution and limit recreational access.

B. Climate and Naturally Occurring Nuisance Species Severely Affect the Aquatic Communities in

Southwestern Reservoirs

These shallow Southwestern waterbodies also are under continuous threat from exotic aquatic fauna (as indeed are waterbodies of all kinds throughout the United States). The list of exotic fauna is long and seems to grow each year. Apart from the expanding number of fish species, the list of exotics also includes invertebrates, such as clam, mussel, and snail species. Recently, a species of estuarine mud crab has been found reproducing in at least four different Texas reservoirs that are several hundred miles from the coast. Each of these uninvited exotics presents new problems and future challenges to each reservoir in which they occur.

As mentioned earlier, the climate also can have a major impact on reservoir water quality and fisheries. In Texas and other more arid states, prolonged droughts and daily high ambient temperatures of over 100°F for extended periods often result in dramatic drops in reservoir volume. This impacts the fisheries by reducing recruitment, altering nesting locations and patterns, and eliminating available habitat. It also subjects the fisheries to additional stresses, such as higher salts concentrations, which necessarily weaken the population. It can take years for fisheries to return to pre-existing levels after a drought episode. There also are floods, such as the Texas floods of July 2002, which alter water quality, redistribute or introduce populations, decrease survivability, and impact historical nesting areas.

Natural conditions also can combine to impact the fisheries negatively. A prime example is the recent occurrence of golden algae blooms in several Texas inland reservoirs. Golden algae (Prymnesium parvum) is a naturally occurring saltwater-tolerant species. When in a “bloom” or period of rampant growth, it causes water discoloration and can be toxic to fish. The toxin released from the algae and concentrated during a bloom affects the gills by reducing their oxygen intake and asphyxiating the fish. The toxin appears to affect scaled fish the most. In the golden algae blooms over the past few years, estimates of mortality of the scaled fish in each reservoir range from 60% to 95%. The effects of golden algae blooms appears to linger in some reservoirs; the length of time needed for the fish populations to recover to previous levels is not yet known.

An additional factor to consider is the gradual natural decline typical of a reservoir’s fisheries. Reservoirs typically experience an initial “boom” in fisheries during the first years following impoundment. After the initial boom, the fisheries generally begin to decline slowly over the years. The National Reservoir Research Program (administered by the U.S. Fish and Wildlife Service) has established that this cycle is related to nutrients. As the reservoir is developed, nutrient levels initially are very high because of the newly inundated soils and vegetation. In subsequent years, however, the watershed typically is not able to sustain as high a level of nutrients. As the nutrient levels decline, so do the fisheries. Since most of the cooling water reservoirs in Texas are more than 30 years old, they are all essentially in the “decline” phase.

C. Southwestern Reservoirs Have Been Managed for Human Use

From the above description, it is easy to see that many reservoirs represent a contrived ecosystem. The fisheries are created, modified, and managed for a variety of human needs, with little initial natural material or conditions to build from. Many reservoirs, such those in the Texas and other parts of the Southwest, also are subject to wide swings in fishery populations, distribution, and makeup because of their comparatively simple ecosystem. These reservoirs do, however, provide a highly valued perennial habitat where historically there may have been only an intermittent streambed. So, for example, despite the importance of sport fishing in Texas, the Texas Parks and Wildlife Department never has identified impingement or entrainment as an impact or concern on the fisheries of these power plant reservoirs.

Many power plant reservoirs nationally, including those in Texas and elsewhere in the Southwest, were built specifically to support power plants. Because of the high value of water in Texas, and the Southwest generally, recirculating cooling impoundment systems (which conserve water when compared to cooling tower systems) are preferred. In a practical sense, these reservoirs are an extension of the plant intake that was installed for multiple uses, including cooling and water storage/reuse. Most serve as classic “cooling ponds,” although changes in state regulations and interpretations have changed their designation to “waters of the State.”

D. Southwestern Reservoirs Are Different from Many Other Waters

The features of Southwestern reservoirs described above illustrate the sort of site-specific factors that affect the environmental impact of cooling water intake structures. Other than the generic term “reservoir,” Texas waterbodies share few characteristics with those on the Ohio River (cited by EPA as the case study for losses and benefits in the proposed rule). They do not share the same flows, water quality, fisheries, climate, vegetation, management objectives, or concerns it is even more difficult to equate a manmade waterbody with a natural lake. Even if a natural lake has been modified to control the water, it still has a significantly higher developed ecosystem and much different physical characteristics.

It is apparent from this discussion that a one-size-fits-all analysis would not be appropriate for all reservoirs, whether in the Southwest or other parts of the country. For instance, establishing a true “baseline” in Texas reservoirs would be virtually impossible. As proposed in the regulations, such a baseline would serve only as a “snapshot.” Dramatic changes to the fisheries, especially ones beyond the control of the power plant, can and do occur with surprising speed and can have long-term effects on the fisheries’ populations and distributions. Such changes render the “baseline” information useless. In any event, the baseline should not be a moving target.

In this regard, exotic fauna present one of the more difficult problems. Their presence should not “count against” the permittee in determining whether EPA’s performance standards are met, given that many states make it a specific priority to remove them from their waters. Their presence does, however, alter the biology of the reservoir. The situation is essentially similar for exotic flora. Their presence too alters the biology, particularly the fisheries.

In short, some reservoirs, as described above, are very different from the case studies that were conducted in support of the Phase II rule and may require special implementation considerations adapted to their characteristics and purpose.

EPA Response

EPA agrees that the biological communities in some reservoirs are not natural and are, in fact, heavily influenced by human management or by nuisance species. However, EPA remains responsible for the protection of water quality under the Clean Water Act and continues to believe that national performance standards are appropriate for these waterbodies. EPA also notes that these reservoirs likely still are considered to be waters of the United States and therefore subject to regulation under section 316(b).

With respect to nuisance species, EPA acknowledges that nuisance species are a problem in some waterbodies. EPA intends to account for these species in today's final rule by requiring that monitoring be conducted in accordance with the verification monitoring plan (125.95(b)(7), the Technology Installation and Operation Plan (125.95(b)(4)(ii)), if selected, and, if applicable, the Restoration Plan required at 125.95(b)(5). A site-specific compliance option might also be available. The Director may consider additional monitoring requirements as well. Specific study parameters may be proposed by the applicant for review and approval by the Director.

ECONOMIC EVALUATION OF EPA'S PROPOSED RULES FOR COOLING WATER INTAKE STRUCTURES FOR NEW FACILITIES

David Harrison, Jr., Ph.D., S. Todd Schatzki, Ph.D.

NATIONAL ECONOMIC RESEARCH ASSOCIATES

PREPARED FOR: UTILITY WATER ACT GROUP

I. INTRODUCTION

Section 316(b) of the Clean Water Act directs the U.S. Environmental Protection Agency ("EPA" or "the EPA") to set regulations for cooling water intake structures that reflect the best technology available ("BTA") to minimize adverse environmental impact. The EPA, in 1977, issued draft guidance based upon a judgment that BTA decisions should be based upon case-by-case decisions. Case-by-case decisions are appropriate because of the enormous variability in the costs and benefits of different cooling water intake structures depending upon the location of the facility and other site-specific characteristics. The EPA's 1977 guidance indicated that the case-by-case determinations of BTA should be based upon a comparison of the costs and benefits of alternative technologies; subsequent cases have interpreted this guidance to mean that a technology could be designated as BTA for a facility if its costs were not "wholly disproportionate" to the benefits.

The EPA draft guidance has been implemented by states through conditions in the National Pollutant Discharge Effluent Standard ("NPDES") permits issued to facilities that are covered by Section 316(b). These facilities include steam electric power generators as well as manufacturing facilities that use substantial quantities of water for cooling purposes.

A. Overview of EPA Proposed Regulation

The EPA on August 10, 2000 proposed 316(b) regulations for new facilities that would constitute a major departure from the existing guidance in two major respects (65 Federal Register 49060). First, EPA proposes to change the basic approach to 316(b) determination. Rather than encourage case-by-case determinations of BTA, the proposed regulations would provide national requirements for the design, capacity, and construction of cooling water intake structures for new facilities based primarily on the location of a cooling water intake structure. Second, the proposal would change the test for determining BTA. Rather than a test that compares costs and benefits of alternative technologies, the EPA proposed test would compare costs to overall facility or company revenues. This latter standard is often referred to as an "affordability" standard, i.e., whether the facility or firm could incur the costs without abandoning the facility or going out of business.

EPA recognizes the fundamental changes that its proposal would bring to 316(b) determinations and has invited comment on a broad array of other alternatives, including— maintaining the current site-specific approach and the current method of determining BTA. In addition, EPA, in August 2000, issued an economic document entitled, Economic and Engineering Analyses of the Proposed Section 316(b) New Facility Rule (hereafter "EEA" or "The EEA"). The EEA is designed to evaluate the costs, benefits and other impacts of the proposed regulations and alternative regulatory options.

B. Objectives and Conclusions of This Report

The proposed rule represents such a fundamental break with past EPA guidance and previous 316(b) permit determinations that it is important to assess whether the new approach is superior from several perspectives, including legal, technical and economic. It is also important to determine whether the evidence presented on economic and engineering considerations in the EEA is complete and accurate.

This report has two major objectives:

1. Assess the economic wisdom of the proposed regulations in comparison to alternative means of achieving the objectives of 316(b); and

2. Assess the economic analyses contained in the EEA, including its conformity to EPA and 0MB guidelines.

Although these objectives are related, it is useful to keep them separate. The first objective relates to the wisdom of the proposed regulations, while the second relates to the accuracy and adequacy of the economic information provided by EPA on the proposed regulations.

We conclude that EPA's proposed breaks with the past interpretations of 3 16(b) are not justified from an economic perspective. Shifting to a national approach from the case-by-by-case approach would waste society's resources by increasing the cost of achieving environmental gains and/or reducing the environmental gains from the resources that are spent to modify new facilities. The Agency argues that a shift to the national approach is warranted in large part by the costs and delays due to a case-by-case approach. But concerns about administrative and delay costs can be accommodated without abandoning the site-by-site approach. A permit applicant, for example, could be given an option of installing pre-approved, highly protective technology in the interest of obtaining a speedy approval of its facility permit.

The EPA's proposed shift to an affordability standard for BTA would also not be desirable from an economic perspective. Indeed, rather than abandoning the cost-benefit approach, the EPA should strengthen this approach. The current "wholly disproportionate" cost-benefit test should be replaced with guidance that BTA technology be selected to maximize net benefits, based dollar values of the costs and benefits of alternative technologies that could be employed at individual sites. This "maximize net benefits" criterion represents the "best" approach from the perspective of economic efficiency. The "wholly disproportionate" test appears to be motivated by concerns about uncertainties related to benefit calculations. But advancements in scientific understanding of fish protection alternatives and in economic valuation in the last two decades mean that accurate forecasts of both costs and monetary benefits can be made. Uncertainties in key parameters can be dealt with directly rather than creating a potentially misleading ad hoc comparison under the "wholly disproportionate" test.

We also conclude that the economic and technical analyses in the EEA are seriously inadequate. There are many concerns regarding the accuracy of the EEA cost estimates. The EEA provides virtually no information on the benefits of the proposed rule. Moreover, the treatment of alternatives to the proposed rule is cursory. In short, the EEA does not comply with EPA or OMB guidelines for cost-benefit assessments, including Executive Order 12866. Before proceeding any further, the Agency should complete its cost-benefit analyses of the proposed rule, provide reliable information on the costs and benefits of plausible regulatory alternatives, and otherwise comply with the requirements of Executive Order 12866.

C. Outline of the Report

The remainder of the report is organized as follows. Chapter II provides an economic evaluation of alternative EPA approaches, comparing the economic advantages and disadvantages of the proposed national standards approach with those of a case-by-case approach. Chapter III considers alternative approaches to making BTA determinations. We consider the proposed EPA approach, the current approach, and a cost-benefit approach that would be more consistent with both economic principles and the principles set forth in the EEA. Chapter IV shifts the focus from the proposed regulations to the EEA. In Chapter IV we consider the adequacy of analysis of several elements in the EEA, including the assessments of costs and benefits and the treatment of alternatives. Finally, Chapter V summarizes our major conclusions and recommendations with respect both to the nature of the regulations and the adequacy of the EEA.

II. ECONOMIC EVALUATION OF ALTERNATIVE 316(B) REGULATORY APPROACHES

This chapter and the following chapter together provide an economic evaluation of EPA's proposed 316(b) regulations for new facilities. As noted, EPA's proposed approach emphasizes the development of national BTA technology-related requirements that are evaluated based upon the affordability of the technology. The EPA proposed approach can be divided into two issues:

1. General approach to setting 316(b) requirements, i.e., national requirements rather than case-by-case determinations; and

2. Criterion for BTA determination, i.e., affordability rather than cost-benefit comparisons.

This chapter analyzes the first issue, i.e, the general approach. In order to isolate our concerns about EPA's proposed general approach, the examples in this chapter assume that BTA standards—either national or case-by-case—are set on the basis of cost-benefit comparisons. The examples illustrate that EPA's proposed national approach is inferior from an economic perspective to the case-by-case approach. Chapter III then addresses the second issue, i.e., the criterion for evaluating potential BTA technologies.

A. Alternative Regulatory Approaches

EPA recognizes the substantial change their approach would mean for 316(b) determinations. They note that a large number of regulatory alternatives are possible. This section summarizes the alternatives identified by the EPA and notes the fundamental shift in approach represented by EPA's proposed approach.

1. Overview of Alternatives Identified in the Proposed Rule

The Preamble to the proposed regulations provides discussions of alternative approaches to setting requirements for new facilities. The following is a list of these alternatives. (More complete descriptions and evaluations are provided in comments provided by the Utility Water Act Group).

1. National minimum requirement based upon the type of water body, with the possibility of additional site-specific requirements (EPA proposed alternative). This approach would set national minimum technology requirements for the location, design, construction, and capacity of cooling water intake structures that would differ depending upon the type of water body. Permit writers would have the authority to implement additional measures on a case-by-case basis.

2. Case-by-case determinations, based upon EPA guidance. This approach would make technology requirements dependent upon a case-by-case review.

3. Rebuttable presumption of national minimum requirements. Under this approach, site-specific factors could be used to rebut the presumption of the national minimum technology requirements.

4. National minimum requirements equal to a zero-intake flow (or nearly zero, extremely low flow) requirement. This approach would set national minimum requirements to be consistent with the results of adding a dry cooling system.

5. National minimum requirements, with the option of trading among components of BTA. This approach would allow facilities to trade off less stringent requirements in one dimension in exchange for more stringent requirements in another dimension. Facilities, for example, would be able to reduce flow below the minimum level in exchange for the opportunity not to reduce velocity as specified by the standards.

6. National minimum requirements that would apply the most stringent requirements to all water bodies. This approach would set uniform stringent requirements for facilities in all locations.

7. Site-specific determinations of Adverse Environmental Impact (AEI) and BTA, based upon a tiered approach. This approach would supplement the site-specific method by introducing a tiered approach. EPA discusses a three-tier version that would include screening, collection of additional information, and assessment of alternatives for BTA.

2. EPA's Preferred Approach

EPA proposes to adopt the first alternative. The proposed rule would set national minimum requirements for the location, design, construction and capacity of cooling water intake structures at new facilities. While EPA does not identify precisely what the technology requirements would be, it notes that the requirements might constitute a "technology suite" that would vary depending on the type of water body in which a cooling water intake structure is located as well as the location of the cooling water intake structure within the water body (65 Federal Register 49075-76).

Although EPA mentions seven alternative approaches, the seven are variations on two major themes.

1. Site-specific approach in which information on individual sites is used to set regulatory requirements; and

2. National approach in which technology performance requirements are set for all facilities in broad classifications.

The national approach would shift decision-making from the States and individual permit writers to the federal government. Permit writers currently make site-specific determinations, sometimes with regional or federal involvement. Under the national approach, however, the EPA would set the requirements. Individual states and permit writers would have limited discretion.

This report considers the economic desirability of the proposed shift to a national approach for 316(b) determinations. We conclude that a shift to a national approach is not justified from an economic perspective. The following section discusses the economic disadvantages of EPA's proposed national standards approach. We then discuss the economic advantages of the site-specific approach. The final section of this chapter considers how the site-specific approach might be modified to take into account the administrative and delay costs of site-specific determinations

B. Economic Disadvantages of EPA's Proposed National Standards Approach

The major economic disadvantage of the national approach is that uniform requirements would be wasteful. The wastes would occur in two ways:

1. National standards would result in greater costs than necessary to achieve a given level of environmental protection; and

2. National standards would produce fewer environmental gains than possible for a given level of resource expenditures.

These disadvantages flow from the large differences in the costs and benefits across facilities that are ignored by the national approach. This section summarizes the variability in costs and benefits across sites and provides examples to illustrate the limitations of the national standard approach.

1. Sources of Variability Across Sites in the Benefits and Costs of a Given Fish Protection Technology

Comments provided in UWAG 2000 supply evidence of the variability in costs and benefits across different facilities. These differences can be summarized as follows:

a. Benefit Variability

Installing a given technology at a new facility can result in vastly different benefits at different sites because of differences in the following factors:

Waterbody Characteristics
—hydrology
—zone of influence of intake
—temperature
—turbidity
—natural debris loading
—meteorological factors, such as ice formation and storm patterns

Biological Characteristics
—life history of species affected by the CWIS
—habitat preferences
—behavioral patterns

Plant Characteristics
—operational patterns/schedule, including planned outages
—likelihood of sedimentation build-up in front of intake
—maintenance/repair needs for all parts of intake structure

Those factors may vary in importance/relevance depending on individual site factors. The net result is that the environmental benefits of installing a given fish protection technology will differ substantially across different sites.

b. Cost Variability

The costs of adopting a given technology can also differ substantially depending upon the specific facility and site. Perhaps the most straightforward example is the case of a closed-cycle cooling water system, a technology that figures prominently in EPA's proposed national approach. (New facilities in many locations would have to reduce water intake flow to a level commensurate with the closed-cycle cooling system under EPA's proposed framework, as summarized in 65 Federal Register 49077.) The costs of this technology can vary depending on cooling water requirements, site conditions for construction, local atmospheric conditions, power costs in the regional electricity system, and the plant characteristics listed above as affecting the benefits.

2. The Proposed Uniform National Approach Would Waste Resources

The national technology minimum approach proposed by EPA largely ignores the variability in both the costs and the benefits of adopting specific cooling water intake structure ("CWIS") technologies—or technology performance standards—at different locations. Although their approach provides some variability in control requirements, the requirements would be uniform for large categories of potential locations. This approach does not appropriately consider the specific costs and benefits when determining which technology to install at specific locations. The national approach leads to three inefficient results:

1. First, the proposed approach would produce smaller fish-protection and other environmental benefits for a given level of costs;

2. Second, the proposed approach would impose higher costs than are necessary to achieve a given level of fish protection and other environmental benefits; and

3. Third, the proposed approach would not provide the appropriate incentives to locate facilities in areas with fewer environmental impacts.

It is useful to illustrate the disadvantages of the uniform national approach with some examples. The first example provides a benchmark for the comparisons by illustrating how BTA technologies would be set to maximize net benefits for two plants under the assumption that both plants have the same costs and benefits. This example assumes that BTA is based upon a benefit-cost comparison. (As discussed in Chapter III, the proposed EPA approach to setting BTA is not based upon cost-benefit comparisons; thus, the economic impacts of EPA's approach would be even worse than illustrated in this chapter.) The second example illustrates the drawbacks of ignoring variability in the benefits across different sites. The third example illustrates the disadvantages of ignoring differences in the costs across sites.

a. National Uniform Technology Standards Would Not Waste Resources if the Costs and Benefits of Alternative Technologies Were the Same for All Facilities

National technology based requirements implicitly assume that the benefits of applying the technology are the same regardless of the site, within broad water body and location categories. Put another way, the uniform approach at best tends to focus on the average values for costs and benefits, rather than consider the wide range of costs and benefits dependant upon the characteristics of the individual facility.

Table 1 provides an illustration of the costs and benefits of three technologies that could be applied in one of the broad groups identified in the EPA proposed approach (e.g., estuary or tidal river). The illustrative technologies represent increasingly expensive means of reducing fish losses at two identical facilities. The table shows the cost of applying each of the three technologies as well as the fish protection (and other) benefits if each of the three technologies were employed. The table also illustrates the incremental cost and incremental benefit of each of the technologies. Incremental cost is defined as the added cost of each technology relative to the previous one. For example, the incremental cost of Technology 2 is $50 million, the difference between the total cost of Technology 2 and the total cost of Technology 1 ($75 million minus $25 million).

Table 1: Illustrative Costs and Benefits of Alternative CWIS Technologies at Two Facilities with the Same Costs and Benefits ($millions)
[see hard copy for table]

The benefit-cost criterion implies that the choice should be based upon maximizing the net benefits, i.e., benefits minus costs. Net benefits are maximized for Technology 2, which is predicted to produce a net benefit of $50 million dollars for each of the two facilities. Although the more expensive Technology 3 has benefits ($175 million) that are greater than costs ($150 million), net benefits would only be $25 million, substantially less than the net benefits of Technology 2.

The rationale for stopping at Technology 2 can also be explained in terms of the incremental costs and incremental benefits of Technology 3 relative to Technology 2. The table shows that the incremental cost is $75 million and the incremental benefit is only $50 million of adopting Technology 3 relative to Technology 2. This illustrates the general rule that a more expensive technology would increase net benefits if its incremental benefits are greater than its incremental costs.

The point of including two facilities in Table 1 is to illustrate that if the costs and benefits are the same for all facilities, the national standards approach is adequate. The following sections illustrate the disadvantages of the national approach under the more realistic cases in which the benefits and the costs differ.

b. Ignoring Variability in Benefits Would Waste Resources and Ignore Opportunities to Obtain Environmental Benefits

The disadvantages of the uniform national approach can be illustrated by considering an example in which the benefits of applying each of the technologies differs for the two facilities. As noted above, applying the same technology can have vastly different benefits depending upon a host of factors. The benefits would be much greater, for example, if the technology were applied in an area where there is a high risk of adverse environmental impact (AEI) rather than in an area with little possibility of AEI.

Table 2 shows hypothetical estimates for the two facilities when this benefit variability is taken into account. Facility A represents a “low benefit” situation. This facility might be one located in an area with little risk of AEI, and thus the benefits from applying expensive fish protection technology are relatively small. Under EPA’s uniform technology approach, Technology 2 would be required at Facility A. That requirement would waste resources. The added cost of Technology 2 relative to Technology 1, which is equal to $50 million ($75 million minus $25 million) is greater than the added benefit of applying Technology 2, which is only $40 million ($70 minus $30 million). Put another way, Facility A would be over-controlled under the uniform technology requirement.

Table 2: Illustrative Costs and Benefits of Alternative CWIS Technologies at Two Facilities with the Same Costs but Different Benefits ($millions)
[see hard copy for table]

A uniform technology requirement also would prevent the opportunity to focus greater controls in “high benefit” areas. Facility B represents a “high-benefit” situation. This facility, for example, could be located in an area with substantial risk of AEI, and thus the benefits of adding fish protection technology to the cooling water intake system would be substantial. Under EPA’s uniform technology approach, Technology 2 also would be required at Facility B. That requirement would limit opportunities. The added benefit of Technology 3 of $160 million is greater than the added cost of $75 million, yielding a change in net benefits of $85 million from technology 2 to technology 3. That net benefit is foregone under the uniform technology approach.

In sum, ignoring variations in benefits tends to waste resources by requiring the same technology at all sites within a broad geographic area. The result is that resources are not targeted where they provide the greatest environmental benefits.

-Facilities in “low benefit” areas would tend to be over-controlled; and

-Facilities in “high benefit” areas would tend to be under-controlled.

Both situations lead to wasted opportunities to maximize the net benefits of regulations on cooling water intake structures at new facilities.

c. Ignoring Variability in Costs Would Waste Resources and Ignore Opportunities to Obtain Environmental Benefits

Facilities also differ substantially in the costs of applying a given technology. Table 3 shows the results of applying the uniform technology approach at two facilities that differ in the costs of control. Facility A represents a relatively high cost situation. Requiring Technology 2 at Facility A would waste resources because the incremental costs for Technology 2 of $105 million are substantially greater than the incremental benefits for Technology 2 of $75 million.

Table 3: Illustrative Costs and Benefits of Alternative CWIS Technologies at Two Facilities with Different Costs and the Same Benefits ($millions)
[see hard copy for table]

Facility B is a relatively low cost facility. Requiring Technology 2 at Facility B would generate substantial net benefits, equal to $65 million. But the uniform requirement ignores the opportunities to exploit the low costs of control at Facility B by applying more stingent controls. Applying Technology 3 to Facility B would lead to net benefits of $85 million, $20 million more than the net benefits under Technology 2.

In sum, ignoring cost variations also tends to waste resources and avoid opportunities tc obtain environmental improvements. Resources are not targeted where they provide the greatest environmental gains.

-High-cost facilities would tend to be over-controlled; and

-Low-cost facilities would tend to be under-controlled.

As with the situation in which benefit differences are ignored, ignoring cost variations leads tc wasted opportunities to increase the net benefits from regulations on cooling water intake from new facilities.

C. Economic Advantages of Site-Specific Approach

Determining the appropriate BTA technology on a site-specific basis avoids th disadvantages of the national technology-based approach. Under a site-specific approach control resources are focused where they provide the greatest benefits. In addition opportunities to obtain cost-beneficial environmental gains can be exploited.

This section illustrates the advantages of the site-specific approach. The examples continue to assume that requirements are based upon a benefit-cost test. (As discussed in Chapter III, the test that EPA proposes for BTA is not based upon benefit-cost comparisons and, indeed, is seriously deficient from an economic perspective.)

1. By Taking Benefit Variability Into Account, the Increases the Net Benefits of Controls

We can use the previous examples to illustrate the gains from taking benefit variability into account. Table 4 illustrates the same three technologies for Facility A ("lower benefit") and Facility B ("high benefit") under the assumption that the costs are the same when a given technology is applied to either facility. Because of differences in the benefits when a technology is added to the two facilities, as noted above, the appropriate technology choice is very different. Under the site-specific approach, Facility B ("high benefit") would have the most expensive technology while Facility A ("low benefit") would have the least expensive technology. Under this hypothetical example, the technology that would be chosen as the national uniform technology would not be appropriate for either of the two facilities.

Table 4: Illustrative Costs and Benefits of Alternative CWIS Technologies at Two Facilities with the Same Costs but Different Benefits ($millions)
[see hard copy for table]

Table 4 shows the gain from the site-specific approach relative to the uniform national approach. Under the site-specific approach, the overall costs are greater than if the two plants were both subject to the uniform technology; the total cost for the two facilities would be $175 million under the site-specific approach, compared to $150 million under the national uniform approach. But the benefits of the site-specific approach would be substantially greater, leading to an increase in net benefits from $130 million under the national uniform approach to $225 million under the site-specific approach.

2. By Taking Cost Variability Into Account, the Site the Net Benefits of Controls

Differences in the cost of control across sites leads to approach. Table 5 shows the case in which benefits are the same for the two facilities but costs vary substantially between the two facilities. Under the site-specific approach, Facility A ("high cost") would have the least advanced technology while Facility B ("low cost") would have the most advanced technology.

Table 5: Illustrative Costs and Benefits of Alternative CWIS Technologies for Two Facilities with Different Costs by the Same Benefits ($millions)
[see hard copy for table]

As in the case with varying benefits at the two facilities, the cost-varying case leads to different overall costs and benefits than under the uniform approach, both overall costs and overall benefits are lower than the net benefits are much greater under the site-specific approach, compared to just $40 million under the national uniform approach.

3. Summary of Illustrative Gains of the Site-Specific Approach

The full advantages of the site-specific approach are evident when the effects of both benefit variability and cost variability are taken into account. Table 6 summarizes the effects o applying the site-specific approach and the national uniform approach. The total net benefits of the national and site-specific approaches are the same when there is no variation in costs an benefits across facilities. But the illustrative net benefits under the two approaches are substantially different when benefit variation and cost variation are taken into account.

Table 6: Illustrative Net Benefits for Two Facilities Under National and Site-Specific Approaches
[see hard copy for table]

These examples illustrate that the site-specific approach is superior to the national approach except under a case in which all facilities have identical costs and benefits. When the costs and benefits vary—as they inevitably will—the site-specific approach provides higher net benefits than the national approach. Put another way, the national “one sized fits all” approach would waste resources by not targeting control expenditures where benefits are relatively high and costs are relatively low.

4. The Site-Specific Approach Also Leads to Appropriate Incentives to Locate Facilities Where Impacts are Low

The EPA at various points in its proposal notes the importance of providing incentives for facilities to locate outside areas where there is a high risk of adverse environmental impact. The national approach sets different requirements for facilities in different locations, which would discourage new facilities from locating where standards are relatively stringent. The proposed national requirements are most stringent for facilities in tidal rivers, estuaries and the “littoral zone” of freshwater rivers, lakes and reservoirs (65 Federal Register 49083).

Although setting different standards for facilities located in different locations provides some of the advantages of the site-specific approach, the requirements are too crude in light of the large differences in benefits among facilities located within the broad areas in the proposed regulations. In contrast, a site-specific approach provides the appropriate incentive for facilities to locate outside areas of important biological activity.

Note that the feasibility of locating facilities outside areas more likely to have adverse environmental impact depends upon the importance of other factors that go into siting decisions for new facilities. As EPA acknowledges, it is sometimes not possible to locate facilities outside of areas likely to experience adverse environmental impacts (65 Federal Register 49083). Many factors enter into siting decisions, including wage scales and other aspects of local labor markets, access to raw materials, and state and local taxes. In the case of electric generating facilities, access to natural gas pipelines for input supplies and proximity to electricity transmission lines are also important siting considerations.

The potential inflexibility of the national approach also could lead to unintended effects on the electricity prices and the reliability of the electricity system. Stringent and inflexible requirements could have the effect of creating “zoning restrictions” for electric power plants and other affected facilities. Indeed, the cumulative effect of 316(b) regulations and other policies—such as wetlands restrictions—could result in significant limitations in the ability to site new electric generating facilities. Such limitations could lead to higher electric rates and possible reductions in the reliability of the overall electricity system. These electric sector impacts could in turn affect overall growth in the U.S. economy (see, e.g., National Research Council 1986).

Because siting decisions can be complicated—and because the energy and other benefits of new facilities are important—it is important that the 316(b) regulations provide sufficient siting flexibility. At the same time, the regulations should reflect the disadvantages of locating facilities where these is a high risk of adverse environmental impact. The site-specific approach would provide such a balance.

5. EPA's Criticisms of the Site-Specific Approach Are Not Justified

EPA argues that it is proposing this new approach "based in large measure on the Agency's experience in attempting to implement section 316(b) on a wholly site-specific basis" (65 Federal Register 49079). The following are the alleged difficulties of the existing case-by-case approach mentioned by EPA in the proposed rule.

-Administrative and information costs. EPA argues that considerable resources have been expended by regulatory authorities and industry to develop case-by-case information.

-Disincentive to consider new technology. EPA claims that the information costs have resulted in reluctance to reconsider permit conditions in light of new technologies.

-Inconsistency. EPA argues that the case-by-case approach "might result in permitting decisions that are less consistent than they would be if national requirements were in place." (65 Federal Register. 49079)

-Predictability. EPA argues that "[t]he case-by-case approach results in less predictability regarding what is or may be required for a particular facility, which makes planning difficult for industry and leaves regulatory agencies uncertain about the appropriate requirements for particular water bodies or facilities." (65 Federal Register.
49079)

None of these alleged difficulties provides a persuasive economic rationale for preferring EPA's proposed national approach to the site-specific approach.

a. The Administrative Costs of the Site Specific Approach Are Justified by Better 316(b) Decisions

EPA claims that the historical case-by-case approach requires significant resources on the part of both regulatory authorities and industry (65 Federal Register 49079). The Agency, however, does not provide any specific information on the administrative costs that have been incurred under the case-by-case approach. Nor does EPA compare the administrative costs of the case-by-case approach with those of the proposed national minimum standards approach (which includes the potential site-by-site evaluation of alternative and supplementary standards).

EPA's concern for administrative costs is justified. Resources spent analyzing the costs and benefits of regulatory alternatives at different sites represent real resource costs. But the objective of efficient and effective regulation is not to minimize administrative costs but rather to maximize the net benefits of regulation. Resources spent to avoid inappropriate decisions— including regulations that are inappropriately stringent in some cases and inappropriately lax in other cases—can represent money well spent. Indeed, the field of decision analysis provides guidelines for determining the value of information collection (see. e.g., Raiffa 1968). The value of information depends upon whether it would influence the decision and the significance of the decision (see Stokey and Zeckhauser 1978).

Site-specific information for 316 (b) decisions may have considerable value because of the wide range of costs for possible fish protection technologies—ranging from relatively simple screens to expensive closed-cycle cooling systems—and the equally wide range of possible benefit circumstances. Collecting information that allows the technology to be tailored to the site conditions thus will pay off in the form of higher net benefits for the decisions that are ultimately made in 316(b) permits. Later in this chapter we illustrate how the site-specific approach might be modified to take administrative costs into consideration. That section also discusses the limitations of EPA's proposed approach to including some site-specific variability in its regulations.

b. The Site-Specific Approach Would Likely Provide Greater Opportunities to Consider New Technology Over Time Than the National Approach

EPA argues that the administrative costs of the site-specific approach have made permit writers reluctant to revisit 316(b) permit conditions in light of new technology. The Agency contends that the reluctance is a "significant concern." (65 Federal Register 49079)

EPA provides no information in the Preamble to support this concern. Thus, it is difficult to assess this argument. In general, the site-specific approach should provide greater incentive to encourage new technology over time than the uniform national approach. Requirements that appear to be based on particular technologies tend to lock in particular technologies and provide little incentives to modify controls in light of improvements (see Portney 1990). Having once put in the technology required under the minimum national requirements, facilities are unlikely to look for more effective or efficient methods. The incentives for long-run innovation of BTA technologies also would be diminished, since market opportunities would be limited to all but a select few technologies.

In contrast, a site-specific approach would provide the opportunity for a periodic review of the costs and benefits of technologies. Although owners may not have incentives to search for more stringent options, the need to review literature on current control options and their costs would provide a mechanism for new developments to be evaluated and considered in the permit renewal process.

c. The Site-Specific Approach Could Provide Greater Economic Consistency Than the Uniform National Approach

EPA argues that the historical case-by-case approach may result in less consistent permitting decisions than the national requirements of the EPA proposed approach. (65 Federal Register 49079) The Agency does not specify its definition of consistency. If consistency means subjecting facilities to the same regulatory requirements regardless of their individual situations, EPA's contention is certainly true. But such consistency seems of little value and would only reflect the lack of appropriate flexibility in the national approach.

The site-specific approach would be more consistent than the national approach if consistency is measured in economic terms, i.e., as effective and efficient regulation. The site-specific approach would allow permit writers to take into account the individual circumstances of individual facilities. Although one could not be certain that all permit writers would use appropriate economic criteria—as outlined in Chapter III of this report—the site-specific approach at least offers the possibility of deciding on controls at individual facilities in an economically rational manner.

d. Any Greater Predictability of the National Uniform Approach Would Reflect Its Lack of Flexibility Compared to the Site-Specific Approach

The EPA argues that the case-by-case approach results in less predictability regarding what is required for a particular facility. This lack of predictability, according to EPA, "makes planning difficult for industry and leaves regulatory agencies uncertain about the appropriate requirements for particular water bodies and facilities." (65 Federal Register 49079)

While a national uniform approach may lead to greater predictability—because the required technologies would be identified in the national requirements—such predictability would come at the cost of flexibility. Indeed, predictability seems another term to describe the inflexibility of the national technology approach proposed by EPA for new sources. In contrast, a site-specific approach would provide appropriate flexibility to industry and permit writers, even if the specific technology requirements were not identified long in advance. Over time, both facility owners and regulatory agencies are likely to develop more accurate predictions of the types of technologies that would be appropriate at individual facilities.

6. The Site-Specific Approach Can be Modified to Deal with Administrative and Delay Costs

The EPA notes that the site-specific approach may lead to greater costs to both permit applicants and regulatory authorities that implement 316(b) requirements. These costs include the administrative costs of developing information on 3 16(b) alternatives as well as the delay costs from any additional time required for the site-specific reviews. EPA uses increased administrative and delay costs as a major rationale for rejecting the site-specific approach (although as also noted above, the Agency does not provide any specific information on the nature or size of these costs). The EPA does, however, propose to include site specific factors in regulatory determinations through proposed procedures for setting additional and alternative BTA requirements (65 Federal Register 49091).

As emphasized above, the site-specific approach allows regulatory agencies and owners of facilities to develop information on the costs and benefits (and other impacts) of alternative CWIS technologies. This information is important to determine which of the possible alternative CWIS technologies should be BTA at the particular site. As noted above, EPA's critique of the site-specific approach ignores the importance of this information to increasing the net benefits of BTA determinations. Substantial administrative or delay costs would be warranted in order to avoid costly mistakes in setting BTA requirements. These mistakes could involve requiring expensive CWIS controls where they are not justified—in which case the mistakes would involve excessive resource costs—or foregoing the possibility of environmental gains from more extensive CWIS requirements than would be set through national requirements. These considerations do not mean, however, that no accommodations should be made to deal with administrative and delay costs.

This section suggests means of taking administrative costs into account in the site-specific approach. We also discuss the disadvantages of EPA's proposed additional and alternative requirements.

a. Possible Modifications to the Site-Specific Approach

The administrative costs of the site-specific approach may not be justified in al] situations. In some cases, the costs of obtaining this information—including the disadvantage-- of the delays involved in collecting the information and developing regulator) determinations—may be greater than its value in improving the BTA determination. This possibility suggests the usefulness of a categorical approach that could be used as an alternative to the site-specific approach.

One possibility is for the 316(b) regulations to include an option in which a prospective facility could choose to install pre-approved, highly protective technology in exchange for obtaining a speedy approval of its 316(b) application. This alternative would provide the flexibility to avoid situations where the administrative and delay costs were large relative to the potential gains from a more accurate assessment. The company would voluntarily incur the higher costs of the pre-approved technology in order to reduce administrative costs and to obtain the gains from getting its project approved more quickly. These latter gains would include the gains from getting its facility in operation earlier, and thus getting its products to he market more quickly. A power producer, for example, could choose to install the pre-approved technology—and thereby reduce the administrative costs of information collection rid regulatory review—in order to enter the market more quickly.

This option would not detract from the economic advantages of the site-specific regulatory approach. The facility would always be free to choose the site-specific approach and thus incur the added administrative and delay costs if the gains from the additional information were considered to be sufficiently large. It seems appropriate to give the option to the facility owner—rather than to the regulatory agency—because the facility owner is likely to be in a good position to provide a preliminary assessment of the likely costs and potential gains of developing a detailed site-specific evaluation of BTA alternatives.

b. Disadvantages of EPA's Proposed Additional and Alternative Requirements

The EPA proposes that permit writers would require additional (i.e., more stringent) requirements where necessary to ensure attainment of water quality standards (65 Federal register 49091). The proposed regulations would also allow the EPA to set alternative (i.e., less stringent) requirements under certain circumstances.

These EPA proposals implicitly acknowledge the significance of site-specific factors. lese specific accommodations, however, are not a plausible alternative to retaining the sitepecific approach, including the modifications noted above. The requirements for determining additional alternatives are excessively vague. The specific requirements for approving alternative standards would not yield the gains from an appropriate site-specific approach.

The proposed 316(b) regulations would require that more stringent ("additional") requirements be included when they are "necessary to ensure attainment of water quality standards, including designated uses, criteria, and anti-degradation requirements." (65 Federal register 49091). This site-specific requirement is extremely vague and does not provide an indication of the circumstances under which particular 316(b) requirements would be made more stringent. Whether water quality standards are met in a particular water body will depend upon many factors unrelated to 316(b) determinations at a single facility. The proposed regulations provide no indication of how such a general mandate would be interpreted and what its likely effects would be.

In contrast, EPA is very explicit about the criterion that would be used to determine whether less stringent requirements would be allowed. The EPA proposes that

"alternative requirements that are less stringent than the requirements of Section 125.84 [the national requirements] would be approved only if compliance with the requirement at issue would result in compliance costs wholly out of proportion to the costs considered during development of the requirement at issue. . . - (65 Federal Register 49091)

This criterion would not result in decisions that obtain the economic advantages of the site-specific approach. This criterion does not allow EPA to consider the costs and benefits of alternative BTA technologies in the particular site. Instead, EPA would only consider whether the costs at the particular site were “wholly out of proportion” to the costs assumed by EPA when it set the national technology requirements. Put another way, if EPA set its national BTA requirements on the basis of costs and benefits, this criterion would address only one of the two elements—the costs and not the benefits.

EPA’s proposed approach for setting alternative BTA requirements raises the general problems with EPA’s approach to setting BTA requirements—BTA is based upon a determination of whether costs are “affordable” rather than whether costs are appropriate in light of the benefits to be obtained. The following chapter discusses the disadvantages of basing BTA requirements on “affordability” and the advantages of using a cost-benefit framework.

III. ECONOMIC EVALUATION OF ALTERNATIVE APPROACHES TO BTA DETERMINATION

This chapter evaluates the test that EPA has proposed for determining what technology constitutes BTA. As noted, EPA’s test focuses on the “affordability” of control costs to the industries covered by 316(b). This chapter discusses this and other BTA tests identified by EPA. We conclude that the affordability test would not be a sufficient test from an economic perspective and recommend that EPA adopt a true cost-benefit test to identify BTA on a site-specific basis.

A. Regulatory Alternatives Identified by EPA

EPA proposes several cost tests for evaluating cooling water intake structure (CWIS) technologies to be used in place of benefit-cost analysis (BCA). EPA claims that the tests could be used “to evaluate [if] the costs that would be associated with this proposal are reasonable in relation to the environmental benefits to be derived” (65 Federal Register 49095). Despite this claim by EPA, none of the tests proposed would serve this purpose. The only test that fulfills this stated purpose is a benefit-cost test that is not included in EPA’s list.

1. Overview of Alternatives Identified in the Proposed Rule

EPA identifies four cost tests for determining BTA.

1. Wholly disproportionate cost test. In the wholly disproportionate cost test, an alternative would not be considered BTA if the costs of implementing the alternative are “wholly disproportionate” to the environmental benefits achieved by the alternative.

2. Compliance cost to revenue test. The compliance cost to revenue test compares the cost of a BTA alternative to the revenues generated by the facility.

3. Compliance cost to construction cost test. The compliance cost to revenue test compares the cost of

a BTA alternative to the construction cost for the new facility.

4. Compliance cost to discounted cash flow test. The compliance cost to discounted cash flow test compares the cost of a BTA alternative to the discounted cash flow due to the construction of the new facility.

Of the four tests, the “wholly disproportionate” test is the only test that considers both the costs and benefits of possible BTA alternatives. As discussed below, the “wholly disproportionate” test is economically inferior to a test that would compare net benefits of BTA alternatives.

The other three tests consider the magnitude of the BTA costs in comparison to other costs or revenues. The apparent rationale for these tests is that they measure the “affordability” of the BTA alternative to facility owners or consumers.

2. EPA’s Proposed Alternative

EPA proposes to use the compliance cost/revenue test as the most appropriate test (65 Federal Register 49095). The Preamble lists several reasons for this choice, including EPA’s extensive experience using the measure, the ready availability of data for the test, and EPA’s belief that the test provides a reliable measure of whether costs are “economically practicable.”

B. Economic Disadvantages of EPA's Proposed Affordability Approach

Although "affordability" is a useful concept, it is not desirable from an economic perspective as the sole criterion for selecting BTA technology. The "affordability" test proposed by EPA for BTA determination provides only a partial assessment of the economic factors and issues relevant to the determination of BTA. The EPA's approach has several disadvantages compared to a true benefit-cost test:

-Affordability ignores consideration of costs and benefits of BTA alternatives.

-Affordability ignores consideration of the incremental effects of increasingly stringent (and expensive) alternatives.

-Affordability ignores the indirect effects of the BTA requirements. The following subsections address these disadvantages.

1. EPA's Proposed BTA Test Ignores Consideration of Costs and Benefits

EPA's "affordability" test does not compare the costs and benefits of alternative BTA requirements. This inadequacy is contrary to well-established economic principles as well as EPA/OMB Guidelines and, indeed, the principles outlined in the EEA for this regulation.

a. Economic Principles Behind Environmental Regulation

As EPA notes in the EEA, environmental regulations are developed to correct market imperfections resulting from externalities (e.g., pollution) associated with the production or consumption of services and goods. Although externalities impose costs on individuals, these costs are not reflected in the prices of goods and services. As a result, the level of these externalities is "too high" relative to the situation in which prices reflect these costs. When prices reflect external costs, the external effects are said to be "internalized" into individual's decisions, thus leading to individual decisions that properly reflect the social costs.

Viewed from this perspective, the development of environmental regulations is an effort to ensure that the production and consumption of goods and services reflect the unpriced costs of these decisions on the environment. This perspective is consistent with the view taken by EPA in the EEA:

The goals of environmental legislation and subsequent implementing actions, such as the 316(b) regulation that is subject to this analysis, is to correct environmental externalities by requiring the responsible parties to reduce their actions causing environmental damage... These actions result in a supply of goods and services that more nearly approximates the mix and level of goods and services that would occur if the industries impinging and entraining organisms fully accounted for the costs of their AEI-generating activities. (EPA 2000, p. 2-6)

Regulations provide a means of internalizing the cost of externalities in the production and consumption decisions of individual producers and consumers.

b. EPA and OMB Guidelines

The importance of cost-benefit analysis as a tool to developing appropriate regulatory requirements is indicated in both EPA and OMB guidelines. The EPA, for example, provides the following recommendations for any economic analysis:

For most practical applications, therefore, a complete economic analysis comprises a benefit-cost analysis, an economic impacts analysis, and an equity assessment. (EPA 1999)

Guidelines by OMB are consistent with this perspective, suggesting that an economic analysis should provide information allowing decision-makers to determine whether, [t]he potential benefits to society justify the potential costs, recognizing that not all benefits and costs can be described in monetary or even quantitative terms, unless a statute requires another approach. (OMB 1996)

The economic test proposed by EPA fails to compare costs and benefits. Thus, the approach fails to provide any assurance that BTA determinations would result in positive net benefits.

c. EPA’s Engineering and Economic Analysis

The lack of a cost-benefit test for BTA is particularly surprising given statements by the EPA in the EEA that appear to support the cost-benefit approach. In justifying regulatory interventions in environmental problems, the EEA states that:

This approach to addressing the problem of environmental externalities will generally result in improved economic efficiency and net welfare gains for society if the cost of reducing the activities causing environmental harm is less than the value of benefits to society from the reduced AEI. (EPA 2000)

While EPA appears to recognize the importance of costs and benefits in describing the rationale for regulatory intervention, the Agency does not follow through with the implications of this position in developing the proposed BTA rule.

By failing to consider benefits, EPA’s proposed BTA test would not determine whether a given BTA alternative produced net social benefits. Failure to consider benefits in BTA determination represents a significant contradiction with the Agency’s position on the proper approach to address externalities.

2. Failure to Consider Costs and Benefits May Lead to Perverse Policy Outcomes

The three economic “affordability” tests fail to account either for the environmental benefits provided by CWIS investments or any adverse environmental impacts associated with CWIS investments. These tests contain no information about whether or not these compliance costs yield commensurate or even any reductions in net adverse environmental impacts.

Table 7 shows an example of how the proposed EPA test for BTA could lead to an economically-incorrect policy decision. Consider an electricity company with two plants facing an “affordability” test. For this example, assume that compliance costs are the same for both plants. Plant A is a high revenue plant, while Plant B is a lower revenue plant. The characteristics of the natural resources affected by these plants differ dramatically.

Using the economic-affordability test, the proposed BTA would pass the test at Plant A and would fail the test at Plant B. Thus, environmental-protection resources would be expended to protect the lake at Plant A, rather than protecting the lake at Plant B.

A BTA test that compares costs with benefits would reach a different conclusion. For this example, we focus on recreational benefits for the sake of simplicity. Plant A uses water from a lake with relatively little recreational value because of its location, characteristics, and substitutes. In contrast, Plant B uses water from a high-value lake. Using EPA’s economic affordability tests, therefore, would expend environmental-protection funds to protect a low-value lake while allowing a high-value lake to go unprotected.

This example uses the compliance cost/revenue test. A similar example could illustrate the problem with the other two affordability tests, based on construction cost and discounted cash flow. If Plant A is a larger plant with higher construction costs or discounted cash flow relative to Plant B, then Plant A would receive the increased environmental protection and Plant B would not. Again, the decision would have nothing to do with the relative value of the environmental resources to be protected.

Table 7: Example of Failure of Economic "Affordability" Tests
[see hard copy for table]

This example illustrates the regulatory mistakes that would arise if decisions are evaluated without careful attention to benefits. Benefits can be difficult to measure and express in dollar terms. It can be difficult to predict the level of actual environmental protection (i.e., reduction in entrained fish) that will be realized. It can also be difficult to determine what resource services are enhanced by the environmental protection and to put a dollar value on those services. Indeed, EPA and OMB both have established methods for evaluating benefits in the face of those difficulties, rather than just ignoring benefits completely. If benefits information is developed for alternatives, decision makers can use the relative levels of benefits to inform the BTA decision. Note that the benefits information would include judgments on the benefits (and costs) that might be omitted in the quantified information. Relying only on the affordability tests, in contrast, means that no information on benefits can inform these determinations.

3. The “Wholly Disproportionate” Test Improperly Compares Costs and Benefits

The cost-benefit perspective also provides important insights into the proper balancing of costs and benefits for a BTA test. The cost-benefit perspective indicates that incremental benefits and incremental costs should be balanced so that net social welfare is maximized. The “wholly disproportionate test” developed by EPA twenty years ago is not consistent with this perspective. The wholly disproportionate approach appears to be motivated by the unsubstantiated assumption that measured benefits are consistently and significantly understated relative to costs. Both costs and benefits include components that are difficult to measure and thus involve some degree of uncertainty. For example, cooling-tower costs are not limited to construction, operation, and maintenance costs. The reduction in operating efficiency will reduce electric power generation, whose value is highly variable in competitive electric power markets.

A careful benefit-cost analysis of BTA alternatives could evaluate uncertainties in the cost and benefit components. EPA's approach of overcorrecting for perceived relative biases in estimates of costs and benefits is incompatible with the economic guidelines. The economic tools available for understanding and quantifying both benefits and costs have improved substantially over the past twenty years. By promoting an unbalanced comparison of costs and benefits, the "wholly disproportionate" test encourages BTA choices that, by definition, could impose social costs potentially much greater than social benefits.

4. EPA's Alternative Ignores Considerations of Incremental Effects

An important element of a complete BTA assessment is the consideration of the costs and benefits of all feasible technologies or operational requirements to achieving 316(b) goals. EPA's recommended BTA test does not appear to incorporate evaluation of multiple BTA alternatives. Failure to examine alternatives seriously limits the usefulness of information derived from the economic analysis by failing to provide any information on the incremental costs and benefits of alternative requirements.

There are a large number of technology and operational requirements that are for BTA candidates. These alternatives include the following:

-Changing/altering intake location;
-Operational requirements (e.g., seasonal flow reductions);
-Technologies to reduce intake velocity (e.g., passive screens); and
-Technologies to reduce impingement and entrainment (e.g., traveling screens, fish baskets, Gunderboom, fish deterrents (strobe lights, air bubble curtains, and sound)).

As noted in Chapter II, the costs and benefits of these alternatives vary significantly depending on a large number of factors, including the following:

-Local aquatic species. The effectiveness of various alternatives at reducing impingement and entrainment varies widely by species.
-Intake design. The feasibility of installing different technologies on existing CWIS varies widely with the type of facility and its intake design.
-Intake location. The impact of a BTA alternative on aquatic species depends greatly on the intake location and the species in the vicinity.
-Seasonal Conditions. Seasonal weather, turbidity and debris affect both the costs of alternatives and their effectiveness.
-River Conditions. River flow and geography affect the ability to site various

Because of the many factors affecting the costs and benefits of BTA alternatives at different locations, the cost-benefit analysis should include all alternatives that are feasible and likely to be effective at the site. Variations in costs and benefits due to these factors will lead to different cost-benefit ordering of BTA alternatives for different facilities. A cost-benefit analysis of alternatives therefore will be the most effective approach for identifying technologies that are most advantageous in terms of the benefits produced and the costs incurred.

Evaluation of the costs and benefits of feasible alternatives provides the information that is necessary to identify the most appropriate technologies at a particular location. This evaluation can provide two types of information on feasible alternatives:

1. Dominated Alternatives. An evaluation of alternatives can identify which alternatives are "dominated" by others. One alternative dominates another if it provides greater benefits at a lower cost.

2. Incremental Costs and Benefits. The incremental costs and benefits of an alternative are the costs and benefits of the alternative relative to the next less stringent alternative.

Chapter II provided an example of the use of incremental analysis. Evaluation of the incremental costs and benefits of alternatives allows permit writers to assess whether the benefits gained by requiring a more costly technology justify the additional costs.

The importance of evaluating alternatives is recognized in EPA's Guidelines for Preparing Economic Analyses, which states that:

In addition to considering a wide variety of possible approaches for environmental protection, analysts and policy makers should also examine other characteristics of regulatory and non-regulatory policies that affect their costs and effectiveness. For example, evaluating the benefits, costs and other effects at different levels of stringency for a given policy can help to determine setting that provide the greatest net benefits to society (EPA 1999).

Thus, EPA's own guidance recognizes the importance of evaluating alternatives to identify appropriate requirements.

5. EPA's Alternative Ignores Important Electric Power Costs

EPA's approach to BTA appears to involve assessing only the construction and operating costs of the proposed requirements. For many facilities, these costs will account for the bulk of the relevant costs. In the case of electric power facilities, however, this approach is seriously incomplete.

Some CWIS alternatives reduce the performance of electric power generation facilities, thus reducing the quantity of power that can be generated. Reasons for these various performance penalties include the following:

- Reductions inflow or velocity. Reductions in flow or velocity reduce the effectiveness of the cooling system. As a result, the quantity of power that can be generated by the electric generation facility declines.

- Reductions in cooling efficiency. Some technologies reduce the efficiency of the cooling water system to condense the steam turbines. Close-cycle cooling systems, for example, generate turbine backpressure due to the reduced efficiency of the cooling system, which reduce power generation performance.

- Auxiliary power requirements. Many CWIS technologies require electricity. These auxiliary power requirements reduce the net electricity generation produced by the facility.

These power costs should be included in an assessment of the costs of CWIS alternatives.

Reductions in power plant performance can also adversely impact the reliability of the electric power system, potentially increasing the risk of brownout, blackouts, or curtailments in load provided to particular users. These reliability impacts should be considered in a full assessment of the impacts of alternative BTA requirements. BTA alternatives that require reduced water flows during active biological periods may particularly exacerbate reliability problems, since these important biological periods often coincide with periods when electric power is in greatest demand.

C. Economic Advantages of the Appropriate Cost-Benefit Test for BTA

The methodology for determining BTA should rely on a procedure that considers alternative feasible technologies and operational requirements for reducing impingement and entrainment. The costs and benefits of alternatives should be estimated to identify the "best" alternative available to achieve 316(b) goals. The "best" alternative is the one that maximizes the net benefits (i.e. benefits minus costs). This section describes an economically-sound process to determine BTA in individual cases.

1. A Cost-Benefit Procedure for BTA Determination

Determination of BTA for CWIS at new facilities requires a reliable and effective approach considers the costs and benefits of alternative technologies and operational requirements for reducing AEI. Economists and other analysts have developed well established procedures to evaluate the benefits and costs of alternatives. The net benefits are maximized by adopting increasingly expensive alternatives only if the incremental benefits exceed (or equal) the incremental costs.

The proper cost-benefit procedure can be summarized in the following process.

1. Identification of alternatives. Identify alternatives for the specific site, including technology combinations.

2. Cost and benefit valuation. Develop information on the expected costs and expected benefits of each alternative, putting the elements into dollar values to the extent feasible.

3. Organization of alternatives. Array the alternatives in terms of increasing expected costs.

4. Incremental analyses. Calculate the incremental costs and incremental benefits of each alternative.

5. Identification of most efficient alternative. Identify the alternative — which could include a combination of technologies — that has the greatest net benefits (i.e., benefits minus expected costs).

6. Uncertainty analyses. Identify uncertainties and elements that cannot be put in dollar terms and the

range of uncertainty in the estimates. Determine the affects of these uncertainties on BTA choice.

This cost-benefit analysis can be supplemented by other assessments as part of a full analysis of BTA alternatives. Two factors may be particularly relevant:

-Affordability constraints. The alternative that maximizes net social benefits may not be financially feasible for the affected plant. This consideration is particularly relevant now as the electric generation sector becomes subject to increasing competitive pressures.

-Distributional equity considerations. The geographic or socioeconomic distribution of benefits and costs for the alternative that maximizes net benefits may be socially unacceptable. For example, the choice of an expensive technology could impose unacceptable job losses in a region of already high unemployment.

2. Specific Issues in Cost and Benefit Estimation

Cost-benefit analyses require the careful enumeration of the monetary value of different impacts resulting from BTA alternatives. These impacts are typically separated into costs negative impacts) and benefits (positive effects), although the two categories are closely elated. Methodologies have been developed to value different impacts using well-established procedures, including the use of procedures to deal with limitations on the availability of sitepecific information. The following sections provide brief discussions of the procedures to valuate costs and benefits.

a. Evaluation of Social Costs

The costs included in cost-benefit assessments should reflect costs to society as a whole. The cost values should not include effects that represent transfers from one group to another. The current EPA Cost-Benefit Guidelines define social cost as follows:

The total social cost of pollution control are the opportunity costs incurred by society because of regulation. They are the value of goods and services lost by society resulting from the use of resources to comply with and implement a regulation, and from reductions in output. (U.S. Environmental Protection 1983, Appendix B, p. 3).

The most significant component of the total costs for regulatory requirements typically is the value of the private resources required by the regulation. The EPA Cost-Benefit Guidelines, for example, state: "The principal component of total social costs is private real-resource costs. These are pretax compliance costs net of any transfers, such as emissions fees, licensing fees, or subsidies."(U.S. Environmental Protection Agency 1983, Appendix B, p.3). Other components of social costs noted in the EPA Cost-Benefit Guidelines include unpriced resources as well as governmental regulatory costs, deadweight welfare losses, and adjustment costs (U.S. Environmental Protection Agency 1983, Appendix B, p. 4).

The most important social costs of BTA alternatives for electric power facility can generally be organized into the following four categories:

1. Capital costs. Capital costs are the one-time costs of constructing and installing the CWIS

technology.

2. Operating and maintenance cost. Operating and maintenance costs are the annual costs to operate and maintain the CWIS technology.

3. Power costs. Implementation of BTA alternatives may lead to power losses due to plant shut-down during construction or impacts of BTA alternatives on plant performance. These power losses lead to social costs.

4. Other Environmental costs. These include the environmental costs that result from the installation of the CWIS technology. They include, for example, potential air pollution increases.

The first two cost categories capital costs and operations and maintenance costs are conceptually simple and will not be discussed further.

Power costs may occur during the following two periods of plant operations:

-Power Costs during Construction Delay. If the alternative would delay the opening of the plant, then the power output (generation and capacity) would be lost during that period. The costs of replacing the lost power represent real costs.

-Power Costs during Continuing Operations. BTA alternatives may lead to reductions in plant performance due to auxiliary power requirements, turbine inefficiencies (heat or performance penalties), and reductions in maximum generation capacity. Each of these impacts results in power costs.

Note that power losses include both the loss in available capacity as well as the loss in expected energy output. The traditional way of calculating these costs is to determine what additional costs would be incurred in the utility's system to make up the loss internally. With increasing competition in wholesale electric power markets, these costs can be increasingly determined from market prices, both for capacity and energy output.

Environmental costs reflect the cost of environmental externalities that can result from implementation of BTA alternatives. These costs can sometimes be difficult to if they are not priced through market exchanges. In a growing number of situations, however, markets for environmental externalities can provide information on the cost of these externalities. The following are examples of potential environmental costs:

- Water contamination. A potential BTA technology might require that a water body be dredged, requiring disposal of potentially hazardous material and possibly releasing that hazardous material into the environment.

-Air emissions. The auxiliary power requirements and performance penalties resulting from cooling towers typically result in power costs. Increased generation from other power sources is necessary to offset the power losses. Replacement power may increase overall electricity air emissions or increase the cost of achieving emissions targets.

-Visibility and wildlife impacts. Implementation of cooling towers, for example, may result in visibility impacts due to the siting of large cooling towers, and wildlife impacts, (e.g. birds that collide with cooling towers).

Markets are sometimes available to price these environmental costs. The prices of emissions permits in cap-and-trade programs for NOx and SO2, for example, provide reliable sources of information on the costs of changes in air emissions. <FN1> When markets are not available for these costs, they should not, however, be ignored. These costs should be included in a quantitative or qualitative fashion as part of the overall cost of CWIS technology alternatives.

b. Evaluation of Benefits

The benefits included in the cost-benefit assessments should reflect benefits to society. Estimates of environmental benefits reflect social benefits when they are based on the willingness to pay (WTP) of individuals who receive the increased environmental services (e.g. recreational fishing services). WTP represents the value of a good or service in monetary terms (i.e., the amount the individual is "willing-to-pay" in dollar terms). The current EPA Cost-Benefit Guidelines for benefits assessment summarize this approach as follows:

The satisfaction that individuals experience because of the environmental improvement is a measure of the benefits of the regulation. Assuming that people are aware of the effects of pollution, these benefits can be expressed in monetary terms by identifying individuals' willingness to pay for an environmental improvement. (U.S. Environmental Protection Agency 1983, Appendix A, p. 2, emphasis in original)

This approach to measuring benefits is consistent with Office of Management and Budget Guidelines (1996) and standard economic texts (e.g., Stokey and Zeckhauser 1978, Tietenberg 1996 and Nau 1997).

The EPA cost-benefit guidelines provide indications of the types of analyses involved in determining benefits from alternative CWIS alternatives. The EPA cost-benefit guidelines identify two components of ecosystem benefits (U.S. Environmental Protection Agency 1983, Appendix A, p. 30). <FN 2>

1. Benefits from Changes in Commercial Species. Regulatory requirements leading to changes in the stock of species used commercially (e.g. commercial fishery stocks) can lead to changes in yields or total production. Under these circumstances, the guidelines state that "[In] the special case of output changes that do not affect market prices, the appropriate measure of producer's surplus is simply the expected change in output multiplied by market price per unit."

2. Benefits from Changes in Recreational Species. Regulatory requirements leading to changes in the stock of species used recreationally (e.g., recreational fishery stocks) can lead to changes in recreational benefits. Under these circumstances, the guidelines suggest using methods that capture individuals' willingness-to-pay for recreational services.

Both commercial and recreational fishing benefits can be estimated using methodologies and specific empirical studies in the economic literature. This information can be used to develop reliable estimates of the benefits to society from CWIS changes.

3. Advantages of the Cost-Benefit Approach

The cost-benefit approach to BTA determination has several important strengths:

-Appropriate BTA standards for individual units. Consideration of the incremental costs and benefits of alternative CWIS technologies allows BTA decisions to properly reflect the trade-off between the costs of BTA requirements and the benefits that would be achieved by those requirements.

-Organizes information. It organizes important information about the large number of potential BTA choices in a logical manner.

-Accounting for uncertainty. The cost-benefit framework provides an explicit approach to accounting for uncertainty about both costs and benefits. In particular, the cost-benefit approach provides a more reliable approach than the “wholly disproportionate” tests discussed by EPA.

a. Appropriate BTA Requirements for Individual Facilities

Comparison of the costs and benefits of alternative CWIS requirements allows the best” technology to be selected in individual cases. Failure to consider the benefits at individual facilities may result in the choice of a CWIS alternative that involves costs not warranted by the resulting benefits (i.e., incremental costs greater than incremental benefits) or that is dominated by another CWIS alternative (i.e., generates fewer benefits at greater costs).

b. Organizes Information

The cost benefit approach provides a clear framework for organizing the many costs, benefits, and other impacts of CWIS alternatives. The approach allows for effects to be assessed through both qualitative and quantitative analysis. The cost-benefit approach provides a framework for organizing information on all of the positive and negative effects of various BTA alternatives.

c. Proper Accounting for Uncertainty

This framework provides a better means of dealing with uncertainty than a “wholly disproportionate” test. A “wholly disproportionate” test would mandate CWIS investments whose measured costs exceed measured benefits by some substantial margin. Such a test is arbitrary and tends to obscure rather than clarify policy choices. The net effect of the “wholly disproportionate” test would be to waste scarce public and private resources.

IV. EVALUATION OF EPA’S ECONOMIC AND ENGINEERING ANALYSES

This chapter shifts from an evaluation of EPA’s proposed regulatory approach to an evaluation of EPA’s economic and engineering analyses. As noted, EPA’s analyses of the costs and benefits of the proposed 316(b) regulations for new facilities are contained in the EEA.

The EEA provides useful information on the industries covered by 316(b) regulations for new facilities—notably electric power generators, chemical facilities, and primary metals facilities—and on the need for regulation. The document also provides EPA's assessments of the numbers of new facilities in each industry that would be affected by the new source rule, the costs that these facilities would incur under EPA's proposed approach, some information on the likely benefits, and some discussion of regulatory alternatives.

This chapter provides a review of some of the technical and economic analyses in the EEA. We begin with summaries of the methodologies used in the EEA to estimate the overall costs and benefits of the proposed rule and an overview of our concerns with the EEA.

A. Overview of EPA's Cost and Benefit Analyses

1. EPA's Cost Analysis.

The EPA's Engineering and Economic Analyses develops an estimate of the national cost of the proposed 316(b) New Facility Rule. This estimate is developed using the following three step process:

1. Step 1: Baseline Projections of New Facilities (Chapter 5). The EPA estimates the number of new facilities that would be affected by the 316(b) New Facility Rule over the period 2001 to 2020.

2. Step 2: Facility Compliance Costs (Chapter 6). In this step, the EPA estimates the total facility compliance costs (including permit renewal costs) for different types of facilities affected by the 316(b) New Facility Rule. Costs are estimated only for additional modifications and technologies to comply with the proposed rule beyond the facility's baseline technologies.

3. Step 3: Social Cost Estimates (Chapter 6 and Chapter 8.2). The EPA develops an estimate of the aggregate social cost of the 316(b) New Facility Rule. This estimate is 2020. The EPA adds state and federal implementation costs.

EPA's analysis concludes that the total annualized costs of the proposed rule are $12.21 million (1999 dollars). This estimate includes $12.13 million in direct compliance costs for facilities, and about $80,000 in state and federal implementation costs. The EPA also performs an "affordability" test of the proposed rule by comparing facility compliance costs to revenues for each affected facility. For electric generation facilities, the EPA also uses an affordability test based on the ratio of facility compliance costs to facility construction costs.

2. EPA's Benefit Analysis

EPA's analysis of the benefits of the proposed 3 16(b) New Facilities Rule does nol develop estimates of the dollar benefits of the proposed rule. The EPA states that "time and data constraints do not permit a quantified assessment of the economic benefits of the proposed rule" (EPA 2000, p 11-16). Instead, the EPA performs an assessment of "potential" benefits that includes the following two elements:

1. Benefits Taxonomy. The EPA provides a qualitative description of the types of benefits that would be generated by the proposed rule. These include market, nonmarket direct use, non-market indirect use, and nonmarket nonuse values.

2. Anecdotal Assessment of Benefits at Existing Sites. The EPA reviews estimates of the benefits of alternative BTA technologies for five existing facilities based on published papers or reports.

The EPA also evaluates the magnitude of the potential impingement and entrainment losses from CWIS. This biological analysis is not discussed in this report.

3. Overview of Concerns with the EEA

We conclude that the EEA suffers from some important inadequacies. These include thc following:

-The EEA's projections may understate the numbers of new facilities affected by th proposed rule.

-The EEA appears to understate the costs of closed-cycle cooling systems.

-The EEA appears to understate the total costs of the proposed rule.

-The EEA has an inadequate evaluation of the benefits of the proposed rule.

-The EEA does not provide an adequate evaluation of regulatory alternatives.

These concerns are important both for an adequate evaluation of this proposed rule and for the precedents they provide for future regulatory decisions and rulemakings. The procedures to estimate benefits, for example, would be critical to a proper implementation of the benefit-cost approach. Moreover, the procedures developed to analyze the engineering and economic effects of proposed 316(b) regulations on new facilities might be used to analyze effects for the forthcoming proposed regulations for existing facilities.

B. Limitations of EPA's Projections of New Facilities

The EEA develops estimates of the number and type of facilities to be affected by the proposed 316(b) New Facility Rule. This section summarizes the methodology used to develop these estimates and lists concerns with the accuracy of these estimates.

1. Overview of EPA Methodology

EPA estimates the number of electric generation facilities affected by the 316(b) New Facility Rule over the period 2001 to 2020. These estimates rely on data from the NEWGen Database of planned electric facilities developed by Resource Data International, Inc. and the Annual Energy Outlook 2000 (AEO2000) published by the Energy Information Administration.

EPA's methodology follows the following four steps:

1. Identify facilities in the NEWGen database relevant to 316(b) rule. The NEWGen database provides information on new electric generation facilities under development. EPA excluded facilities that were: (1) not in the U.S.; (2) had been "cancelled" or "tabled"; (3) are to be complete after August 13, 2001 (the assumed promulgation date); (4) use steam as a prime mover; and (5) provide

insufficient information on the facility's source of cooling water. These criteria eliminated 410 of the 466 facilities in the NEWGen database.

2. Identify "in-scope "facilities within the NEWGen database. Facilities that fall within the scope of the proposed 316(b) New Facility Rule are identified. EPA uses the following criteria to identify "in-scope" facilities: (1) withdraws from U.S. waters (i.e, not municipal water or "gray water"); (2) does not have an existing CWIS; (3) must require or possess an NPDES permit; (4) has an intake flow greater than 2 million gallons per day; (5) more than 25 percent of the water used is for cooling purposes. Of the 56 new facilities identified by EPA as relevant to the proposed rule, 7 were in-scope and 49 were out-of-scope.

3. Estimate the number of in-scope facilities over the period 2001 and 2020. EPA estimates the total number of facilities affected by the proposed 316(b) rule based on projections of total capacity additions from one most recent.

- Projected Number of Facilities from 2001 to 2010. EPA estimates the number of new generation facilities over the period 2001 to 2010 by dividing total capacity additions over this period from the AEO2000 by an estimate of average plant size. The ratio of in-scope facilities to total new facilities from the NEWGen data is used to scale up the total number of in-scope plants. The resulting estimate is that there would be 13 in-scope plants over the period 2001 to 2010, with 7 identified in the NEWGen database.

- Projected Number of Facilities from 2011 to 2020. A similar methodology is used to estimate the number of in-scope facilities over the period 2011 to 2020, resulting in an estimate of 27 in-scope facilities over the period 2010 to 2020. Of these 27 in-scope facilities, 16 are anticipated to be coal-fired and 11 are anticipated to be natural gas combined cycle units.

2. EPA May Understate the Electric Generation Facilities Subject to this Proposed Rule

EPA's analysis of the number of facilities affected by proposed 316(b) regulations relies on the accuracy of the NewGen database, many assumptions regarding future conditions in the electricity sector, and the reasonableness of extrapolation procedures. A recent study by OnLocation and the EOP Group (OnLocation/EOP Group 2000) assesses the various elements of the EPA projections of the number of new facilities subject to the proposed regulations. Thai study raises concerns with the following elements of EPA's analysis.

- EPA's Sampling Procedure. EPA should undertake additional measures to ensure that data from the NEWGen database provides an unbiased sample of future capacity additions, and that EPA's use of the NEWGen data does not introduce biases. An evaluation of the NEWGen data by OnLocation/EOP suggests that such biases may exist. For example, EPA excludes information on the 38 facilities that provided inadequate or incomplete information on CWIS. Simply excluding these facilities may, however, bias the results. A subsequent, independent sampling of these facilities suggests, in fact, that a large percentage of these facilities would be affected by the rule. The OnLocation/EOP analysis finds that 50 percent of the facilities in this group of excluded facilities would need to comply with the proposed rules. In comparison, EPA finds that only 12.5 percent of facilities providing information would be affected. More accurate estimates could be developed by the EPA by surveying facilities with incomplete information, rather than simply excluding them.

- Energy Sector Projections. The EPA's methodology is based on projections for generating capacity additions developed by the EIA. The projections, however, are based on fairly conservative assumptions regarding anticipated growth in demand for electricity. While demand for electricity has grown by 2.4 percent annually over the period 1994 to 1999, the EIA projections assume only 1.4 percent growth in electricity demand through 2020. Even EIA's high economic growth scenario, which assumes 1.7 percent growth in demand, is less than recent growth trends. The EPA's appear to potentially understate actual growth over the next two decades, thus understating the number of facilities that would be affected. The uncertainty in future conditions and alternative assumptions about future growth in demand should be more fully examined in EPA's analysis.

- Geographic Sample. Geographic biases may be present in the NewGen since reporting requirements for facilities under development differ substantially across states. Facilities in states with more stringent reporting requirements may be more likely to be included in the NewGen data base (OnLocation/EOP 2000). EPA should take steps to ensure that its analysis accurately reflects national conditions, rather than those of particular regions.

-Facility Size. EPA assessment of the average size of future facilities may be overstated. Overstating facility size would lead to an understatement of the number of facilities affected. Data from the NEWGen data base and other sources suggests that the size of combined-cycle gas generation and coal generation units may be smaller than assumed by EPA (OnLocation/EOP 2000).

These issues could have a substantial effect on the number of facilities subject to the proposed regulations. OnLocation/EOP (2000) finds that 209 facilities would be affected by the proposed rules, in contrast to EPA's estimate of 40 facilities. The five-fold difference in results between two estimates suggests the importance of an expanded assessment of the number of facilities likely to be affected by 316(b) rules that takes into account the concerns raised in OnLocation/EOP report (2000).

C. Limitations of EPA's Estimates of Facility Compliance Costs

1. Overview of EPA's Methodology

For new electric generators, EPA develops estimates of the costs of several different technologies or modifications that facilities could be required to implement:

1.Changing location of the CWIS in the water body
-Extending the intake pipe.
-Deepening the intake canal.

2.Reducing the intake flow
-Switching to a recirculating system (cooling towers).
-Using a water other than those of the U.S.

3.Reducing intake velocities
-Passive screens (cylindrical wedge wire screens).
-Velocity caps.

4.Other design and construction technologies to reduce impingement and entrainment
-Traveling screens with fish baskets.
-Adding fish baskets to existing traveling screens.

The EPA develops costs estimates for each of these technologies or modifications. These cost estimates include capital and operating costs, and vary across a range of parameters representing local conditions and facility characteristics, such as water depth, water flow, and intake size. EPA also develops estimates of the administrative costs to obtain and renew NDPES permits, and the costs to comply with monitoring, recording, and reporting requirements of the proposed rule.

The following sections of this report focus on EPA's estimates of closed-cycle costs. Comments on EPA's assessments of technologies other than closed-cycle cooling systems are included in UWAG (2000).

2. EPA Understates the Cost of Closed-Cycle Cooling Systems

The EEA's assessment of the cost of closed-cycle cooling systems appears to reflect a failure to consider fully the technical complexity and details of the design of these facilities. As a result, the EEA makes several inaccurate or incompletely documented assumptions, leading to cost estimates that significantly understate the likely costs of these systems. The following are among the flaws in the EEA cost estimates:

1. Capital Costs. EPA understates equipment and capital costs of cooling system construction due to both flawed assumptions and methods. These include the following:

- EPA fails to account for many capital cost components; and
- EPA's assumes design criteria that understate costs.

2. Operations and Maintenance Costs. EPA underestimates operating and maintenance costs of cooling systems:

- EPA assumes inaccurate cost components for operating and maintenance.
- EPA's assumptions understate makeup water costs.

3. Dry Cooling Costs. EPA does not document the capital and operating costs of dry cooling systems.

a. EPA Understates the Capital Costs of Cooling Towers

(1) EPA Fails to Account for Many Capital Cost Components

EPA's methodology for estimating capital costs is to multiply the cooling system capacity (in gallons per minute, or gpm) by a "rule of thumb" cost factor (in dollars per gpm). Used correctly, these "rule of thumb" cost factors provide a good approximation of the furnished and erected costs of a wet cooling tower. The proper use of such factors has been outlined in many engineering reference books (CEH 1969, Guthrie 1974).

The "rule of thumb" factors used by EPA provide an estimate of the cost of cooling tower. These estimates do not, however, include many essential components of the cooling system, such as wiring, foundations, condenser pumps, noise attenuation treatment, the cost of other equipment, or the cost of construction. These costs of these components and their installation would not be incurred were cooling towers not installed. To account for construction costs, EPA has multiplied the tower equipment costs by a factor of 1.8 (i.e., EPA has marked up the equipment cost by 80 percent) to reflect the costs of erecting cooling towers. However, EPA has not made any additional adjustments to account for the costs of any of the other necessary cooling system equipment noted above. Cost factors that include these costs are typically many times larger than cost factors of the tower alone. For example, in a wet cooling vs. dry cooling comparison study recently completed for UWAG, the capital cost (including construction costs) of a newly built cooling tower for a 250 MW steam turbine-generator in a combined cycle plant was roughly 15 percent of the total capital cost for the entire cooling system (Burns & Micheletti 2000). By estimating only the costs of the cooling tower and ignoring the additional costs associated with the other necessary components of the entire cooling system, EPA significantly understates the costs of these systems.

(2) EPA Assumes Design Criteria that Understate Costs

The cost of a closed-cycle cooling system depends on design criteria for the particular system being considered. Some of the assumptions regarding system design made by EPA when developing its costs estimates lead to an underestimate of the true costs of these systems. One example is EPA's assumptions regarding the "approach" value used in plant cooling systems. <FN 3> As the approach value decreases, the cooling tower size increases, resulting in higher costs. EPA suggests that the approach value should be set between 5-10°F. EPA's cost factors, however, assume an approach value of 10°F, resulting in a smaller cooling system. In practice, however, an 8°F approach value is typically used for cooling towers. <FN 4> Since the system with an 8°F approach would be larger and therefore more costly, EPA understates the likely costs oi closed-cycle cooling system.

b. EPA Understates Operations and Maintenance Costs for Cooling Towers

(1) EPA's Assumptions for Chemical Treatment and other Cost Components are Inaccurate

The EEA report assumes that the operations and maintenance costs associated with cooling towers decline from 5 percent of capital costs for the smallest towers to 2 percent of capital costs for the largest towers (pages 6-4 and A-20). EPA implies that this is the appropriate way to treat presumed economies of scale associated with cooling tower operations and maintenance costs, but provides little justification for these values. An examination of operations and maintenance costs for existing cooling towers suggests that the EEA assumptions are inaccurate and reflect in inadequate technical assessment of operations and maintenance costs.

The major operations and maintenance costs for cooling systems are: (1) makeup water to replace evaporation and blowdown losses; (2) power for fans and pumps; (3) labor and materials, primarily for maintenance; and (4) cooling water chemical treatment for scale, corrosion, and biofouling control. The cost of makeup water is negligible unless the water must be purchased from a municipality. Assuming that the cost of makeup water is minimal, only the final three costs are significant. Of these three items, EEA only discusses its rationale for "economies of scale" with respect to chemical treatment.

Cooling water chemical treatment costs are extremely site-specific. Variations in the availability and quality of makeup water, construction materials, and cooling system operating practices make it difficult to generalize about cooling water chemical treatment programs and costs. Empirical data from a recent EPRI study suggests that actual operations costs differ significantly from EPA's assumptions (EPRI 1999). Figure 1 presents data on annual chemical treatment costs from almost two dozen power plant recirculated cooling systems (represented by the solid diamonds). This data shows that costs increase with recirculating flow. In contrast, EPA's data (represented by the open circles), suggests that costs decrease as recirculating flow increases. Since EPA fails to provide any background on the source of its data and the conclusion that total costs decrease with size is somewhat suspect, these assumptions raise concerns about the methodological approaches and empirical values EPA has used to developed its component costs for closed-cycle cooling system operating costs.

Figure 1. Annual Cooling System Chemical Treatment Cost vs. Recirculating Cooling Water Flow
[see hard copy for figure]

(2) EPA's Makeup Water Assumptions Understate Costs

Based on EPA's estimates, a closed-cycle cooling system would operate at or below 2 cycles of concentration. This means that the quantity of makeup water <FN 5> would be twice the blowdown (i.e., the quantity of cooling water periodically discharged into the water body). In practice, however, most power plant cooling systems operate at about 5 cycles of concentration, resulting in significantly less frequent discharge of water into the water body. EPA's assumptions reflects a misunderstanding of the actual design and operation of closed-cycle cooling systems.

The EPA also fails to make facility design consistent with these assumptions. At the lower cycles EPA suggests, more makeup water would be required to operate the plant. Although the costs of additional makeup water itself would be minimal (as noted above), the higher makeup requirements would necessitate larger water pumps as well as higher power use. EPA has failed to account for these cost impacts in its analysis. In addition, the higher makeup water requirements under 2 cycles would increase the cost of CWIS equipment, which must designed and operated to minimize intake water velocity. These cost impacts have not been adequately accounted for either.

c. EPA's Cost Estimates for Dry Cooling are Not Well Substantiated

In addition to the above criticisms, which apply to EPA's estimates of the costs of wet cooling systems, there are a number of additional criticisms that apply specifically to EPA's analysis of dry cooling systems. EPA's estimates of the costs of these systems are not well substantiated. Although dry cooling systems would not be required under the proposed 316(b) rule, they would be required in the "zero flow" regulatory alternatives considered by EPA.

(1) The EEA Does Not Provide a Foundation for Dry Cooling Capital Costs

EPA suggests in the proposed rule that dry cooling is a viable alternative to wet cooling systems (10-2), but does not provide cost equations or curves for dry cooling. The EEA implies that the methodology used to calculate dry cooling costs is based on curves similar to those developed for wet cooling towers. The EEA, however, presents no discussion of the specific calculations or equations used to estimate the costs of dry cooling.

The EEA's methodology suggests that there is a close engineering and cost relationship between wet and dry cooling systems. There are, however, many engineering distinctions that suggest that the methodology used to estimate costs should be very different between wet and dry cooling systems. In particular, it is inappropriate to use a "rule of thumb" (i.e., dollar per gpm) cost factor based on cooling water flow to estimate dry cooling costs, since the most prevalent dry cooling systems (based on a direct, non-contact, air-cooled steam condenser) have no cooling water flow. Consequently, use of a dollar per gpm rule of thumb is completely inappropriate.

EPA has failed to provide a complete and detailed description of its cost methodology for dry cooling capital costs As a result, it is impossible to assess whether its methodology and data appropriately represent the true costs of dry cooling systems. Development of costs estimates for dry cooling systems requires more detailed cost and engineering assessment than is presented by EPA in the EEA.

(2) The EEA Provides No Foundation for Dry Cooling Operating Costs

EPA bases the operations of dry cooling systems on those of wet cooling systems. As with capital costs, the analysis thus assumes an underlying relationship between dry tower Operations and Maintenance costs and wet tower operations and maintenance costs. The operations and maintenance activities required for a dry cooling systems, however, are very different from those required for a wet cooling systems. There is no technical reason to think dry tower operations and maintenance would be related to wet tower operations and maintenance by some common factor, yet EPA has taken that approach.

In fact, there are many significant differences between the operations and maintenance of dry and wet cooling systems. For example, the operation of a dry cooling systems during the winter is significantly more complicated than the winter operation of a wet cooling tower. As a result, the costs of dry cooling systems are significantly greater. During extremely cold periods, operators of dry cooling towers must run the turbine at a higher backpressure than they would normally to prevent the tubes from freezing. Operating this way leads to inefficient plant use. To avoid such measures, dry towers would require special winterization measures and would probably involve a more complex winter-time operation. In addition, the auxiliary cooling system of a dry cooling tower would also be more prone to winter operational problems. The complications associated with winter operation of dry cooling towers would increase the likelihood of forced outages.

These examples suggest that EPA has failed to provide an adequate technical and cosi assessment of dry closed-cycle cooling systems. The EPA should develop a more complete assessment of operations and maintenance costs based on a more detailed engineering assessment.

3. EPA Fails to Consider All Closed-Cycle Cooling Costs

The EEA's analysis of the cost of closed-cycle cooling systems considers only their capital costs and the annual operations and maintenance costs. The analysis fails, however, to consider other important costs resulting from implementation of cooling towers. In particular, the following costs are not considered by EPA:

1. Power Costs. Closed-cycle cooling towers reduce the performance of generation facilities by increasing auxiliary power loads and reducing the efficiency of the steam turbines through turbine backpressure (“performance penalties”). These impacts results in two sorts of impacts that produce social costs:

- Replacement Power Costs. Both auxiliary power requirements and performance penalties may result in reductions to quantity of energy or capacity provided to end-users. Replacing this power from other higher-cost sources will result in social costs.

- Fuel Costs. As a result of performance penalties which reduce effective heat rates, the quantity of fuel required to generate the same quantity of energy increases.

2. Air and other Environmental Costs. Through performance penalties and auxiliary power requirements, closed cycle cooling towers result in reduced net power generation with no commensurate reduction in fuel use. As a result, air emissions from sources replacing lost power will increase. In addition, cooling towers may result in the following additional environmental impacts:

-visibility impacts from cooling towers;
-local climate change from wet cooling tower plumes;
-wildlife losses (e.g., birds colliding with towers);
-fish losses due to loss of heated aquatic plumes to over-wintering habitats; and
-increased impediments to waterway navigation due to icing in northern regions.

Power costs include both energy and capacity costs. Cooling towers reduce the quantity of energy that can be delivered to end-users and also reduce the quantity of generation capacity available to ensure the reliability of the electric power system. Both of these impacts result in social costs as other resources must be used to replace these lost resources. As noted in Chapter III, these costs can be modeled using data on the market price of energy and capacity from competitive wholesale power markets.

Concern for the power costs and impacts for cooling towers is particularly significant since many of these power impacts are greatest during the summer when demand for energy and capacity is greatest. Performance penalties due to turbine backpressure, for example, will be greatest during periods of high temperatures, also the periods of highest demand. These performance penalties potentially exacerbate current reliability concerns in many regions.

Although these costs are important components of the cost of cooling towers and have been incorporated into cost-benefit analyses of 316(b) alternatives for existing facilities, EPA fails to consider these costs when evaluating cooling tower costs. The EPA only acknowledgement of the issue is in the last sentence of its chapter on facility compliance costs (EPA 2000, p.6-24):

Finally, estimated costs do not account for reduced energy efficiencies that may result from switching to the use of cooling towers from a once-through cooling system. This energy “penalty” may be considerable and is dependent on specific site characteristics, such as plant type.

While acknowledging that these penalties may be “significant”, the EEA relegates this issue to qualification to its cost assessment, rather than making any attempt to integrate these costs into the analysis.

[comment text continued in 316bEFR.041.603]

Footnotes

1 Under the Title IV SO_2 trading program and NOx SIP Call, the overall quantity of emissions does not change if emissions go up in some facilities, but the distribution of emissions across facilities may change. As a result, changes in air emissions due to SWIS technologies would lead to changes in the cost of achieving emissions caps.

2 These guidelines apply in cases in which the ecosystem is not in jeopardy.

3 Approach value is the difference between the lowest water temperature in the cooling towers and the “wet bulb’ temperature, which is a measure of the outside ambient air temperature with a wet rather than dry bulb. (The difference between wet and dry temperatures is a measure of the atmospheric humidity.)

4 One source suggests that the increase in cost for a system with an 8°F approach relative to a 10°F approach is at least 15 percent (Cherimisinoff and Cherimisinoff 1981).

5 Makeup water is the quantity of water drawn into the close cycle system. Water leaves the system primarily through either blowdown or evaporation.

EPA Response

For a response to this comment, which was submitted with the commenter's Phase I proposal comments in November 2000, see the Phase I Comment Response Document (DCN 3-0091) beginning at comment 316bNFR.068.300.

Subject Matter Code NEW
Comment on new (Phase I) facility rule

[comment continued from 316bEFR.041.602]

D. Limitations of EPA's Benefits Analysis

EPA has recently updated their 1983 guidance for conducting benefit-cost analysis (EPA 1999). EPA ignores both their own guidance and good professional practice in assessing benefits in the proposed rule. This section summarizes the analytical requirements specified in the guidance and describes how the proposed rule deviates from these requirements.

1. EPA's Assessment of the Expected Benefits Does not Conform to EPA's Own Guidance

EPA's guidance describes benefits analysis as a process to develop monetary values to inform the policy-making process (EPA 1999, p. 7-1). EPA's benefit-cost guidance relies primarily on techniques that transfer existing benefit estimates to new regulatory situations. Specifically, the guidance requires analysts to rank significant sources of benefits, to assess the quality of published studies, and to account for uncertainty (EPA 1999, p.7-l, 7-6, 7-8). The benefits estimates in the proposed rule meet none of these requirements. Furthermore, the guidance states that benefit values are important in helping policy-makers make direct comparisons to the costs (EPA 1999, p. 7-1). The proposed rule ignores the fundamental purpose of the analysis because it never compares estimated benefits to costs. Thus, the benefits analysis in the proposed rule has no relevance for assessing whether the rule is good policy.

The general approach for assessing the benefits of environmental policies, as stated in the guidance, requires three steps: (EPA 1999, p. 7-5)

1. Identify potentially affected benefits categories.

2. Quantify significant physical effects to the extent possible, working with risk assessors, ecologists, physical scientists, and other experts.

3. Estimate the values of these effects, using studies that focus on the effects of concern or transferring estimates from studies of similar impacts.

The EEA ignores the guidance requirements for each of these steps.

a. Step 1: Identify Potentially Affected Benefits Categories

EPA's guidance requires first evaluating which effects are likely to be significant in the overall benefit analysis. The purpose of this step is to focus analytical resources on the most important categories of potential benefits. The guidance defines significant benefits category as whether there are likely to be observable changes in the benefits category as a result of implementing a policy option (EPA 1999, p.7-6).

The EEA fails to provide any rationale for the benefit categories that are included and excluded or to establish links between identifiable environmental outcomes of the policy and monetary benefits. Because the proposed rule provides no documentation for how decreased biological losses increase commercial and recreational fish catch, it is impossible to assess the benefits claimed.

b. Step 2: Quantify Significant Physical Effects

EPA's guidance requires economists to communicate with other experts to ensure that the information provided is both adequate to support the benefits analysis and includes a discussion of the uncertainty of the estimates of physical effects (EPA 1999, p. 7-7). One of the most important pieces of information required to document aquatic benefits is the relationship between decreased losses from impingement and entrainment and increases in angler catch. It is not sufficient just to document an increase in mortality. There must be a link between the increase in fish mortality and a decrease in services from the fishery. An obvious link between fish mortality and decreased resource services is a change in fishery catch. If there is no significant change in catch, then the change in mortality is not relevant to recreational fishing and does not cause a change in the value of the fishery. EPA's analysis does not discuss the critical link between environmental effects and angling benefits. Rather, the proposed rule merely cites estimated physical effects from five studies for the sites in those studies.

EPA's guidance notes that baseline conditions can have a profound influence on the measurement and interpretation of results (EPA 1999, p. 5-3). Suppose the study site has excellent baseline water quality, excellent fish habitat, and healthy fish populations of highly valued fish species. Conversely, suppose the policy site has poor baseline water quality and fish populations. Any benefits estimated for the policy must be defined in relation to changes from the actual baseline conditions at the policy site, not the study site. Thus, using unadjusted benefits estimates from the study site will overstate benefits. In fact, as we note below, differences in baseline conditions between the sites may make the original study an inappropriate source of benefit-transfer estimates for the policy site. At a minimum, analysts would have to modify the original study estimates to reflect differences in the two situations. EPA's benefits analysis fails to discuss how either the baseline conditions or policy-induced changes at the study sites differ from those of the policy sites.

Baseline CWIS technologies also will have a large impact on the magnitude of quantifiable benefits. The additional benefits of technologies and modifications typically decline as more stringent controls are added onto CWIS with existing fish protection technologies. Thus, an analysis of the costs and benefits of alternative BTA requirements must be performed relative to the same technological baseline. EPA's cost analysis assumes that almost all future electric generating facilities would install closed-cycle cooling even in the absence of the proposed rule. In contrast, EPA's benefits assessment is performed using studies based on CWIS with a wide range of baseline technologies. Thus, EPA's assessments of the 'potential" benefits of the rule, as well as its estimates of the potential impingement and entrainment losses of new facilities, are grossly overstated since they are based on facilities with much less stringent technologies.

c. Step 3: Estimate the Value of the Effects

EPA's guidance requires analysts to assess the quality of studies used to transfer benefit estimates to expected policy outcomes (EPA 1999, p. 7-1). The guidance provides specific information to assist in evaluating the methods used in existing studies (EPA 1999, p. 7-15 to 7-34). The guidance also describes the attributes necessary to assess the applicability of a study. (EPA 1999, p.7-33). Finally, the guidance requires that benefits analysts clearly describe the sources of all values used and assess the uncertainty associated with value estimates (EPA 1999, p. 7-8). It is evident that the proposed rule does not comply with the guidance requirements in assessing or using existing benefits studies.

According to EPA's guidance, an important step in transferring benefits is to identify relevant studies after reviewing candidates in the available literature for applicability and quality (EPA 1999, p.7-33). To determine the applicability of the original study for transfer, analysts should compare resource characteristics that effect value. Specifically, physical characteristics, services provided, and number and quality of available substitute sites are important determinants of benefits. For example, suppose a site is located on a typical warm-water river and there are numerous comparable fishing opportunities on five similar rivers located within 20 miles of the site. In contrast, suppose an alternative site is located on a well-managed trout stream and the only other comparable fishing opportunity is located 50 miles away. A decrease in catch at the site with many substitute recreational alternatives will have a much smaller effect on anglers than a similar decrease in catch at the site with few recreational substitutes. Thus, a study that estimates benefits from increased catch at one of these sites may not provide sufficiently comparable values to transfer to increased catch benefits at the other site.

The guidance requires that analysts assess not only the comparability of the resources involved, but the quality of published studies, as well (EPA 1999, p. 7-1 .). Several economists (Smith, 1992; Brookshire, 1992; Desvousges, Naughton, and Parsons, 1992; McConnell, 1992; and Boyle and Bergstrom, 1992) recommend reviewing existing studies for their scientific soundness because existing studies have varying levels of quality. In transferring value estimates from a previous study to a different site, the analyst also transfers the assumptions and flaws of the methodology in the original study.

In some cases, a study cannot be used for benefits transfer simply because not enough information is available to properly evaluate it. Analysts must be able to assess the quality of the data and the suitability of the statistical analysis used in the study. This appraisal is the basis for determining the implications for uncertainty in transferring the results to a new context. The poorer the comparability in resources between study sites and policy sites and the poorer the empirical basis for estimates in the original study, the greater the uncertainty in the imputed benefit estimates for the policy site. EPA follows none of these requirements in their discussion of the studies that provide benefits estimates in the rule.

2. EPA's Anecdotal Information on Benefits is Incomplete and Misleading

The studies included in the proposed rule fail to satisfy the agency's own standards for benefits transfer. The proposed rule cites only five studies that estimate the physical effects of CWI5 (Rule, p. 49104). .EPA's was of benefits studies does not follow procedures specified in their own guidance. In particular:

-EPA fails to evaluate the quality of the analysis and reliability of methods used in the reference studies.

-EPA fails to show that the studies cited in the proposed rule are relevant to the facilities that will be affected by the policy or how estimates should be modified to account for] differences with policy sites.

-EPA fails to document reported values, citing values that do not exist in the studies themselves.

-EPA fails to evaluate sensitivity of results to assumptions and to provide decision makers with an assessment of uncertainty in the estimates.

There are numerous published studies providing angling values for a variety of species, locations, and types of water bodies. The proposed rule provides no motivation for choosing the particular studies selected from the large literature on aquatic benefits. Appendix A provides a detailed assessment of each of the studies used by EPA to evaluate the benefits of the proposed 316(b) rule. The Appendix A assessment raises many concerns with the studies chosen by EPA to consider the benefits of the proposed rule. EPA should develop a more thorough assessment of benefits based on its own benefits evaluation guidelines.

3. EPA's Suggestion That Nonuse Values are 50 Percent of Use Values is Based on Dated Studies and an Overly Simplistic Assessment of Nonuse Values.

EPA's proposed rule reports sample calculations of total consumer surplus that could be generated by improvements in CWIS technology (65 Federal Regulation 49105). In these calculations EPA assumes that nonuse benefits would amount to 50 percent of use-value benefits (a so-called "50 percent" rule). EPA bases this assumption on two studies that have evaluated the results of studies that have estimated both user and non-user benefits deriving from water resources (Freeman 1979; Fisher and Raucher 1984).

The estimation of non-user values is an important and particularly controversial issue. There is significant debate on the appropriate techniques for measuring such values, whether existing methodologies can measure such values, and the contexts in which such values exist. EPA assessment of nonuse benefits, however, fails to discuss these considerations. The EPA should perform a more complete and thorough assessment of whether non-user benefits should be considered in the context of 316(b) BTA evaluations, and, if so, what methods should be used to evaluate non-user benefits.

EPA's use of the so-called "50 percent" rule approach to non-user benefits relies on studies that are over 20 years old and were only intended to provide rough estimates. The studies clearly note the limitations of the ad hoc estimate. Freeman (1979), for example, states that assuming non-user benefits are 50 percent of use benefits "is a very tenuous basis from which to estimate national nonuser benefits." The EPA acknowledges the limitations of the 50 percent rule, stating that "the overall reliability and credibility of this type of approach is, as for any benefits transfer approach, dependent on the credibility of the underlying study and the comparability in resources and changes in conditions between the research survey and the 316(b) rule's impact on selected site" (EPA 2000, p.11 -20). The EEA, however, fails to assess the applicability of the studies underlying the Freeman (1979), and Fisher and Raucher (1984) studies, and fails to develop methods to consider resource comparability in the benefit transfer process.

Given the significant debate over non-user valuation methods, significant advances in contingent valuation methodologies over the past 20 years, and significant advances in developing benefit transfers that account for site-specific factors affecting benefits levels, EPA's reliance on the so-called "50 percent" rule is inadequate. EPA should perform a more thorough assessment of the applicability and magnitude of non-user benefits than was presented in the EEA.

E. Limitations of EPA's Evaluation of Alternatives

The EEA considers three alternative BTA requirements:

1. Proposed BTA requirements. The proposed requirements include flow, velocity and technology requirements specific to the location of the CWIS.

2. Require Estuary and Tidal River BTA for All Locations. This alternatives would require that CWIS sites in any location meet the BTA requirements for CWIS in estuaries and tidal rivers. These requirements are the most stringent of all BTA requirements.

3. "Zero Flow" Requirements. This BTA requirement would require flow levels commensurate with those achieved through dry cooling systems.

1. EPA's Analysis of Alternatives is Too Limited

The range of BTA alternatives considered in the EEA is too limited. In a three-page chapter, the EEA sketches two alternatives to the proposed BTA requirements that would both result in significantly more stringent requirements. One alternative applies the most stringent set of BTA requirements to all facilities regardless of their location. The other alternative imposes a more stringent "zero flow" requirement on the electric generation facilities, which would require flow levels commensurate with those achieved through dry cooling systems. As a result of the increased stringency, both alternatives would result in costs that are significantly greater than the costs of the proposed alternative.

The EPA fails to consider any alternatives that would achieve the AEI goals of 316(b) rule through less stringent requirements or more flexible means of compliance. Such alternatives could include the following:

1. Alternative Technologies. Many technologies are available to significantly reduce impingement and entrainment at significantly lower costs than EPA's proposed BTA requirement. Evaluation of the incremental costs and benefits of these technologies relative to cooling towers may reveal that these technologies provide significant biological benefits at a fraction of the social cost of cooling towers.

2. Case-by-case BTA. Allowing facilities the flexibility to make a case-by-case BTA determination would lead to the selection of BTA technologies that provide a proper balancing of the costs and benefits of alternative technologies.

The EPA thus considers on two alternatives to its proposed requirements. This assessment of alternatives is too limited to provide useful information on whether the proposed rules are the jest regulatory alternative. In addition, EPA's approach fails to comply with EPA and OMB guidelines, as discussed below.

2. EPA's Analysis of Alternatives Does Not Comply with EPA and OMB Guidelines

The EPA's analysis of the economic impact of 316(b) regulatory alternative does not comply with the basic guidelines for regulatory assessments developed by both EPA and OMB. The Administration has enshrined careful incremental analysis of well-chosen regulatory alternatives in Executive Order 12866 and in guidance documents issued by the 0MB advising agencies how to conduct economic analysis of regulations. About one-third of OMB's 1996 'Best Practices Guidance" on economic analysis addresses how to assess alternatives. To comply with Section 638 of the Fiscal Year 1999 Omnibus Appropriations Act and Section 628 of the Fiscal Year 2000 Treasury and General Government Appropriations Act, OMB released guidelines in March 2000 standardizing the measurement of costs and benefits. These guidelines state that agencies "should especially consider all appropriate alternatives for the key aittributes or provisions of the rule." (Lew 2000, p. 3).

Analysis of regulatory alternatives is critical to a proper evaluation of the proposed regulations. Even if the overall net benefits of the proposed regulations were positive—that is, significant elements of the proposed regulations pass a benefit-cost test. That is, for any given provision, the costs of that provision may outweigh the benefits. In this context, it would be important to consider the alternative regulatory approaches to achieving the AEI goals of 316(b) aside from EPA's proposed regulations.

As discussed above, the economic analysis in support of the 316(b) regulations has virtually no discussion or analysis of alternatives. The EPA's neglect of other alternatives ignores the letter and spirit of Administration policy. President Clinton's Executive Order 12866 states that regulatory agencies "shall provide" to the Office of Information and Regulatory Affairs:

"an assessment, including the underlying analysis, of costs and benefits of potentially effective and reasonably feasible alternatives to the planned regulation, identified by the agencies or the public (including improving the current regulation and reasonably viable nonregulatory actions), and an explanation why the planned regulatory action is preferable to the identified potential alternatives." <FN 6>

The EPA should analyze "potentially effective and reasonably feasible alternatives,' particularly less stringent alternatives than those proposed.

The EPA's analysis is also inconsistent with OMB's recent directive on benefit-cost analysis, which states, "You should analyze the benefits and costs of different regulatory provisions separately when a rule includes a number of distinct provisions. If the existence of one provision affects the benefits or costs arising from another provision, the analysis becomes more complicated, but the need to examine provisions separately remains [emphasis added]." <FN 7> The EPA's assessment has not analyzed costs and benefits of individual provisions separately. Examination of the costs and benefits of the flow requirements, velocity requirements, and technology requirements of the EPA's proposed 316(b) regulations on an individual basis may reveal important differences in the cost-effectiveness of these individual requirements.

The EPA's approach is also not consistent with the recently updated Economic Guidelines, which state that (EPA 1999, p.10-4):

The incremental benefits, costs and net benefits of moving from one regulatory alternative to more stringent ones should also be presented. This should include a discussion of incremental changes in quantified and qualitatively described benefits and costs. It is sometimes necessary to evaluate all combinations of options and alternatives when key sources of benefits and costs of a policy are affected by more than one option.

These guidelines provide important guidance in the determination of the appropriate level and design of 316(b) requirements in order to achieve net welfare gains to society. The process of maximizing net welfare gains to society, as well as ensuring that those gains are positive, requires a full consideration of alternative regulatory requirements and the development of estimated costs and benefits for each alternative. EPA's failure to incorporate a complete analysis of alternatives in the EEA is a significant omission.

V. CONCLUSIONS AND RECOMMENDATIONS

This chapter provides a brief summary of the conclusions and recommendations of our review of EPA's proposed 316(b) regulations for new facilities and economic and technical analyses in the EEA

A. Regulatory Alternatives

1. The Regulatory Approach Should Allow Site-Specific Comparisons

EPA has proposed a major shift in the approach to establishing 316(b) determinations. Rather than provide 316(b) determinations on a site-specific basis, the proposed rule would require national minimum technology-based requirements.

The national technology minimum approach largely ignores the substantial variability in the costs and benefits of adopting specific technologies at different locations. Although the proposal would provide some variability in control requirements, the requirements would be uniform for large categories of potential locations. This approach does not appropriately consider costs and benefits when determining which technology to install at specific locations.

We conclude that allowing 316(b) determinations to be made on the basis of site-specific evaluations would produce more desirable results in three principal respects:

1. First, the site-specific approach would produce greater fish-protection and other environmental benefits for a given level of costs.

2. Second, the site-specific approach would impose lower costs to achieve a given level of fish protection and other environmental benefits.

3. Third, the site-specific approach would provide appropriate incentives for new facilities to locate outside environmentally-sensitive areas.

2. The Site-Specific Approach Should Allow an Option to Install Pre-Approved Technology to Reduce Administrative Costs

The cost of developing and implementing a site-specific approach—including the costs of delay in getting facilities constructed—may not be justified in all situations. It would be useful to include an option to allow a facility to install pre-approved highly protective CWIS technology in the interest of reducing administrative costs and reducing the delay in obtaining a permit. Such a provision would not detract from the gains from the site-specific approach— which the facility owner could select—and would have the advantage of providing greater flexibility. It is appropriate to give the facility owners the option because they would be in the best position to judge whether the added costs of developing site-specific information justify the added gains from a tailored site-specific determination.

3. BTA Determinations Should be Based upon the Criterion of Maximizing the Net Benefits of Fish Protection Alternatives

EPA also has proposed a major shift in the criterion for determining BTA. EPA proposes to change from a criterion based upon comparison of costs and benefits to a criterion that compares costs to the revenues from the facilities. This "affordability" test is not a sufficient test from an economic perspective for determining what technology should be BTA.

-Affordability does not provide a way of systematically evaluating the environmental benefits and costs of alternative technologies.

-Affordability ignores consideration of the costs and benefits of BTA alternatives.

-Affordability ignores consideration of the incremental benefits and incremental costs of increasingly stringent (and expensive) alternatives.

-Affordability ignores other impacts of cooling water intake technologies.

We conclude that BTA determinations should be based upon a benefit-cost test. This test would involve determining the applicable fish protection alternatives, assessing their incremental costs and benefits in dollar terms to the extent feasible, determining major uncertainties in the analysis, assessing whether relevant costs or benefits have not been quantified, and developing a BTA choice that is likely to maximize net benefits in the particular case. This cost-benefit test would identify the best technology from an overall societal perspective.

This cost-benefit test is superior to the current "wholly disproportionate" test for BTA determinations that were developed more than twenty years ago. The "wholly disproportionate" test is not consistent with the economic objective of maximizing the net benefits from BTA determinations. The test appears to be motivated by an unsubstantiated assumption that measured benefits are consistently and significantly understated relative to costs, perhaps based upon limitations in benefit assessment methodology. Whatever the motivation, advancements in benefit assessment methodologies and empirical studies in the last two decades provide ample basis for using an appropriate cost-benefit test.

B. EPA's Engineering and Economic Analyses

1. EPA Should Reevaluate Its Cost Analyses in Light of Various Concerns

The EEA provides estimates of the potential costs of the proposed regulations that appear to suffer from several major concerns. These concerns include an understatement of the number of facilities subject to the regulation, understatement of the full costs of closed-cycle cooling water systems, and disregard for some potential options that would be more cost-effective.

We recommend that EPA reevaluate its cost analysis in light of these concerns. The objective should be to develop a reliable methodology for estimating the costs of the proposed alternative as well as the costs of regulatory alternatives.

2. EPA Should Complete Its Benefits Analyses

The EEA does not provide an analysis of the potential benefits of the proposed regulations. Indeed, EPA's benefits analysis does not conform to the Agency's guidance for preparing benefit assessments. Although EPA's guidance indicates that the analysis should include assessments of the physical effects of the proposed regulation on recreational and commercial catch, for example, the EEA does not include such estimates. The EEA also does not provide monetary values for benefits.

The EPA should complete its benefits analyses. The complete analysis should conform to the Agency's guidelines. The objective of the benefits assessment is to provide the basis for evaluating the benefits of the proposed alternative as well as the benefits of regulatory alternatives.

3. EPA Should Prepare an Appropriate Evaluation of Alternatives

The EEA considers three alternatives: (1) the proposed national BTA standards that differ somewhat by location; (2) National BTA standards equal to the most stringent that would apply at all locations; and (3) "Zero flow" requirement. These represent too limited a set of alternatives. Neither of the two alternatives is less stringent than the proposed regulations. Moreover, the discussion of even these limited alternatives is cursory. The analysis of alternatives does not comply with Agency guidelines.

The EPA should expand its evaluation of alternatives for the proposed rule. The EPA requests comments on a wide range of regulatory alternatives. EPA's analysis should provide information on a sufficiently large number of these alternatives so that it is able to make (or explain) its choices. At the very least, the analyses should include assessments of the costs, benefits, and other effects of the site-specific approach as an alternative to the national minimum technology-based approach.

4. EPA Should Comply with the Requirements of Executive Order 12866

Executive Order 12866 requires agencies to prepare economic analyses of potential regulations. The EEA does not conform to the requirements of Executive Order 12866 for reasons that include the following:

-The EEA does not document that the potential benefits to society justify the potential costs.

-The EEA does not document that the proposed regulations would maximize net benefits to society.

-The EEA does not show that the EPA has considered the most important alternative approaches.

The EEA should be completed and revised to comply with these and other requirements of Executive

Order 12866.

APPENDIX A — ASSESSMENT OF EPA'S ANALYSES OF BENEFITS STUDIES

This appendix provides a detailed assessment of the benefits studies referenced by EPA in the Engineering and Economic Analyses of the Proposed 316(b) New Facility Rule. Section A provides an overview of various valuation methods. This section provides background for interpreting the specific studies. Section B provides a detailed assessment of EPA's use of specific benefits studies.

A. Alternative Benefits Valuation Methods

This section summarizes the advantages and disadvantages of alternative valuation methods. The methods considered include the single site travel-cost method (TCM), the Random Utility Model (RUM) approach, and contingent valuation (CV).

1. Travel Cost Method

The logic underlying the TCM is simple. Recreators at a particular site pay an implicit price for using a site's services through the travel and time costs associated with visiting that site. Recreators will choose to visit a site if the enjoyment or value of going to the site is at least as great as the travel expense and the opportunity cost of the time spent traveling. The major limitations of this approach are its inability to adequately account for substitution among recreation sites and its inability to value marginal changes in site characteristics. An increase in travel costs or reduction in quality at one site induces some people to visit a substitute site rather than choose not to recreate. This substitution means that the total value of the trip is not lost, it is only reduced because recreators visit a second-choice site.

EPA's guidance emphasizes that the TCM cannot model recreators' choice among sites, and thus does not account for the effect of substitute alternatives on values (EPA 1999, p. 7-18). Ignoring substitutes biases value estimates upward (Freeman 1993, p. 453—454). The single-site TCM also cannot estimate recreators' value for changes in site characteristics (Cameron and James (1987), Morey, Shaw, and Rowe (1988), Smith and Desvousges (1986), and Samples and Bishop (1985)). Instead, this approach can only estimate a value for site visitation as a whole, not the value for an improvement in a site characteristic. To value a marginal change in a resource, such as a change in the fish population, estimates for several sites with different characteristics must be obtained. Differences in consumer surplus among the sites are then explained by differences in the site attributes among sites.

2. Random Utility Model Method

RUMs represent a significant methodological improvement over the simple TCM. This approach takes a more realistic view of the decision-making process involved in choosing a recreation site. A RUM estimates the probability that a recreator will choose to visit a given recreation site. This probability depends on the characteristics of the site, the characteristics of available substitutes, and the travel costs to all the sites in recreators' choice sets. The RUM can accommodate the fact that different people have different choice sets of recreation opportunities. These choice sets are based on factors such as the individual's income, free time, and place of residence. To the extent that the individual trades off these factors against the quality of recreation opportunities, researchers can model the relative value of these variables as revealed by recreators' decisions. The better the characteristics of a site, the higher the probability that an individual will choose that site, and thus the higher the value of that site will be. RUMs thus combine observed variation in travel behavior with observed variation in site characteristics to estimate the value of marginal changes in site characteristics.

3. Contingent Valuation Method

The CV method for estimating the value of natural resource services involves a direct survey of individuals to elicit their willingness to pay (WTP) for different levels of services. For example, the survey may ask respondents a question such as, "What is the maximum amount you would pay for a 25% increase in fish catch at this site?" The responses are analyzed to determine the incremental WTP for the resource. This method requires that individuals be able to express their value for marginal changes in fishery services and, that their responses to such hypothetical questions indicate their actual valuations of the changes described in the questions. EPA's guidance warns analysts of concerns about CV value estimates because of various forms of bias that may affect the validity and reliability of such values (EPA 1999, p.7-29). The guidance reminds analysts that there are tests that can enhance the credibility of CV studies and that surveys without these tests should be suspect (EPA 1999, p.7-29).

B. EPA's Selection and Use of Reference Studies

This section reviews three of the five benefits studies discussed by EPA in its benefits assessment. (We do not review the other two studies because one does not provide specific benefits estimates and the other does not contain the benefit estimates reported by EPA.) The final subsection provides an overview of concerns with EPA's selection and use of these studies.

1. Rowe et al. (1995)

EPA's first reference study is Rowe, et al. (1995). This study transfers values from existing studies to calculate damages to commercial and recreational fishing on the Hudson River from CWIS. Rowe, et al. (1995) reference Norton, Smith, and Strand's (1983) TCM of the recreational value of striped bass. Because the TCM cannot estimate marginal values for changes in catch, Norton, Smith, and Strand derive the value for catching one fish by dividing the total value by the number of fish. This value is not the benefit of catching one more fish but rather the average value of catching a fish. The value of catching one more fish will be less than the average because of the economic principle of decreasing marginal value. For example, an angler generally will value the tenth fish caught much less than the second fish caught. Thus, the average value of catching a fish overstates the marginal benefit associated with increased catch to an unknown degree. For example, if the relationship between marginal value and catch is linear, marginal value declines to zero at the point where average value is half the value of the first fish caught. EPA's analysis does not comment on or modify these TCM estimates for these obvious sources of upward bias.

Rowe, et al. reference Englin, et al. (1991) for the value of increased catch for other species. Englin et al. use a RUM to estimate the value of catching one additional fish from lakes in New York, New

Hampshire, and Vermont during the summer of 1989. Rowe et al.'s transfer of estimates from this study includes an arithmetic error that more than doubles the benefits estimate. EPA's evaluation of this study fails to detect this error. Rowe et al. inflates the estimate to 1992 dollars, the year of their study. Although Rowe's description of the inflation is correct in the text, the accompanying table uses an estimate inflated from 1976 dollars rather than 1989 dollars. Consequently, rather than using $0.27 to $1.25 as the range of values for increasing catch by one fish, the study uses $0.59 to $2.71. As a result, estimates are more than doubled.

In addition, the proposed rule misrepresents the Rowe, et al. estimates. Rowe, et al. warn that their damage estimates include considerable uncertainty and potential biases. In particular, the authors caution that the site-specific estimates could overstate values for other sites and that future damages may be overstated because mitigation measures may improve over time. Furthermore, fish-population dynamics could entirely offset mortality from impingement and entrainment which would result in zero damages. Thus, the authors report a lower-bound estimate of zero losses. Without explanation, the proposed rule reports the midpoint of the Rowe, et al. range as the lower bound loss estimate rather than reporting zero as the authors suggest.

The proposed rule fails to assess the applicability of either Rowe, et al.'s recreational or commercial benefit estimates to sites affected by the new-facilities rule. The appropriate measure for recreational benefits is the change in consumer surplus, while the appropriate measure for commercial benefits is the change in producer surplus. The rule suggests measuring benefits from commercial fishing using increased revenues as an indication of producer surplus (Rule, p.491 04). Economists agree, however, that incentives, for exploiting common property resources, like fisheries, result in producers' increasing effort until economic rents are zero (Tietenburg, 1988, p.266). Thus, producers drive any potential producer surplus to zero unless the fishery is regulated.

Producer surplus is greater than zero in the Rowe et al. study because there is a quota system for striped bass in the studied fishery. However, the study results are not directly transferable to sites that are unregulated or regulated differently, involve different species, use different catch technologies, etc. EPA does not explain how the study site differs from policy sites, how differences would affect value estimates, or how characteristics of the study combined with differences between the study site and policy sites would affect uncertainty in either the commercial or recreational benefit estimates. The rule does not demonstrate that circumstances in their case study would lead to positive producer surplus, much less whether it is appropriate to measure producer surplus using gross revenues rather than net revenues.

2. Huppert (1989)

EPA' s second reference study, Huppert (1989), also uses the TCM to estimate the value of angling for anadromous species in Central California. Huppert's estimates are overstated because TCM does not account for substitute alternatives. Furthermore, Huppert also misrepresents travel costs, which play a central role in deriving reliable estimates of recreators' WTP for access to a site. The TCM relies on the cost of travel to estimate the value of a recreation site. EPA's guidance explains that part of the cost of travel is the angler's opportunity cost of time, which varies with angler's income and work schedules (EPA 1999, p. 7-19). The guidance indicates that most studies use some fraction of the wage rate in calculating these costs. However, Huppert uses the full wage rate, which overstates the cost of travel and thus overstates the value of the trip.

More significantly, EPA departs from its own guidance in not documenting how the Huppert analysis was used to derive value estimates. The proposed rule reports an increase in consumer surplus from catching an additional striped bass as a range from $8.87 to $13.77 (Rule p. 49104). However, Huppert does not report this number, and the proposed rule does not explain how EPA's estimate is derived. According to the guidance, a benefits transfer often requires that analysts use judgment to adjust point estimates from a study to the relevant policy being considered (EPA 1999, p.7-33). The guidance requires that this judgment be based on economic theory, empirical evidence, and experience (EPA 1999, p.7-33). Because the proposed rule does not clearly present this information, there is no means for assessing the appropriateness of various assumptions or potential uncertainty introduced by such adjustments.

Huppert also compares TCM estimates with corresponding CV estimates, but does not report reliability tests for the CV estimates as suggested by the guidance. In the absence of documentation on the rule's value estimates, it is impossible to determine whether EPA derived their estimates from the CV or TCM values. In either case, using Huppert violates the guidance's procedures for selecting reliable transfer studies.

3. Jones and Sung (1993)

Jones and Sung (1993) is the third study used in the proposed rule. Jones and Sung use a RUM to estimate the recreational benefits of closing a facility. One of the most important pieces of information required to document aquatic benefits is the relationship between decreased losses from I&E and increases in angler catch. It is not sufficient simply to document an increase in mortality. Analysts must also document the link between the increase in fish mortality and a decrease in services from the fishery. As EPA's second cited study, Rowe, et a!., indicates, the lower bound of the range of possible effects may be zero. Jones and Sung's estimates of the value of increased catch assume that reduced I&E not only decrease losses of angler-targeted species, but also decrease losses in forage species. Without explanation, Jones and Sung assume that a 1.1—3.2% decrease in losses of forage species results in increases in catch of 10% for chinook salmon, 3.3% for coho salmon, 13.7% for lake trout, and 8.6% for rainbow trout. It is impossible to determine what confidence analysts should have in these assumptions or how sensitive benefits estimates are to variations in these assumptions. Using Jones and Sung without documenting the required links or evaluating the uncertainty of these assumptions violates the guidance requirement that analysts provide adequate information to facilitate appropriate interpretation of results (EPA 1999, p. 7-7).

Jones and Sung also use the full wage rate to value the opportunity cost of time, which, according to the guidance, biases benefits estimates upwards. Moreover, Jones and Sung violate guidance procedures for treating multiple-site or multiple-purpose trips. EPA's guidance clearly states that visits to multiple sites or trips with multiple purposes confound attempts to measure changes in values (EPA 1999, p. 7-19). Because travel costs determine benefits, anglers who travel long distances for trips lasting multiple days imply a large value for the trip. However, when such trips include visits to relatives, visits to theme parks, and other non-angling activities, it is impossible to identify what part of the total trip value should be assigned to fishing. Jones and Sung attribute the full value of multiple-day, multiple-purpose trips to fishing, which overstates benefits.

EPA's analysis again violates guidance procedures for evaluating the applicability of the transfer study to affected policy sites. Jones and Sung estimate the benefits from closing the Ludington Pumped-Storage plant on Lake Michigan. At the time of the study, this plant was the largest hydropower facility of its kind in the country. It is not clear how this example relates to new thermal plants located on quite different water bodies than Lake Michigan and involving very different species. Furthermore, estimates from this study assume plant operations that lack fish-protection measures. The Jones and Sung estimates clearly overstate benefits for the types of water bodies, species, and control technologies relevant for policy sites. Contrary to guidance requirements, the proposed rule does not evaluate the applicability of these values to assess benefits, how the estimates should be adjusted to account for differences between study and policy sites, or what the implications of such differences are for uncertainty in the estimates.

4. Summary

These comments suggest that EPA's use of individual benefits studies in the EEA does not conform to the Agency guidance. Moreover, the basis for selecting the studies is unnecessarily restrictive. The studies appear to be chosen because they estimate benefits from changes in cooling water intake structures. Many other studies develop estimates of recreational and commercial fishing values that could be used to assess the benefits of the proposed rule.

In sum, EPA should complete its benefit assessment of the proposed rule. The complete assessment should include an evaluation of benefits valuation results from a larger number of relevant studies.

Footnotes

6 See E.O. 12866, Section 6(a)(3)(C). Note that BLM acknowledges that the regulation is "significant" in the meaning of section 3(f) of the E.O. See BLM Proposed Rule, p. 6449.

Costs

Review of the Technical Development Document and the Economic and Benefits Analysis Document on Costs of Intake Technologies

Thomas C. Cook and E. P. Taft
Alden Research Laboratory, Inc.

Introduction

Alden Research Laboratory, Inc. (Alden) has reviewed two documents prepared in support of the EPA's Proposed Regulations to Establish Requirements for Cooling Water Intake Structures at Phase II Existing Facilities:

Technical Development Document for the Proposed Section 316(b) Phase II Existing Facilities Rule. 2002. USEPA. EPA-821-R-02-003 (the "TDD").

Economic and Benefits Analysis for the Proposed Section 316(b) Phase II Existing Facilities Rule. 2002. USEPA. EPA-821-R-02-001 (the "EBA").

Our review focused primarily on the TDD <FN 1> and only generally on the EBA. The TDD explains how EPA (1) estimated costs associated with retrofitting certain cooling water intake structure (CWIS) technologies at existing facilities and (2) used those generic costs to develop estimates of CWIS technology retrofitting costs for all in-scope Phase II facilities. Because the EBA analyzes the economic impacts on facilities, firms, and the industry as a whole using that cost data, our comments also are relevant to the EBA. The results of our review are summarized in the following discussion.

Overview of EPA's Methodology and Assumptions for Estimating Costs

EPA's cost estimates are very general and focus on a few selected technologies and associated design criteria, using data it developed for new facilities. TDD pp. 2.15, 2.28. EPA apparently chose to focus on retrofitting fine mesh screens and/or fish handling/return systems because it had concluded in the course of the § 316(b) rulemaking for new facilities that the costs of such technologies would, as a general matter, be higher than costs for other CWIS technology options. TDD p. 2.15.

For each technology it examined, EPA estimated capital and O&M costs for a "typical" retrofit, then applied a "capital cost inflation" or "retrofit" factor to "account for activities outside the scope of cost estimates" that it developed for new, greenfield facilities. EPA does not provide any data supporting this retrofit cost factor, although EPA does list some of the activities the factor might cover. <FN 2> The Agency does not provide any clue as to how each of those activities might affect cost or contribute to the factor selected. EPA also applies "regional cost factors" based on the RS Means database. TDD p. 2.27. For purposes of its analysis, EPA applied the "weighted average factor category for total costs" by state.

Impingement Mortality Reduction

For impingement mortality reduction, EPA assumed a facility would:

-retrofit “fish handling panels,” spray systems (without a differential control system and installation, or spraywash pumps), fish troughs, housing and transitions, and convert from intermittent to continuous operation; <FN3> and

-operate at a through-screen velocity of 1.5 feet per second (ft/s) (which EPA says (TDD p. 2.3) is the “median facility value” from the data it collected).

With respect to the velocity metric of 1.5 ft/s, EPA says it used this value only to size the fish handling/return system for which it developed cost factors and that the metric is not intended as a performance standard. TDD p. 2.3. Therefore, for purposes of our review, we assumed that existing CWIS with higher through-screen velocities would not be required to increase their size to achieve a lower, 1.5 ft/s velocity.

To calculate fish handling/return equipment costs, EPA used data it had collected for new facilities. Compare TDD pp. 2.6,2.14 with Technical Development Document for the Final Regulations Addressing Cooling Water Intake Structures for New Facilities (New Facility TDD), p. 2-47. To the calculated equipment costs, EPA applied a factor of 20% to account for upgrading existing equipment to convert from intermittent to continuous screen operation. EPA does not provide a reference for this factor.

To account for the cost of installing the fish handling/return equipment on existing traveling screens, EPA assumed that such costs would be “75% of the cost of installing a traveling screen (based on BPJ).” TDD p. 2.15.

Entrainment Reduction

For entrainment reduction, EPA assumed that a facility would:

-in lieu of larger mesh screens, retrofit fine mesh screening with a “screening efficiency” (by which we assume EPA means an overall “open area”) of 50% (TDD p. 2.2);

-account for the lower cross-sectional open area provided by fine-mesh screens, by expanding the existing intake structure (i.e., “fanning” it), which EPA assumed would entail demolishing one side wall of the structure and constructing a new wall, including one additional concrete pillar (TDD pp. 2.2-2.3);

-account for “the operational requirements of the screen and.. . balance the impingement reduction benefits of lower velocities with the physical constraints of velocity reduction for existing intake structures” (TDD p. 2.1) by reducing, where necessary, through-screen intake velocity to 1.0 ft/s. <FN 4>

As it does for impingement, EPA stresses that the 1.0 ft/s through-screen velocity metric is not intended as a performance standard. TDD p. 2.1. EPA recognized, however, that use of that metric would have a substantial effect on the retrofit cost for facilities with velocities over l.0 ft/s. TDDp.2.2.

To estimate the equipment costs of retrofitting fine mesh screens, EPA apparently used information it collected from one or more sources (most likely equipment vendors but EPA does not say which source or sources it used) during the new facility § 316(b) rulemaking. Because they were developed for new facilities, for which EPA chose to require closed-cycle cooling with much lower intake flow rates, the data provide cost estimates for flows up to 204,000 gallons per minute (455 cfs, or 294 MGD) at a through-screen velocity of 1.0 ft/s. TDD pp. 2.5-2.6. As EPA notes, at higher flows, additional screen assemblies or custom designs would be necessary. TDD p. 2.4. EPA used the new facility data to develop equations from which it derived equipment costs for the flow rates at those in-scope plants which EPA identified as likely to retrofit fine mesh. See TDD p. 2.2; 2.4-2.8; Appendix B. The only independent variable in those equations is flow. See TDD pp. 2.11.

To estimate installation costs, EPA again relied on estimates it developed for the new facility rulemaking. According to the TDD pp. 2.7-2.10, EPA took estimated costs for on-shore site preparation/excavation work <FN 5> for installing conventional traveling screens at a 10-foot well depth, and then scaled them up for screen wells of greater depths (up to 100 feet). EPA based its scaling factor on the assumption that such site preparation costs increase at a rate of an additional 25 percent per depth factor (calculated as the ratio of the well depth to the base well depth of 10 feet). EPA also took the costs it had developed for a hypothetical scenario for the underwater installation of twelve t-24 passive (not traveling) screens 75 yards offshore, via barge. Those installation costs essentially reflect the costs of positioning the intake screens and bolting them onto the inlet flange. <FN 6>

Separately, EPA appears to have calculated the demolition, excavation, and construction costs associated with its “fanning” scenario (that is, the “intake modification construction costs” described at TDD pp. 2.2-2.3) and compared those costs to its estimate of the costs of constructing an intake structure for a new facility (which it derived from equations developed for that purpose during the new facility § 316(b) rulemaking, and which included site-preparation and installation costs). TDD p. 2.2. EPA used the results of that comparison to develop “construction ratios” that vary depending on whether the plant is nuclear or non-nuclear and whether the retrofit involves installation of both fine mesh screens and fish handling/return systems, or only fine mesh screens. <FN 7> TDD p. 2.2, Table 2-1. (For facilities required to install only fish handling/return systems, EPA did not develop any construction factor; rather, it assumed that only the installation costs described above would be incurred.) Id.

Analysis of EPA CWIS Technology Cost Estimates

As noted above, EPA limited its cost analysis to two technology alternatives — retrofit of fine mesh traveling screens and/or fish handling/return systems because it says that data from the new facility rule indicate those are likely to be higher than other options. We do not believe that the cost data for new facilities, which were developed under the much lower flow conditions EPA imposed on such facilities, are particularly relevant for existing facilities with once-through cooling. Indeed, EPA itself concluded as much during the new facility rulemaking, suggesting that facilities with higher flows would not use such technologies at all, for economic and practical reasons. New Facility Rule TDD at 2-23. UWAG’s comments on the new facility rule disagreed strongly with EPA’s conclusion that using other technologies, such as passive screens and fabric filter barriers, would not be feasible and showed that they were in use at higher flow facilities. UWAG 2000 Phase I Rule Comments, pp. 173-202. But UWAG found that the costs for such technologies would be higher than EPA's estimates suggested and would not necessarily increase in a simple linear fashion with increased flow. Thus, it is important for EPA to state clearly in any final rule that its characterization of the costs of other technologies at new facilities (the principal basis for the cost data and resulting equations provided in the TDD) does not necessarily reflect the site-specific costs of applying such technologies at existing once-through facilities.

As for the two technologies EPA did examine, the Agency recognizes that the through-screen velocity design metric used has a significant effect on its cost estimate, because for any given flow rate, the desired velocity and total open area are the factors that determine both the number of screen assemblies needed and the total size of the intake structure needed to contain those screens. A simple pair of examples illustrates this point.

Assume three existing CWISs have traveling screens, each of which has a design flow rate of 500 &/s and incorporates 3/8-in, square mesh with an open area of 65% (similar to many such meshes). However, the design through-screen velocity differs due to differences in screen width and depth, as follows:

[see hard copy for table and equations]

Similarly, velocities for Facilities B and C would be 1.5 and 1.1 ft/s, respectively. If a designer needs to reduce velocity to meet performance requirements (i.e., 1.5 ft's through-screen for impingement and 1.0 ft/s through-screen for entrainment), the degree of modifications needed will vary greatly even though the total flow rate for all three hypothetical facilities is the same. Since flow and velocity are now specified in this example, the only way to reduce velocity would be to increase area. Thus, to achieve a through-screen velocity of 1.5 ft/s, facilities B and C would not have to be expanded or fanned since they already have velocities of 1.5 ft/s or less. However, Facility A would require an increase of 60% in area to reduce the velocity from 2.4 to 1.5 ft/s. The costs for this facility would be substantially higher than for Facilities B and C.

To achieve a velocity of 1.0 ft/s through-screen, as specified by EPA for fine mesh screens, the screening area of all three facilities would have to be increased. Assuming EPA's screen open area of 50%, the formula for calculating required through-screen area would be as follows for Facility A:

[see hard copy for equation]

The existing through-screen area is 208 ft^2 (8 ft wide by 40 ft deep by open area of 0.65%). Therefore, the screen area would have to increase nearly 2.4 times. Similarly, the existing through-screen area for Facilities B and C would be 325 and 468 ft^2, respectively. The screen area for Facility B would have to be increased by only about 1.5 times, while Facility C would require little, if any, change in screen area.

Clearly, for all three facilities, the equipment costs (that is, the number of screens and, possibly, the layout) and the size of the intake structure will differ dramatically. EPA correctly recognizes that, above the flow rates for which it collected cost equipment cost data , multiple screens or customs designs would be necessary. TDD p. 2.4. EPA's equations may account for the cost of multiple screens, but they do not account for custom designs, the cost for which would need to be estimated on a site-specific basis.

It also is not clear whether the 1.0 ft/s velocity metric EPA used to size its retrofit represents a maximum velocity that accounts for the non-uniform velocity distribution that occurs in many CWISs. Velocities at CWISs are determined by factors such as the presence or absence of skimmer walls and the direction and magnitude of ambient currents approaching the CWIS (which are not only site-specific but also seasonally specific). If EPA assumes that the value to be used in sizing a retrofit or otherwise applying technologies is the maximum value that cannot be exceeded at any single point in a CWIS or through a screen, such a design criterion would impart greater variability in costs across all facilities.

Most important, the actual cost of the expansion for any given site will be determined by the existing site layout, the type of excavation required (e.g., rock versus soil), the availability of space in which to expand, and the degree to which existing piping and pumps can be used as opposed to replaced. For example, sheet piling is not possible in many locations; more expensive cofferdams will be required at these sites. Similarly, the amount of concrete demolition and additional concrete needed depends on the design and layout of the existing CWIS (e.g., availability of space and navigational impacts). Modifications could be as simple as adding columns, as EPA assumes. Alternatively, it may be necessary to construct major new intake elements (concrete, steel, piping, pumps). For example, to achieve a uniform distribution of flow through screens (existing and new) at some facilities, pumps and/or piping may need to be rearranged, relocated, and/or replaced. Such a distribution also could be achieved by placing a new screen array immediately upstream of the existing screenwell structure and constructing cut-off walls to channel the flow through the screens. The costs associated with each of these examples will vary substantially depending on site-specific requirements.

As another example, the effort and cost of retrofitting screens with fish baskets, low-pressure sprays, and fish troughs is dependent on the existing screen design. Some existing screens are of the front-wash design (debris is rinsed into a debris trough from the ascending, front screen face). To convert such screens to a back-wash design compatible with the current Ristroph screen basket design, it often will be necessary to raise the head shaft/sprocket to make room for additional, low-pressure spray wash headers and a fish trough. Alternatively, it may be more cost-effective to simply replace the entire screen and associated troughs with new components designed specifically to protect fish.

While EPA does include a retrofit cost factor, we have no way of assessing EPA's development of that factor, nor does it appear to fully account for all site-specific factors that may arise. As noted above, EPA does not tell us what each activity might cost, how site-specific variables would affect the cost of each activity, and how those activities contribute to the retrofit factor(s) EPA selected.

Equally important, EPA says that a "capital cost inflation" factor of either 20% (in the case of conversion of cooling systems, as would occur with installation of a cooling tower) or 30% (in the case of retrofitting/upgrading water intake structures and screens) appropriately adjusts its new facility costs for use as existing facility retrofit costs. TDD p. 2.28. While admitting that retrofit activities are "site-specific [and] may vary between sites," EPA nonetheless applies generic adjustment factors that cannot be accurate for every site. For example, at some facilities foundations for cooling towers would be extremely expensive to construct because of unstable soil conditions. At such sites, EPA's 20% adjustment would be inadequate.

Likewise, the 30% adjustment for retrofitting screens will be too low to capture the costs at some sites. This is particularly true for CWIS technologies, given the many site-specific factors that determine the ultimate cost, which a percentage adjustment factor tied to capital costs cannot capture. Indeed, in some cases, the factors that drive up the costs of retrofitting CWIS technologies may be largely unrelated to the costs of the retrofitted technologies. For example,
to secure necessary permitting for the retrofit construction activities, environmental assessments (e.g., freshwater mussel surveys) or other information may need to be generated. Unusual demolition or construction requirements (i.e., relocation of existing barge loading facilities to allow space for screening technologies) also may be unrelated to capital costs. Therefore, EPA's retrofit cost factor methodology, by its relationship to capital costs, likely will underestimate retrofitting costs at some sites. Thus, EPA's final rule should caution against reliance on such simplistic factors to estimate site-specific retrofitting costs.

In short, a construction factor reflecting a simple "fanning" scenario, the use of installation costs for passive screens (not traveling screens, which EPA apparently assumes will have similar costs), and a retrofit factor that is simply a percentage of those costs will not capture the full extent of retrofit costs for some sites. In practice, costs will vary widely, so that EPA's general estimate may not — in fact, likely will not — be "typical" for any given site. Thus, it is very important for EPA to acknowledge that site-specific factors not captured by its general analysis may work to increase (or possibly, in some cases, decrease) costs.

Conclusion

Based on its 30 years of experience designing CWISs at a wide variety of sites, Alden believes it is clear that the costs of retrofitting fish protection technologies at CWISs are highly site-specific. Site-specific requirements will result in costs that span a wide range that has not been completely and accurately captured in EPA's national estimates. EPA should make clear that such factors must be considered when any final rule is applied.

Footnotes

1 Our review of the TDD did not include reviewing any of EPA's assessment of the engineering attributes or costs of retrofitting closed-cycle cooling at existing facilities.

2 EPA says that the retrofit cost factor covers: branching or diversion of cooling water delivery systems, reinforcement of retrofitted conduit system connections, partial or full demolition of conduit systems and/or intake structures, additional excavation activities, temporary delays in construction schedules, expedited construction schedules, potential small land acquisitions, hiring of additional (beyond those typical for the "greenfield" cost estimates) equipment and personnel for subsurface construction, administrative and construction related safety precautions, and potential additional cooling water (recirculating or make-up) delivery needs. TDD p. 2.28.

3 It is not clear from the TDD whether EPA considered any energy penalty stemming from the increased auxiliary power needed to run screening systems continuously and to run the fish return system, or for system down- time during CWIS retrofit construction/installation/reconnection. A more detailed evaluation of this issue is beyond the scope of this report. EPA says it estimated annual O&M costs for traveling screens with and without fish handling/return systems based on "discussions with industry representatives" whom it does not identify. EPA then expressed those costs as a percentage of capital costs. But EPA does not explain what cost elements it considered as part of O&M. TDD p. 2.12.

4 EPA also considered possible costs for a design through-screen velocity of 0.5 ft/s but apparently decided not to develop national estimates based on that metric. See TDD pp. 2.1, 2.4-2.5.

5 According to EPA, this includes clearing and grubbing, earthwork, paving and surfacing, and structural concrete. TDD p. 2.7. For structural concrete, EPA assumed use of four 12-by-12 inch reinforced columns with depths varying between 1.5 and 3 yards. Id.

6 Bolting the screens to the inlet flange is only a minor part of the total installation process. It is not clear how EPA has accounted for the other installation procedures.

7 It is unclear why, in Table 2-1 of the TDD, p. 2.2, EPA shows a “construction factor” for fine mesh screens alone (65%) that is greater than the factor for fine mesh screens with fish handling (30%).

EPA Response

The Agency notes that it dramatically revised its cost estimation approach for fish protection technologies to account for greater recognition of site-specific conditions. The Agency presented this analysis in the Notice of Data Availability and received comments from this same commenter (i.e., Alden labs) regarding the revised methodology. See responses to comments 316b.EFR.306.042 through 316b.EFR.306.053.

Performance standards

The Performance of Intake Technologies in Light of EPA's Proposed Performance Standards

E. P. Taft, Alden Research Laboratory, Inc.

In Chapter 3 of its Technical Development Document for the Proposed Section 316(b) Phase II Existing Facilities Rule (EPA 2002) and Attachment A thereto, EPA presents information that it compiled on the "performance of the range of technologies currently used to minimize impingement and entrainment (I&E) at power plants nationwide." Despite EPA's stated limitations of the data, it is clear that there exists a variety of cooling water intake structure (CWIS) technologies that, when used alone or in combination, act to reduce I&E. Further, ongoing research with a number of promising technologies may lead to improvements in their performance in the future. Therefore, UWAG generally concurs with EPA's assertion that "significant general performance expectations can be implied for the range of technologies and that one or more technologies (or groups of technologies) can provide significant I&E protection at most sites." However, as discussed below, UWAG questions whether the available data support the adoption of a performance standard that can be applied across-the-board at all existing sites with all species and life stages of fish and shellfish.

In Chapter Al of its Economic and Benefits Analysis for the Proposed Section 316(b) Phase II Existing Facilities Rule (EPA 2002), EPA characterizes technologies as follows:

"technologies that minimize impingement and entrainment"

-Exclusion systems such as wet cooling towers, fine mesh screens, intake traveling screens, and aquatic filter barriers

-Passive systems such as wedge wire screens, perforated pipes, porous dikes and artificial filter beds

-Diversion/avoidance systems

"technologies that maximize survival of impinged organisms"

-Fish handling systems such as bypass systems, fish buckets, fish baskets, fish troughs, fish elevators, fish pumps, spray wash systems and fish sills

"operational measures that minimize I&E"

-Seasonal flow reductions

-Variable speed pumps

There exists a relatively large database on the biological effectiveness of technologies in reducing I&E. Some technologies, such as modified traveling (Ristroph) screens, have been studied in-depth with a wide variety of species in most, if not all, waterbody types. Others, such as aquatic filter barriers (AFB), are relatively new and have been evaluated for use at CWIS in only one waterbody with fewer species. (See Attachment A to this Appendix for a summary of ongoing research on AFBs and other intake technologies.) Therefore, the data available to estimate the potential effectiveness of a technology, as applied to a given site, will vary by technology.

In some cases, the existing data may not be sufficient to determine whether the technology could meet EPA's proposed performance standard. Regardless, EPA has selectively presented the data in a way that supports its proposed performance standard. In that sense, EPA's selection of target values for the performance standard (80-95 percent reduction in impingement mortality; 60-90 percent reduction in entrainment) is somewhat arbitrary. While available technologies may "maximize" impingement survival and "minimize" entrainment, EPA's presentation of the information ignores much of the variability in the data related to species- and site-specific issues. A thorough knowledge of the data points to the fact that currently available technologies cannot meet the performance standard across all species/life stages at all sites.

Further, EPA's proposed performance standards are measured against a calculation baseline that may not be quantifiable with precision in some instances. If the existing CWIS at the site under evaluation is not on a shoreline, it may be difficult to estimate existing I&E for a hypothetical shoreline intake representing the baseline. EPA suggests that this baseline "could be estimated by evaluating existing data from a facility nearby without impingement and/or entrainment control technology (if relevant) or by evaluating the abundance of organisms in the source waterbody in the vicinity of the intake structure that may be susceptible to impingement and/or entrainment" (p. 17,176, col. 2). As discussed elsewhere (e.g., Appendix 4, Narrative Factors Report), many biological, engineering, and hydrologic/hydraulic factors influence whether an organism will interact with a CWIS and whether or not the organism will survive that interaction. EPA's simplistic approach ignores many of the points that were made in the Narrative Factors report.

Assuming that a reasonable baseline can be calculated, the next step is to determine the effectiveness of a technology in reducing impingement mortality and entrainment. Where adequate data exist to estimate potential effectiveness of a technology at a given site, it is important to consider site-, species- and life stage-specific factors that influence whether an organism will be protected to the level of the performance standard. These factors are discussed below.

Site-specific factors influence both (1) where the technology can be located and (2) whether it can be operated in such a way as to maximize biological benefits (or even meet the performance standard). As such, these factors determine how effective a technology will be in protecting organisms.

Consider, for example, the potential retrofit of wedge wire screens to achieve optimum hydraulic conditions for fish protection at an existing, shoreline CWIS on a river. To protect the earliest life stages, such screens need to be located in an area where ambient currents exist to carry organisms and debris away from the screens. At one site, this might be easily achieved. At another site (even nearby), this area may not be available due to navigational or other site-specific constraints. If adequate area for installation is not available within the bulkhead line, it may be necessary to locate the screens in another area with less desirable hydraulic conditions. This adjustment could jeopardize the ability to meet the performance standards for certain species and life stages.

Species- and life stage-specific factors relate mainly to the size, swimming capabilities and relative hardiness of different species and life stages. These factors also can be closely interrelated to site-specific factors. The size of an organism determines whether its movement will be blocked by a technology designed to collect it (e.g., fine mesh screens) or passively divert it (e.g., wedge wire screens). Thus, the opening size of a screen (e.g., screen mesh size) determines whether an organism will be entrained or impinged. In turn, the minimum pore size that can be installed at a given site is related to the type and amount of silt and debris in the water. Therefore, the pore size that will protect a given species at one site may not be practicable to install and operate at another site to protect the same species.

The swimming capability of the species and life stages requiring protection at a given site influences both what technologies might be considered for reducing impingement mortality and entrainment and the ability of a selected technology to meet the performance standard. Accordingly, older fish (juveniles and adults) with strong swimming capabilities can be protected relatively easily with a variety of technologies. Early life stages (e.g., eggs and early larvae) with little or no mobility must be protected with passive devices (e.g., wedge wire screens and aquatic filter barriers) or collection systems that handle fish gently (e.g., fine mesh screens). See Appendix 4, Narrative Factors Report.

Hardiness relates mainly to the ability of an organism to survive interaction with a technology. Survival of impinged fish and macroinvertebrates varies widely among species and between life stages of a given species. Some species (e.g., blue crab, flounder, catfish) are very hardy and show very high survival rates following impingement on, and removal from, traveling screens. Other species (e.g., menhaden, bay anchovy, herring) are sensitive to impingement stress and suffer higher mortality under the best of conditions. In addition, impingement survival of individual species has been observed to vary widely at different times of year. Reduced survival may be related to seasonal increases in debris loading and the presence of organisms with hard exoskeletons (e.g., crabs) which appear to cause an increase in injury and a reduction in survival of other impinged species. Occurrence of debris and its blockage of intake screens is a highly site-specific factor. The physiological state of organisms at the time of impingement may also affect their survival. In particular, seasonal water temperatures near the upper or lower temperature tolerance limit of the species may increase their sensitivity to the subsequent stress of impingement, thereby lowering impingement survival relative to that observed at other times of the year.

In summary:

-Technologies are available that can reduce impingement mortality and entrainment;

-Some promising technologies have not been evaluated to the point where their ability to meet a performance standard is understood;

-Through the selective presentation of available data, EPA has overstated the ability of existing technologies to meet the performance standard for all species/life stages at all sites;

-Site-specific, species-specific, and life stage-specific factors all interact to influence the ability of a technology to meet the proposed performance standard at a given site.

Attachment A

Recent CWIS Technology Research and Applications

Alden Research Laboratory, Inc.

In Chapter 3 of its Technical Development Document for the Proposed Section 316(b) Phase II Existing Facilities Rule (EPA 2002) and Attachment A thereto, EPA draws heavily on a 1999 EPRI report for much of its information on the ability of existing cooling water intake structure (CWIS) technologies to meet its proposed performance standards for reducing impingement survival and entrainment. Alden Research Laboratory, Inc. (Alden) is currently performing a due diligence review of EPA's information for the Electric Power Research Institute (EPRI) to determine the accuracy of the data used.

The review points to the fact that considerable research is ongoing, particularly with regard to two technologies that EPA endorses: wedge wire screens and artificial filter barriers. Based on the history of emerging fish protection technologies, several years of laboratory and pilot-scale study typically are needed to develop baseline information on a technology's potential. When a technology eventually is tested on a CWIS for the first time, it is reasonable to assume that several years of fine tuning will be needed to optimize the design for site-specific conditions (e.g., species and life stages and debris loading). Following the first full-scale application at one site, further experience will be needed at other sites with different design and operational features and species/life stages. Only after this multi-year investigation process will the full data available to predict the technology's level of performance at a given CWIS.

Two examples support the need to take emerging technologies through a development process. At Tampa Electric Company's Big Bend Station in Florida, the results of laboratory studies were followed by one year of small-scale and two years of prototype-scale studies at the site. Only with the combined information from these studies did EPA determine that fine mesh screens would be BTA for Units 3 and 4. At Mirant's Lovett Generating Station in New York, the first full-scale application of an aquatic filter barrier (AFB) at a CWIS has undergone over four years of design development and testing. Additional laboratory and field evaluations of the AFB are currently underway. It is clear that the industry is years away from understanding the full potential of this promising technology.

[see hard copy for table]

EPA Response

EPA has discussed the range of technologies used to establish the performance standards (see Sections VII.B.2 and B.3 of the preamble to today's rule). Available data indicate that, when considered as a suite of technologies, barrier, and fish handling technologies are available on a national basis for use by Phase II existing facilities. These technologies exist and are in use at various Phase II facilities and, thus, EPA considers them collectively technologically achievable. For example, currently, 14 percent of Phase II existing facilities potentially subject to this final rule already have a closed-cycle recirculating cooling water system. In addition, 50 percent of the remaining potentially regulated facilities have some other technology in place that reduces impingement or entrainment. Thirty-three percent of these facilities have fish handling or return systems that reduce the mortality of impinged organisms. The fact that these technologies are collectively available means that one or more technologies within the suite is available to each Phase II facility. Economic practicability is discussed in Sections VII.B and XI.B of the preamble to today's final rule.

EPA finds that the design and construction technologies necessary to meet the requirements are commercially available and economically practicable, because facilities can and have installed many of these technologies years after a facility began operation. Typically, additional design and construction technologies such as fine mesh screens, wedgewire screens, fish handling and return systems, and aquatic filter fabric barrier systems can be installed during a scheduled outage (operational shutdown

Overall, the performance standards that reflect best technology available under today's final rule are not based on a single technology but, rather, are based on consideration of a range of technologies that EPA has determined to be commercially available and economically practicable for the industries affected as a whole and have negligible non-water quality environmental impacts, including energy impacts. Because the requirements implementing section 316(b) are applied in a variety of settings and to Phase II existing facilities of different types and sizes, no single technology is most effective at all existing facilities, and a range of available technologies has been used to derive the performance standards. In addition, while these technologies may be available and practicable for the category of existing facilities as a whole, EPA recognizes that this will not be the case for some individual facilities. EPA has codified a site-specific compliance alternative to account for these situations. In addition, EPA has authorized compliance to be demonstrated pursuant to a Technology Installation and Operation Plan in order to account for the fact that biological variability and other factors may interfere with the consistent achievement of the national performance standards even when the model technologies are installed and properly operated.

EPA has based the performance standards for impingement mortality reduction, compared with conventional once-through systems, on the following technologies: (1) design and construction technologies such as fine and wide-mesh wedgewire screens, as well as aquatic filter barrier systems, that can reduce mortality from impingement by up to 99 percent or greater compared with conventional once-through systems; (2) barrier nets that may achieve reductions of 80 to 90 percent; and (3) modified screens and fish return systems, fish diversion systems, and fine mesh traveling screens and fish return systems that have achieved reductions in impingement mortality ranging from 60 to 90 percent as compared to conventional once-through systems.

Available performance data for entrainment reduction are not as comprehensive as impingement data. However, aquatic filter barrier systems, fine mesh wedgewire screens, and fine mesh traveling screens with fish return systems have been shown to achieve 80 to 90 percent greater reduction in entrainment compared with conventional once-through systems. EPA notes that screening to prevent organism entrainment may cause impingement of those organisms instead. Questions regarding impingement survival of relatively delicate fish, larvae, and eggs should be considered by the Director and the facility in evaluating the efficacy of the technology. In addition, all of these screening-and-return technologies should be evaluated on a case-by-case basis to determine if they are capable of screening and protecting the specific species of fish, larvae and eggs that are of concern at a particular facility.

See Chapter 3 of the Phase II Existing Facility Technical Development Document and DCN 5-4420.

Cooling system costs (e.g., dry, wet, recirculating)

Initial Analysis Of Cooling Tower Retrofit Costs

January, 2002

To help inform EPA's current rulemaking on how § 316(b) of the Clean Water Act applies to existing (i.e., already-built) facilities that withdraw cooling water, the Utility Water Act Group has sought information on what it would cost to abandon open-cycle cooling systems at existing facilities nationwide and install wet cooling towers instead. We made a number of simplifying assumptions, as required by the large scope of' the study and the fact that many costs are heavily affected by individual site features. The limitations of this sort of study need to be kept in mind, lest these numbers be viewed, incorrectly, as UWAG's final and best estimate of costs.

UWAG's current rough estimate of the nationwide cost of retrofitting cooling towers on electric generating facilities is about $40 billion. By comparison, the total electric power industry revenues from sales to ultimate customers for 1999 was $217 billion. Hence the cost of retrofitting cooling towers calculated here is some 18% of the industry's yearly revenues.

The estimated costs calculated here are very large, but real-world costs might be even higher. Some of UWAG's consultants feel that the total cost could be in the range of $44 to $66 billion dollars. In part this is because many construction and design problems might have to be solved, depending on the specific sites. For example, a retrofit must reflect the engineering and construction to:

-Modify existing once-through pump bays to accept the return cold water piping from the tower to the condenser.

-Modify the once-through discharge piping or canal to convey the heated water back to the cooling towe

-Substantially upgrade the mechanical integrity of the condenser (such as the cooling water expansion joint hold-down tie rods, the inlet and outlet waterboxes,' anchor bolts, tubesheets and peripheral tube restraints) to accommodate the much higher hydraulic pump head of a recirculated system.

-Substantially upgrade the cooling water piping already inside the turbine hail to handle the hydraulic pump pressures.

-Add a pumphouse at the tower with all of the facilities (overhead cranes, etc.) needed to operate and maintain large cooling water pumps.

-Add electrical wiring. Compared to other plant systems, cooling towers are isolated components which usually require extensive electrical service connections including high-voltage load centers, motor control centers, cable, switchgear, etc. There are also considerable wiring and electrical costs with co.

-Provide noise abatement. Depending upon location (which may be constrained on existing plant sites), many retrofit towers will require some type of noise attenuation (low-noise fans) to avoid community complaints at or near the property line.

-Construct cooling tower basins. The cost factor for the saltwater cooling tower basin should be greater than the freshwater basin to reflect the need for specialized, sulfate-resistant concrete.

-Provide foundation support. Some piling may be necessary for the new cooling water system components.

-Make provisions for demolition or abandonment-in-place for the old cooling water intake and discharge structures and piping, since these items may eventually become hazards without ongoing operation and maintenance.

Step 1: The WGI Modeling Run

UWAG began by asking the Washington Group International (WGI) to take the Utility Data Institute's Database of North American Power Plants (June 2000 Update) and, using the powerplant data in that base, use the WGI proprietary cost model to calculate the capital cost of cooling towers for all the plants withdrawing more than 2 million gallons of cooling water a day. As this was intended to be only a initial analysis, and the information was needed quickly, UWAG did not ask WGI to undertake the complex task of estimating total retrofit costs, which would include incremental increases in operating and maintenance (O&M) costs, as well as the often substantial costs associated with buying replacement power during cooling system conversion and absorbing any energy penalties associated with increased auxiliary power needs or turbine backpressure effects.

As with any study of this kind, WGI also had to make certain simplifying assumptions. WGI assumed:

-Space is available on each plant site for locating the new cooling tower(s).

-Replacement circulating water pumps are included in the estimates to reflect the static height differential of lifting water to the top of the tower(s).

-An allowance of 1000 linear feet of circulating water pipe is made for interconnection between the existing system and the cooling tower location.

-A material cost differential for saline/brackish versus fresh water is considered.

-Cost estimates are based on 0.0005% maximum drift loss from the cooling tower.

-Cooling tower estimates include sound attenuation measures to limit noise to 60 dBA at 400 feet.

-No allowance is included for permitting costs.

-Treatment of blowdown from the cooling tower system is not considered except for de-chlorination.

WGI was not asked to consider costs such as the following:

-Plant emissions relative to allowable permit discharge levels.

-The costs of purchasing replacement power during cooling system conversion

-Plant output (kW) and heat rate (BTU/kW-br) due to potential changes in turbine backpressure with conversion to cooling towers.

-Plant HV electrical systems due primarily to new circulating water pumps, auxiliary transformers, and cooling tower fans

-Increased O&M costs.

The WGI model calculated, under these assumptions, that the nationwide cost of cooling towers retrofitted to existing facilities would be $22.234 billion. The WGI report and accompanying spreadsheet are attached to this paper.

Step 2: Adjusting the WGI numbers in accordance with case studies

WGI, as requested by UWAG, based its numbers only on the cost of installing towers and did not include certain other cost items. UWAG then performed a rough adjustment of the WGI numbers based on several plant-specific studies of cooling tower retrofit costs that were available to us. In particular, § 316(b) studies for the Salem, Mercer, and Hudson plants, on file with the New Jersey Department of Environmental Protection, were examined.

We used a very simple approach of station-to-station comparisons using the data provided for the above three plants (note that the following numbers for those plants were escalated to 2001 using an annual rate of 0.0265, so that a three-year escalation would be

(1.0265)E3 = 1.082), as follows:

	Retrofit Cost ($/kW)		Factor
Plant Type	PSE&G	WGI	PSE&G/WGI
Salem Nuclear, saltwater	268	95.91	2.8
Hudson Fossil, saltwater	115	66.55	1.8
Mercer Fossil, freshwater	81	57.80	1.4

These factors can be used to adjust the national estimates generated by WGI. Multiplying the nuclear costs (both saltwater and freshwater) by 2.8, the fossil saltwater by 1.8, and the fossil freshwater plants by 1.4, we arrive at the following estimate:

69 nuclear units (fresh and salt) = $4.799 billio x 2.8 = $13.44 billion
294 fossil saltwater plants = $5.506 billion x 1.8 = $9.91 billion

905 fossil freshwater plants = $11.829 billion x 1.4 =$16.56 billion
1204 other plants, mostly cogeneration facilities = $0.14 billion (WGI's "upper bound")

Adding these four numbers together, we reach a sum of $40.05 billion.

Be cautioned that our adjustment is superficial and does not address many of the cost items that would be encountered in actual construction projects. Consequently, the resulting "adjusted" estimates should be considered very preliminary.

ESTIMATED CAPITAL COST OF RETROFITTING COOLING TOWERS AT EXISTING FACILITIES WITH OPEN CYCLE COOLING

WASHINGTON GROUP INTERNATIONAL
December 2001

FINDINGS

Washington Group International (WGI) has performed an analysis to determine (1) which existing steam electric power plants/units included in the Utility Data Institute's Database of North American Power Plants (UDI Database) are likely to be subject to rules that the Environmental Protection Agency (EPA) is developing under § 316(b) of the Clean Water Act; and (2) for the subset of those plants that currently use open-cycle (or "once-through") cooling systems, the likely capital costs of retrofitting mechanical draft cooling towers. The analysis indicates that 69 nuclear units and 1199 fossil units, comprising 57,343 MW and 276,641 MW respectively of installed capacity, could be subject to the rules. An additional 38,884 MW are undefined relative to their condensing mode or condensing steam and may not be totally subject to the regulations. These are discussed separately below. The combined cost impact, utilizing the assumptions identified below, would be on the order of approximately $ 22.134 billion in present-day US dollars. The findings above reflect only those units/plants currently installed and operating. Washington Group International (WGI) has assumed that all plants, indicated as indefinitely deferred, planned or under construction in the source database, will use some form of cooling towers or air-cooled condensers.

The above once-through systems are reflective of units/plants utilizing more than 2 MGD each of cooling water (the threshold EPA has adopted for new facilities) and only consider the steam actually condensed in cogeneration and combined cycle facilities. Units designated as combined cycle single shaft configuration (abbreviated CCSS in the source database) are handled in the same manner as other combined cycle units.

The findings further indicate that of the 69 nuclear units that employ once-through cooling systems, 25 units (25,161 MW) are in saltwater or brackish water applications. These units would require an investment of approximately $ 2.437 billion to retrofit mechanical draft cooling towers; the balance of 34 utilizing fresh, ground or gray water (32,182 MW) for cooling, would require approximately $ 2.362 billion to provide the same. Similarly, the sample of existing once-through fossil-fueled plants consist of 294 units (72,805 MW) in salt or brackish water applications will have an estimated retrofit of approximately $ 5.506 billion while the 905 units (203,836 MW) in fresh water installations would require an investment of approximately $ 11.829 billion.

Simplifying assumptions, detailed below, were necessary in order to proceed with the cost analysis due to the large number of units and the extent of possible site arrangements involved in retrofitting cooling tower.

An additional 1,204 units, comprising 38,884 MW of power plants with unknown or undesignated cooling systems were also found in the database. These plants utilize fossil, biomass or other fuels to generate steam. Most of these plants are cogeneration plants exporting some or all of their steam to a host instead of a condenser and many have cooling towers or air-cooled condensers; thus, it is impossible to estimate the cost to retrofit mechanical draft cooling tower systems to these plants with any degree of accuracy.

An upper bound was estimated by assuming that the proportion of plants having air-cooled condensers, hyperbolic towers, or forced draft towers is the same as the plants we analyzed in the study (73 11(731 + 1199) = 38%. On the basis of this and utilizing a simplifying cost factor per MW and investment cost potential of approximately $ 140 million was developed. This could be anticipated as an upper bound.

Issues not addressed in this report include impacts on:
-Plant emissions relative to allowable permit discharge levels.
-The costs of purchasing replacement power during cooling systems conversion
-Plant output (kW) and heat rate (BTU/kW-hr) due to potential changes in turbine backpressure with conversion to cooling towers.
-Plant HV electrical systems due primarily to new circulating water pumps, auxiliary transformers, and cooling tower fans.
-Increased O&M costs.

INTRODUCTION

Washington Group International (WGI) was engaged by the Utility Water Act Group (UWAG) to provide a cost estimate for the conversion of US power generating units currently operating with once-through cooling systems to closed cycle cooling. For study purposes, mechanical draft cooling towers were assumed to be the closed cooling system of choice.'

UWAG commissioned this analysis in order to get a preliminary estimate of the costs that might be imposed on the industry if EPA were to require cooling tower retrofits for existing facilities (an option EPA has said it was considering) in rules EPA is developing under § 316(b) of the Clean Water Act (CWA). In rules EPA recently adopted for new facilities, EPA exempted from coverage units with water withdrawal rates less than 2 MGD. This report focuses on units/plants exceeding that threshold.

The estimate of implementation costs are categorized as fossil or nuclear and, in addition, are broken down into brackish/saline and fresh water applications.

METHODOLOGY

1. Report Database

WGI utilized the UDI Database, June 2000 Update, as a starting point for identifying units affected by the new EPA rules. This database contains in excess of 25,000 power generating units. Data contained in this report were screened to delete non-applicable units and reduce the database down to only those units to be considered in this program. This effort included:

-deletion of units below the 2 MGD threshold
-elimination of non-US generating units
-deletion of retired or standby units, not subject to the new regulation
-deletion of all non-condensing steam turbines
-deletion of all simple cycle gas turbines
-deletion of units indefinitely-deferred, planned or under-construction, which were assumed either to be new facilities or would have cooling towers.

Based on the above data reduction, the field of over 25,000 generating plants was reduced to slightly under 2,500 that would be subject to the regulations.

The database was then sorted into fossil-fueled versus nuclear-fueled units. The remaining units were sorted further to separate saline water applications from fresh water applications for each fuel type. The resulting database is organized into the four requested reporting categories.

As indicated, some 1,204 units of the database of operating units lack an entry in the "COOL" (cooling system type) column. These units represent too large a sample to be ignored. As a result, WGI reviewed the entire database of non-nuclear units to determine the proportions of known once-through cooling and cooling tower applications as well as saline and fresh water sectors. These same proportions were then applied to the sample without cooling system identification to arrive at an allocation of these units into the four considered categories.

2. Cost Basis

Do to time constraints and the available unit details, WGI has made certain simplifying assumptions as a basis for developing the cost models for the various applications. These assumptions can be summarized as follows:

-Space is available on each plant site for locating the new cooling tower(s).
-Replacement Circulating Water Pumps are included in the estimates to reflect the static height differential of lifting water to the top of the tower(s).
-An allowance of 1000 linear feet of circulating water pipe is made for interconnection between the existing system and the cooling tower location.
-A material cost differential for saline/brackish versus fresh water is considered.
-Cost estimates are based on 0.0005% maximum drift loss from the cooling tower.
-Cooling tower estimates include sound attenuation measures to limit noise to 60 CIBA at 400 feet.
-No allowance is included for permitting costs.
-Treatment of blowdown from the cooling tower system is not considered except for de-chlorination.

These assumptions are considered reasonable in the absence of more definitive data or the ability to study/develop more specific solutions.

3. Cost Modeling

Modeling for this study did not consider impacts of the tower conversion on the unit/plant such as:

-Limits on particulate and other emissions in unit/plant air permits
-Icing effects on other plant equipment due to tower drift
-Reduction in net unit power output due to increases in steam turbine exhaust pressure or in circulating water pump and cooling tower fan power
-Costs of purchasing replacement power during cooling system conversion
-Operating limitations imposed by existing equipment/conditions
-Increased O&M costs
-Other impacts not specifically addressed below

These types of considerations would have a significant impact on actual cost and require a more in-depth site-specific study.

The modeling methods applied in developing the cost estimates for cooling tower retrofits have utilized the following approach:

3.1 Estimate of Condenser Heat Duty

WGI has grouped all the units in the report database by thermal cycle and steam conditions and size (output). Condenser heat duties, in millions of Btus per hour (MMBtu/hr), were based on heat balances, each representative of a specific grouping. Factors for turbine exhaust flows and turbine exhaust enthalpy change were developed for each grouping. Factors include consideration of heat from feedpump turbine exhaust, heater drains or other sources, as appropriate. Condenser duties were then calculated from factored turbine exhaust flow and enthalpy change.

3.2 Estimate of Cooling Water Flow versus Steam Turbine Output

Based on WGI experience with once-through cooling systems, the temperature rise of the cooling water traveling through the condenser was assumed to be 12°F for all generating units. When the heat duty is divided by the temperature rise and then by 500 the result is the cooling water flow through the condenser in gallons per minute (gpm). We then applied a multiplier of 1.05 to account for auxiliary cooling water flow requirements. This number is the total cooling water flow.

For the purposes of the study, it was assumed that the total cooling water flow will not change when retrofitting a cooling tower. We believe that this approach is reasonable since the condenser will be reused and the velocity through the condenser tubes cannot be significantly increased without the potential for erosion in the tubes.

Having obtained the total cooling water flow, the cooling water flow per unit output (gpm/kW) factor is calculated by dividing the steam turbine output (kW) into the total cooling water flow (gpm). Following this procedure, a cooling water flow per unit output factor is calculated for each representative heat balance.

3.3 Verification of Condenser Pressure (Turbine Backpressure)

Condenser pressure is likely to increase when converting a generating unit from a once-through system to a wet cooling tower application. This will likely result in a concomitant reduction in output. WGI set a limit on condenser pressure of four inches of mercury absolute (4.00 in. HgA) as a result of a conversion. Pressures above this limit might preclude reuse of an existing steam turbine or result in additional cost due to an increased surface area in the cooling tower.

Figure 9.5.2 1 in Mark's Standard Handbook for Mechanical Engineers, Tenth Edition, is a map of the US with wet bulb isolines for a five percent level of annual cumulative frequency of occurrence. This figure was used to determine the highest ambient wet bulb temperature in the country of 80°F, which occurs in Louisiana. To this maximum ambient wet bulb WGI added a 1°F increase to account for recirculation from the cooling tower fan discharge to the air inlet. We then selected an approach of 7°F, which along with the temperature rise of 12°F and an 81°F wet bulb, produces a cooling tower Rating Factor of 1.0. (The Rating Factor comes from a technical report, Managing Waste Heat with the Water Cooling Tower, 3rd Edition by the Marley Cooling Tower Company.)

Adding the range of 7°F, the rise of 12°F and 8°F for the Terminal Temperature Difference (TTD) across the condenser to the wet bulb temperature of 81°F, we estimated the condenser saturation temperature at 108°F. This saturation temperature yields an corresponding saturation pressure of 2.45in.HgA. Since this saturation pressure is produced at the highest ambient wet bulb in the US and is below the 4.0 in. HgA limit established above, we can conclude that a cooling tower in any US location with a rating factor of 1.0 will result in an acceptable condenser pressure.

3.4 Estimation of Cost per Unit Cooling Water Flow

A cost estimate was developed for a simplified scheme associated with each thermal cycle/steam conditions grouping. Each scheme included circulating water pipes, mechanical draft cooling tower, circulating water pumps, and all make-up and circulating water treatment systems. The cost estimate did not include the condenser, since it was assumed that the existing condenser would be reused. Each scheme had a different circulating water pipe diameter, varying from three feet to ten feet. All schemes use the same temperature rise of 12°F, and a pipe velocity of 9 ft/sec. Capacity of the schemes ranged from approximately 29,000 gpm for the scheme with a three-foot pipe to 317,000 gpm, for the scheme with a ten-foot pipe. This range of cooling tower flows was large enough to be cover most power plants considered in this study with some extrapolation for the largest plants.

Separate cost estimates were developed for each scheme using saline water and fresh water as make-up. From these cost data for saline and fresh water, WGI fit two exponential curves by plotting cost per unit cooling water flow versus cooling water flow.

Assumptions used in developing costs are given below:

Cooling Tower Structure Costs: The structure costs represent the scope typically quoted by a cooling tower vendor, and include fans/motors/gearboxes, fill, distribution headers, etc., and field erection costs. Structure costs assume a fiberglass mechanical draft tower with standard noise and drift abatement and no plume abatement. These costs were estimated by scaling cooling tower costs provided by cooling tower vendors for fresh water make-up cooling towers. Costs were determined by using a constant US dollar per tower unit ($/TU) cost and multiplying it by the number of tower units (TU). (A tower unit is a measurement to the Marley Cooling Tower Company method in the technical paper cited above.) The number of tower units for a particular application is obtained by multiplying the cooling water flow in gpm by the cooling tower Ratin Factor. As explained above, WGI has set the Rating Factor equal to 1.0 for all freshwater units.

WGI determined costs for saline make-up towers by making two adjustments to freshwater tower costs. First, we increased the number of tower units by to account for the lower cooling tower efficiency when cooling with saline water. Then, the costs (based on the higher tower units) were increased to account for the changes in materials required due to the higher salinity of the cooling water.

Cooling Tower Basin Costs: Cooling tower basin costs are essentially proportional to the cubic yards of concrete in the basin and circulating water pump pit. As it would be difficult to estimate the sizes of these structures for every plant in the report database, we have multiplied the cooling water flow in gpm by a cost factor to obtain an all-in-one cost for the cooling tower basin. This cost factor is based on costs developed for some recent projects with large cooling tower basins and has been normalized to the same scheme considerations as other cost factors developed for this report. The same cost factor will be used for both fresh and saline make-up units.

Circulating Water Pump Costs: Circulating Water Pump costs have been calculating as a function of pump brake horsepower (BHP). When calculating BHP, it was assumed all pumps would impart 70 feet of total head at an efficiency of 75%. Different cost factors have been used for saline and fresh water pumps due to the need for more corrosion resistant materials in saline applications. The cost per unit brake horsepower ($/BHP) factor was based on qoutes from a pump vendor. When calculating the total cost of pumps for a generating unit, WGI assumed two (2) 50% capacity pumps at lower flow rates and three (3) to six (6) pumps at higher flow rates. No spare capacity was included for any pumps.

Circulating Water Pipe Costs : Costs for circulating water piping were based on "all-in" costs, which include pipe, excavation in average soil and application of an engineered backfill. Based on WGI experience, a constant cost per diamater (ft) per linear foot (lf), US$/(ft-lf), facor was developed. This factor was found to be constant across a wide range of pipe diameters. Pipe costs were calculated assuming 500 linear feet of pipe in each direction, suply and return. This total length of 1000 linear feet is higher than typically seen in new construction projects, but was considered justified since the cooling towers will most likely be located at a larger distance from the condenser in these retrofit applications. The developed costs also considered the riser piping and distrubition header alongside each tower.

Make-up Water Treatment System: Both fresh and seawater are assumed to require clarification before entering the heat cycle. These costs are awwumed proportional to make-up water flow in gpm, with the cost factor for saline clarifiers higher than the cost factor for freshwater clarifiers. Make-up water quantity is a function of cooling water flow, range and cycles of concentration. When calculating make-up flow, two cycles of concentration have been used for saline systems and five cycles of concentration for fresh water systems.

Circulating Water Chemical Treatment System: This system includes all equipment needed to inject chemicals into the circulating water system for chlorination and de-chlorination. No allowance has been included for any existing systems. The chemical feed system cost is assumed to be constant for all plants since this equipment tends to be relatively constant from plant to plant due to the small quantities of chemicals injected.

Make-up Water Pump Costs: Costs for Make-up Water Pumps are also a function of pump brake horsepower (BHP). BHP for all pumps was calculated assuming a total head of 75ft and pump efficiency of 75%. WGI assumed two 100% capacity pumps were installed for each unit. Since the horsepower of the pumps vary over a narrow range, WGI have used a constant cost per unit brake horsepower ($/BHP) factor based on our experience. Similarly, a constant, but higher, factor was also applied for saline make-up service.

Electrical costs: Electrical costs have been assumed to be a fixed fraction of mechanical and civil costs, based on WGI experience in constructing power plants and in estimating costs.

Additional Cost Multipliers: Additional project costs were accounted for by assuming that they are proportional to installed equipment costs, i.e., direct construction costs. Indirect construction costs include costs for mobilization and other miscellaneous field costs. Engineering, construction management, and startup costs were lumped into another multiplier as was construction interest, a contingency and fees.

Cost factors used in this report are summarized in the table below.

Table 1: Cost Factors
[see hard copy for table]

3.5 Grouping of Units in Report Database

The four categories in the report database described above (saline/nuclear, freshwater/nuclear, saline/fossil and freshwater/fossil) were each further sorted into reheat and non-reheat units. Each of the resulting lists were then sorted by steam turbine throttle pressure, throttle temperature, and size (output). At this point, all of the units can be grouped around the representative heat balances described in Section 3.1 above. WGI then assigned the cooling water flow per unit output ($/kW) cost factor developed for each representative heat balance to all the units in a particular grouping.

3.6 Calculation of Retrofit Costs

Four columns were added to the database. The first contains the cooling water flow per unit output (gpm/kW) factor. The second contains total cooling water flow (gpm), calculated by multiplying the gpm/kW factor by the steam turbine output (kW). The third column is cost per unit cooling water flow ($/gpm), an exponential function of cooling water flow. The last column contains the total cost of the cooling tower retrofit.

4.0 Plant Groupings with Estimated Cooling Tower Retrofit Costs

The complete listings of the plants in each of the grouping requested, namely

Nuclear Fueled
-Once Through Using Sea/Brackish Water
-Once Through Using Fresh Water

Fossil Fueled
-Once Through Using Sea/Brackish Water
-Once Through Using Fresh Water

Are included in Appendices A through D to this report.

Question 21
EBA Chapter C3
Table C3-3

Please provide a spreadsheet that lists all in-scope facilities; and for each in-scope facility that did not claim operational flow was CBI, lists: (1) the operational flow (used to compute the flow index for the facility), (2) the flow index value and (3) the waterbody type of the facility.

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

For its regional extrapolations, EPA used the average annual operating flow as provided in response to EPA's survey of the industry. The survey ("Section 316(b) Survey Questionnaire Database") is DCN# 4-0016D, which is CBI, so we cannot provide the requested flow information to the commenter.

Question 22
EBA Chapter C3
Page C3-2

EPA stated that: "Since this flow index is a value between 0 and 1, dividing the baseline loss at the case study site by the flow index yields an estimate of the total baseline loss at all facilities drawing cooling from the same type of waterbody." However, the baseline loss estimate for Salem (Table C3-3) divided by the Salem flow index (Table C3-1) does not produce the total baseline loss estimate (Table C3-3) for the Estuary – Non Gulf waterbody type. Please provide an explanation for this discrepancy.

EPA's response does not answer the question. EPA's response discusses derivation of values for the Pittsburg and Contra Costa plants, rather than the problems with the Salem data that we raise in this comment.

EPA Response

This question refers to the loss and benefits estimates presented in the analysis for the proposed rule. EPA did not extrapolate loss and benefit estimates for Contra Costa and Pittsburgh at proposal. The loss estimates for these facilities were included directly in the analysis.

For the final rule, EPA estimated I&E losses and benefits for all facilities in Northern California. Thus, no extrapolation was needed for Pittsburgh or Contra Costa in the final analysis.

Please refer to EPA's response to comment 316bEFR.041.041 for a further discussion of issues related to extrapolation.

Question 23
EBA Chapter C3
Table C3-3

Please provide complete documentation (including equations and assumptions) for EPA's method of estimating national baseline losses based on its flow index.

EPA's response does not answer the question. As EPA knows, DCN4-2070 and DCN4-2213 are listed as being contained in the CBI docket and therefore are unavailable to UWAG. DCN4-2212 is a spreadsheet that apparently is unusable without a link to the CBI docket.

EPA Response

In the cost-benefit analysis for the final 316(b) Phase II rule, baseline losses are extrapolated (by flow) to estimate losses at facilities for which EPA did not have I&E data:

(total loss estimate at facilities with data / % of flow at facilities without data) * (% of flow at facilities without data)

Note that this is mathematically equivalent to:

(total loss estimate at facilities with data / flow at facilities with data) * (flow at flow at facilities without data)

This value was summed with the estimated losses at facilities with data to calculate the total for the region.

A very similar method was used at proposal, but the extrapolation was done by waterbody type rather than by region. EPA also based the final regional extrapolation on many additional facilities (a total of 46). See also Chapter A10 of the Regional Analysis Document (DCN #6-0003) concerning EPA's commercial fishing benefits methods.

Question 5

We request an explanation of the procedure of estimating commercial fishing losses based on the cited communications and studies.

EPA's response does not answer the question, because it (1) offers no analysis of the papers cited to show how they support the conclusions EPA has drawn, and (2) continues to rely on an unpublished paper by Bishop (2002). Both of these points go to the crux of the question posed.

EPA Response

The Bishop (2002) paper is no longer used in the cost-benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on commercial fishing, please refer to the response to 316bEFR.005.029.

For details on the revised methods used to estimate commercial fishing losses and benefits, please refer to the regional study document for the final rule. See especially Chapter A10: Methods for Estimating Commercial Fishing Benefits (DCN #6-0003).

Question 9

We request an explanation of how the use of ranges obviates the need to perform sensitivity analyses on key assumptions/estimates.

EPA's response does not answer the question and, if anything, suggests that EPA's analysis lacks any credible statistical foundation.

EPA Response

The most important part of the cost-benefit analysis is the I&E modeling because this clearly drives the results for the evaluation of commercial, recreational, and nonuse benefits. Please refer to Chapter A6 of Part A of the Phase II Regional Study Document (DCN #6-0003) for a discussion of uncertainty in relation to EPA's analysis of I&E for the analysis of the final rule.

For the final rule, the commercial and recreational benefits comprise a relatively small portion of the total benefits of the rule. Thus, ranges of the values should be sufficient to convey uncertainty. Additional analyses will offer little new information. Several basic sensitivity analyses were prepared for the various non-use valuation methods. Please refer to Part A of the Phase II Regional Study Document (DCN #6-0003). See especially chapters A9, A12, and A13.

Delaware

Question 10

With regard to the electronic files for the Delaware Case Study (DCN 4-1000 to DCN 4-1042), DCN 4-1000 lists the set of SAS/LIMDEP/ArcView programs and datasets used to generate RUM models and recreational benefits. Please provide all program files in a text file format rather than a portable document format (PDF). Please provide all SAS datasets as uncompressed files, not export files. In addition, please provide the LIMDEP dataset, cst.res3.dta as an uncompressed SAS dataset.

EPA's response partially answers the question. However, due to poor documentation of the programs, it is difficult to follow their rationale for making certain assumptions.

EPA Response

EPA disagrees that its programs and files are poorly documented. First, the Agency followed standard docket compilation procedures that govern how background and supporting materials should be provided to the public docket. EPA is not required to include data files in the formats other than those used in the analysis in the docket. For EPA's rationale for making various assumptions see Chapter B5 of the Cooling Water Intake Structures - Section 316(b)
Proposed Section 316(b) Phase II Existing Facilities Rule Case Study Analysis document (DCN #4-0003).

In addition, EPA no longer uses case studies of individual facilities for the final Section 316(b) regulation.

Question 11

With regard to the electronic files for the Florida Case Study (DCN 4-1100 to DCN 4-1124), DCN 4-l110 lists the set of SAS/LIMDEP/ArcView programs and datasets used to generate RUM models and recreational benefits. Please provide all program files in a text file format rather than a portable document format (PDF). Please provide all SAS datasets as uncompressed files, not export files. In addition, please provide the LIMDEP datasets brum.dat and btrips.dat as uncompressed SAS datasets.

EPA's response partially answers the question. However, due to poor documentation of the programs, it is difficult to follow the Agency's rationale for making certain assumptions.

EPA Response

EPA disagrees that its programs and files are poorly documented. First, the Agency followed standard docket compilation procedures that govern how background and supporting materials should be provided to the public docket. EPA is not required to include data files in the formats other than those used in the analysis in the docket. For EPA's rationale for making various assumptions see Chapter D5 of the Cooling Water Intake Structures - Section 316(b)
Proposed Section 316(b) Phase II Existing Facilities Rule Case Study Analysis document (DCN #4-0003).

In addition, EPA no longer uses case studies of individual facilities for the final Section 316(b) regulation.

Question 13

What evidence indicates that impingement and entrainment (I&E) data from the 1970's are relevant for 2000? Were any adjustments made to reflect the differences in the number of turbines that were operating in the late 70's versus the late 90's at each of the case study sites?

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

EPA was constrained in its analysis by the available I&E monitoring data provided by facilities, much of which is over 30 years old, as noted by the commenter. However, EPA did adjust historical I&E data to reflect any technology to reduce I&E that may have been implemented subsequent to the collection of the original I&E data.

Revealed preference

Question 16

The estimated dollars spent on the CALFED Bay-Delta program to protect threatened and endangered (T&E) species was used to estimate society's value of a T&E fish in the San Francisco Bay/Delta case study.
A) What T&E species does this plan propose to protect?
B) Were any adjustments made to reflect the value of only those species that are in fact threatened and endangered near the power plants?
C) How were the ratios of program costs determined for each program element?
D) What is the evidence that this ratio is constant among program elements?

A) EPA's response answers the question.
B) EPA's response answers the question.
C) EPA's response answers the question.
D) EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

The Societal Revealed Preference (SRP) method for estimating non-use benefits, which relies on CALFED information, is not used in the cost-benefit analysis for the final Section 316(b) Phase II rule. Therefore, the issue is now moot.

Organization obo Utility Water Act Group

Subject Matter Code 10.02.06.02

Revealed preference

Question 17

What evidence suggests that the value of foregone water use is a proxy for society's value of T&E fish?

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

The societal revealed preference (SRP) approach is no longer applied by EPA in this rulemaking, and so no longer is used to gain insight on the potential benefits of the 316b regulations. Further discussion on the SRP is provided under response to comment #316bEFR.005.006. In response to the specific question posed, the water uses are foregone because that is the action taken in order to preserve the Bay Delta ecosystem and associated special status fish. The water uses are foregone because society has opted instead to preserve the fish species, hence the value of uses foregone may be indicative of the value of the resources protected by that choice.

Question 19

Electronic files for Economics Analysis: DCN 4-3024 to DCN 4-3043; DCN 4-3050 to DCN 4-3059; DCN 4-3070 to DCN 4-3076 DCN 4-3000 lists the documents and data used to conduct the Economics Analysis. Please provide above listed files in SAS (Version 8.0 for PCs) file format rather than a portable document format (PDF).

EPA's response does not answer the question. As EPA knows, many of these files are unusable due to CBI material that is not enclosed and therefore unavailable to UWAG.

EPA Response

A CD of electronic files that do not contain confidential business information or otherwise sensitive data was prepared and made available to the commenter in June 2002. EPA conducted the economic analyses in Excel, not in SAS. Therefore, the files were provided in Excel format. The CD contained the following files: 4-3008, 4-3027, 4-4042, 4-4043, 4-3052, and 4-4053. The public record for this rule contains a considerable amount of data and information as well as a discussion of EPA's rationales, assumptions and methodologies. EPA believes the public record was sufficient to provide the public with a meaningful opportunity to comment upon this rule. All other economic analysis files contain confidential business information or otherwise sensitive data and cannot legally be made available to the public.

Mkt-level impacts/Reliability/EO 13211: Energy Effects

Question 1

What energy penalty input, if any, was used with IPM 2000? Does IPM 2000 account for seasonal variability in energy penalties? The model should account for the normally higher energy penalties during peak load periods (i.e., usually summer, but in some areas winter) and associated differences in pricing. If the model doesn't capture seasonal increases in the energy penalty, which tend to co-occur with seasonal spikes in demand and price, then it is inadequate for capturing revenue effects, effects on reliability, and likely plant closures.

EPA's response answers the questions, essentially conceding that its analysis of mean annual energy penalty values does not account for seasonal variations in unit efficiency associated with different ambient conditions that increase turbine backpressure and, affect energy availability and cost.

EPA Response

First, EPA notes that the final Phase II rule does not require installation of technologies that would lead to energy penalties at complying facilities, as would have been the case if EPA had chosen to base today's rule on closed-circuit cooling. As a result, any changes to the energy penalty analysis has no effect on EPA's analysis for the final Phase II rule. Still, in response to comments on the proposed rule, EPA modified its energy penalty assumptions for the energy market model runs conducted for the Notice of Data Availability (NODA). For the proposed Phase II rule, the average annual energy penalty, by region and fuel type, was applied to each facility upgrading to a closed-cycle, recirculating cooling system. Based on comments received, for the NODA analyses, EPA changed the energy penalty assumption to attempt to account for seasonal, peak effects. For the NODA analyses, the energy penalty applied was the greater of (1) the peak-summer penalty or (2) the average annual penalty, for each facility projected to convert its cooling system to a closed-cycle, recirculating cooling system. EPA agrees that the approach used at proposal might have understated potential impacts of the energy penalty on generating capacity. EPA revised its approach for the NODA analyses to ensure that impacts are not underestimated (see also Notice of Data Availability, 68 FR 13525).

Extrapolation of Case Study Ben. to National Level

Question 2

Why did EPA select the facilities it did for purposes of doing the national extrapolation by waterbody type? In other words, why did it use some (e.g., Salem and Pilgrim) and leave some others for the same waterbody type?

EPA's response partially answers the question but does not discuss what attributes of the data it did not use led it to conclude that that data was less reliable than the chosen data, and also what attributes its chosen data (other than the Salem data, which it discusses) make that data the most reliable.

EPA Response

This comment refers to the sample of facilities examined for proposal. For its final analysis, EPA based its regional extrapolations on all of the many facilities evaluated in each region. In the case of California, this included all facilities with I&E data. In all, a total of 46 facilities were evaluated and used as the basis for estimating the relative magnitude of I&E at Phase 2 facilities.

EPA notes that most of the facilities in scope of the rule have not conducted I&E studies. The facility studies that are available, have many limitations. Facility studies generally include only 1 or 2 years of data collected nearly 30 years ago, when aquatic conditions and species abundances may have been substantially different from what they are today. Moreover, I&E rates are usually estimated for only a subset of the species impinged and entrained, and therefore underestimate total losses.

Although EPA recognizes these limitations, EPA had no alternative but to use available data, given the effort that would be required to conduct original studies to obtain less uncertain and more current data, including the need for multiple years of intensive monitoring of hundreds of species at representative facilities throughout the country.

To address data limitations, EPA expended considerable effort to obtain the most complete and highest quality I&E data available for representative facilities in each region. In addition, EPA made adjustments to older data, as needed, to reflect reductions in I&E rates that may have occurred as a result of technology implementation that occurred after the old studies were conducted.

Please see response to Comment 316bEFR.072.055 for a discussion of the size and represenativeness of the sample of facilities used in EPA's analysis for the final rule.

Monroe

Question 1

Tables I4-2 and I4-3: The data in the column titled Total Catch (#) appear to be harvestable catch data, but no explanation or reference is given as to the source of the data.

EPA's response does not answer the question. The question asks for references to support the recreational or commercial catch or harvest figures presented in the tables we reference. EPA's answer merely sends the reader back to the chapter in this case study which discusses how entrainment and impingement losses are estimated. That chapter does not address the issue raised. UWAG hereby requests that EPA provide references for all of the data catch, yield, and other data presented in Tables I4-2 and I4-3, as well as all other analogous tables presented in any of the other case studies.

EPA Response

In tables I4-2 and I4-3, all of the values are estimated losses due to impingement (I4-2) or entrainment (I4-3). None of the values reported in these tables come from a document that can be referenced. The estimates were developed using the methods described in Part A of the Case Study document (DCN #4-0003).

The columns are all estimates and are defined as follows. Impingement Count (#) is the total number of organisms lost. Age 1 Equivalents (#) is the number of organisms lost, translated into Age 1 fish as described in Part A of the Case Study document. Total Catch (#) is the total number of Age 1 fish that are lost to harvest by commercial and recreational fishermen. Commercial Catch (#) and Recreational Catch (#) are the number of fish lost to the commercial fishery and the recreational fishery, respectively. Total Yield (lb), Commercial Yield (lb), and Recreational Yield (lb) are the lost harvest estimates expressed in pounds instead of numbers of Age 1 fish.

Subject Matter Code 10.03.07.02

Monroe

Question 2

Table I4-11: identify actual references in AFS (1993) from which came the "Hatchery costs ($/lb)". Addendum: I also need to know where the EPA got the poundages for the three species that were multiplied times the hatchery costs to get the annual replacement costs.

EPA's response does not answer the question. DTE requested references to specific sections of the AFS tables that support the hatchery costs EPA has used. EPA's discussion of the sources of the AFS values is not responsive.

EPA Response

Hatchery costs per pound are calculated from Appendix 3 in AFS (1993, DCN #4-1302) in two steps. First, EPA calculated the average replacement cost in per pound, in 1990 dollars, across all fish size categories. Second, EPA used the Consumer Price Index to convert the 1990 costs to 2000 costs.

The weight of an Age 1 equivalent for each fish species is estimated by EPA as part of the I&E model, as described in Chapter A5 of the case study document (DCN #6-0003).

In the cost-benefit analyses for the NODA and the final rule, EPA no longer uses hatchery costs to estimate impacts on forage species. Instead EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule. See Chapter A5: Methods Used to Evaluate I&E (DCN #6-0003)

Comment ID 316bEFR.041.826

Author Name Hunton & Williams

Organization obo Utility Water Act Group

Subject Matter Code 10.03.07.02

Monroe

Question 3

Table I4-12: explain how this table was compiled, in particular, how the annual loss values were apportioned/calculated for each species. For example, how were the $673,405 and $1,133,734 low and high values, respectively, for whitefish derived?

This response simply restates what was already in the text of the Monroe facility case study, which simply referred the reader to Chapter A5. No explanation was provided in either Chapter I4 or Chapter A5 as to how the (three) forage species were allocated and values derived among the (fourteen) commercially and/or recreationally harvested species nor was an explanation provided in EPA's response to this question.

EPA Response

The material from this preliminary case study is not used in the final analysis. Generally, the values are generated in two steps.

1) A trophic transfer model is used to translate lost forage fish into lost fishery yield, as described in Chapter A5 (DCN #4-0003). In this case the forage losses reported in Table I4-9 are translated into lost yield of the commercially and recreationally caught species indicated in Table I4-12.

2) This lost yield is valued based on the commercial and recreational methods described in Chapter A9 (DCN #4-0003). The high and low estimates are a result of the

For the cost-benefit analysis for the final Section 316(b) Phase II rule, EPA applied a similar but slightly different methodology for estimating the value of lost forage fish. EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. These lost yields are then valued in the commercial analysis assuming the average value per pound for commercially harvested fish in the region. In the recreational analysis, the lost yields are included in the RUM analysis.

In the documents for the final Section 316(b) Phase II rule, improved documentation is provided on EPA's estimation of the value of forage losses. See the regional study document, Chapter A5: Methods Used to Evaluate I&E, especially Section A5-4.4 Evaluation of Forage Species Losses (DCN #6-0003).

Also of note - EPA no longer uses hatchery costs to estimate the value of lost forage species.

Question 4

Is implementation and verification of the HRC methodology, particularly the "streamlined" version, practical? Combining steps 2 – 4 and limiting the data gathering raises some real concerns about the credibility of, essentially, an unproven methodology.

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

EPA did not use the HRC method for the estimation of benefits for the final Phase II rule. For additional information on the method, please refer to the document entitled "The Habitat-based Replacement Cost Method" (DCN #6-1003) and EPA's response to Comment 316bEFR.005.035.

San Francisco Bay Delta

Question 1

Chapter E3, pages E3-11 to E3-16 -- Why does Stratus use 1978-1979 I&E monitoring data and average it with the 1987-1990 I&E monitoring data? The 1978-1979 data pre-dates the BTA program that Pittsburg and Contra Costa have implemented (see discussion on Pages E2-5 and E2-6). Averaging I&E losses from this earlier monitoring period inflates fish losses and economic benefits, and does not accurately reflect current conditions. Mirant suggests that only the 1987-1990 monitoring data be used for this case study.

EPA's response does not answer the question. Mirant asked EPA to explain why it chose to use pre-BTA I&E data from Mirant's two Delta Estuary plants, when those data were collected beginning back in the late 1970's before I&E reduction benefits of BTA were in place. This appears inconsistent with EPA's claim that it attempted to characterize I&E after application of any current technologies.

EPA Response

I&E rates for the Pittsburg and Contra Costa facilities were revised as suggested by the commenter.

Comment ID 316bEFR.041.829

Subject Matter Code 10.03.04

San Francisco Bay Delta

Question 7

Chapter E4, Table E4-1 - In place of the Huppert-based reported striped bass value range of $9.14 to $14.14 per fish, Mirant believes that the mitigation costs identified in Mirant's Striped Bass agreement with the CA Department of Fish & Game would be a more accurate replacement value for stripped bass. This value is currently less than $2.00 per striped bass yearling.

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

In the analysis for the final rule EPA no longer uses a benefits transfer approach to estimating the recreational benefits of the Section 316(b) Phase II rule. Instead, a set of random utility models (RUM) have been estimated. For details on EPA's methods used in the RUM analyses, please refer to the regional study document for the final rule (DCN #6-0003). See especially Chapter A11: Estimating Benefits with a Random Utility Model (RUM) and the recreational chapter for each region (B4, C4, etc).

Ecosystem/Food Web Modeling

Question 10

EPA case study analysis for proposed section 316(b) phase II existing facilities rule, Part A, page A6-6 has this paragraph.
Competition and predation can interact in complex ways with other sources of mortality to alter stock-recruitment relationships. For example, a model of trophic dynamics among fish populations in the Patuxent River that are subject to harvesting as well as CWIS impacts predicted a significant reduction (over 25%) in striped bass, bluefish, and weakfish production as a result of power plant losses of preferred prey species such as bay anchovy and silversides (Summers, 1989). Thus, CWIS losses can contribute to reduced overall ecosystem productivity, irrespective of any potential compensation in populations directly affected by CWIS mortality (Boreman, 2000). The estimate of over 25% reduction in game fish was based on an early estimate of up to 76% population losses for bay anchovy that was superseded by further extensive studies conducted by Pepco (Bailey et al. 1999 Proceedings of the EPRI Coolfont Workshop). Following these studies Maryland Power Plant Siting Program reduced its estimate of bay anchovy losses to 10 – 20% PPERD (1990). There was no additional modeling done to determine how estimate game fish production losses would be affected by the lower estimates of bay anchovy loss but it is safe to assume that these estimates would be substantially reduced as well. [Excerpt from Bailey et al. omitted]

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

The version referred to by the commenter of Chapter A6 of the Case Study Document (DCN #4-0003) presented at proposal is not included in EPA's Regional Analysis Document (DCN # 6-0003) in support of the final rule. However, EPA notes that (1) the differing estimates of population impacts noted by the commenter illustrate EPA's position that much greater uncertainties in estimates occur when estimating fishery populations than I&E numbers, and (2) reductions in forage species due to I&E can result in significant reductions in populations of highly valued fishery species.

Commercial Fishing Benefits

Question 5

Could you provide the details behind the derivation of the same 22.2% value in Holt and Bishop 2002?

EPA's response does not answer the question, because it (1) offers no analysis of the papers cited to show how they support the conclusions EPA has drawn, and (2) continues to rely on an unpublished paper by Bishop (2002). Both of these points go to the crux of the question posed.

EPA Response

The 22.2% value was calculated in research by Bishop and Holt. At the time of the proposed rule, their research was not published. An article on this research has since been published as:

Bishop, R. and M. Holt. 2002. A semiflexible normalized quadratic inverse demand system: an application to the price formation of fish Empirical Economics, 2002, vol. 27, issue 1, pages 23-47.

Regardless, the 22.2% is not used in the cost-benefit analysis for the final Section 316(b) Phase II Rule.

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment 316bEFR.005.029.

Subject Matter Code 10.02.02

Commercial Fishing Benefits

Question 6

Could you confirm that the reference to Bishop, personal communication 2002 (below) includes only the following paragraph and does not contain the derivation of the empirical estimate of 22.2%?
PERSONAL COMMUNICATION-PHONE AND E-MAIL CONVERSATION
From: Richard Bishop, Professor of Agricultural Economics, University of Wisconsin

EPA's response does not answer the question. The document to which EPA's answer refers does not confirm or discuss the full extent of the personal communication with Dr. Bishop.

To: Bob Raucher, Stratus Consulting
Date: February, 2002
RE: Total economic surplus associated with commercial fishery landings
Asked about and discussed/confirmed proper interpretation of several papers authored by Dr. Bishop, including a litigation support document ("Economic Implications of Treaty Fishing in Michigan, July 19, 2000) that was not formally available for citation. Discussion revolved around how (and by how much) a change in commercial fishery landings created a total economic benefit that embraced surplus measures for fishermen, wholesalers, retailers, suppliers, and consumers. Confirmed that we had interpreted the empirical evidence correctly, and that the citations were to the proper public documents.

EPA Response

The 22.2% value was calculated in research by Bishop and Holt. At the time of the proposed rule, their research was not published. An article on this research has since been published as:

Bishop, R. and M. Holt. 2002. A semiflexible normalized quadratic inverse demand system: an application to the price formation of fish Empirical Economics, 2002, vol. 27, issue 1, pages 23-47.

The 22.2% is not used in the cost-benefit analysis for the final Section 316(b) Phase II Rule.

For EPA's response to comments on the methods used to estimate commercial fishing losses and benefits please see the response to comment 316bEFR.005.029.

RFC: Entrainment vs. entrainment mortality

Question 6

Although I understand that there are some issues with the way data was collected or handled in some of the case studies of I&E effects, I think it is probably not valid to assume 100% mortality all the time. Clearly, in some situations and with some species, survival occurs for early life stages of fish (e.g. bay anchovy eggs – 50% {A7-9}, striped bass larvae – 76-79%, winter flounder of 10-97%, etc. as cited in the case studies). I would suggest that perhaps what is needed is a "bounding" exercise where the model is run with some acceptable levels of survival of different life stages and this run be used as a bound on the impacts (with 100% mortality as is now assumed as the upper bound). This will give us a more reasonable range of values in which to evaluate impacts in the case studies.

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

Please see the response to comment 316bEFR.306.506 for the discussion regarding EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule.

RFC: Entrainment vs. entrainment mortality

Question 7

B3-28. The assumption that blue crabs are all killed when entrained is likely a severe overestimate.

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

EPA did not review any studies that specifically analyzed the entrainment survival of blue crabs. The Anclote studied crab larvae but the species of crab was unclear. Please see the response to comment 316bEFR.306.506 for the discussion regarding EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule.

Question 1

We are still having difficulty opening some of the files on the case study CD, specifically for the Delaware Case Study. The ZIP files give an error message when we try to open them. The BDAT, SD2, IN, OUT, and XPT files cannot be opened. What programs do they use? Tables are not well-defined (specifically the uos table in folder 4-1022).

These referenced datasets do not appear to be in ASCII format. We are still having difficulty opening and/or converting these files.

EPA Response

EPA has made every effort to provide assistance to the public to access and understand data used to support today's final rule.

Comment ID 316bEFR.041.840

Organization obo Utility Water Act Group

Subject Matter Code 10.03.01

Delaware

Question 2

How is the Hay Road facility having an effect on the DE estuary? Based on the CSA, EPA is assuming and including Hay Road in mean annual data charts, when the facility does not have the ability or structures to directly intake surface water from the source.

In EPA's response, EPA refers to a 1996 DRBC document. This document could not be located on the Agency's website. The intake water for the Hay Road facility's circulating water system as well as the fire suppression system is withdrawn from the Edge Moor Power Plant (an in-scope facility for the Case Study) discharge canal. In essence, the water is recycled. Hay Road does not have the capability nor structures to impinge or entrain aquatic life.

EPA has considered, in their Case Study Analysis for the Delaware Estuary, the Hay Road facility in The Evaluation of I&E Data (Chapter B-3), The Economic Value of I&E Losses Based on Benefits Transfer Techniques (Chapter B-4), and in The RUM Analysis (Chapter B-5).

EPA Response

EPA agrees with the commenter that Hay Road is not in scope of the Phase 2 rule. The Hay Road facility was not part of EPA's mid-Atlantic analysis for the final rule (DCN #6-0003).

The document cited by the commenter is in the docket (DCN # 4-1474) and is available on the web. The full citation is DRBC, 1996. 1996 Delaware River Withdrawal and Consumptive Use Estimates (Tidal Estuary Portion). http://www.state.nj.us/drbc/withdrawals96.htm

Commercial Fishing Benefits

Question 2

The assumed carrying capacity of the water body is not identified when discussing entrainment and impingement impacts.

EPA's response technically answers the question but does not deal with the issue. We believe that in a discussion during the teleconference call the question was rephrased as follows: How were the upper limits of the model set to prevent gross overestimates of potential fisheries production? We recall the answer as being that the economic model was used to set upper limits based on catch value relating to a particular base year. Can this be clarified?

EPA Response

In the modeling for the cost-benefit analysis for the final Section 316(b) Phase II rule, EPA did not use the economic model to set upper limits based on catch value. No upper bound limits were set in the model.

Instead, EPA compared results from the I&E model to actual fishery harvest levels - for recreational and commercial fishing - from the 1990s and early 2000s to ensure that the results are not gross overestimates of potential fisheries production. Overall, as reported in the regional study document for the final rule, the predicted increases in harvest are a very small portion of the total recreational and commercial harvest in each region of the analysis. See section XII.D of the preamble for the final rule and regional analysis document (DCN #6-0003) for discussion of projected increases in harvest.

Question 4

Estimates of annual operating capacity in the text do not comport with the proportions of annual average intake flow to design flow given in Table D1-2.

EPA's response does not answer the question. UWAG hereby raises the question for the public record.

EPA Response

The intake flow data used in EPA's I&E analyses were average annual operating flows obtained through EPA's survey of the industry. Background chapters and other materials may include flow information from other sources, but these are provided to provide general background only. To the extent that there are any conflicts, EPA intends for the survey data to be used.

Case Study Specific Comments

Question 5

How can there be no estimate of error levels or confidence intervals? The lack of such implies that the model output may be unreliable and contain vast errors.

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record. We believe this was a valid question, but we rephrase the question as follows: What are the estimates for error levels (variance, confidence intervals) for fisheries foregone and economic benefits? Impingement and entrainment are shown with means and standard deviations in Tables D3-2 to D3-9. The mean and standard deviation should also be shown in subsequent tables, e.g., the estimates of fisheries foregone and economic benefits.

EPA Response

The lack of confidence intervals in EPA's results does not, as the commenter maintains, imply that the results are unreliable or incorrect. Rather, the lack of confidence intervals reflects the lack of information in facility documents on the variance in facility estimates of I&E. In many cases only 1 or 2 years of annual estimates are presented. Moreover, given the complexity of EPA's analysis, involving I&E data from 46 facilities, dozens of species, and hundreds of life history values, a formal, quantitative characterization of uncertainty would be a large undertaking in and of itself. Please see Chapter A6 of Part A of the Phase II Regional Analysis Document (DCN #6-0003) for a discussion of uncertainty in the context of EPA's analysis. This chapter also provides an example Monte Carlo analysis exploring uncertainty associated with foregone yield estimates. The example illustrates the high level of effort involved with conducting such an analysis for only one type of loss (entrainment) for one metric (foregone yield) for one species at one facility.

Question 6
Can any of the model conclusions can be tested or measured in any manner?

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record. We feel the following was a valid question: Can any of the model conclusions be tested or measured in any manner? Or rephrased as "Can the model be validated with any existing data?"

EPA Response

In response to the commenter's question about model validation, EPA's estimates of age 1 equivalent losses, foregone yield, and production foregone could be compared to estimates from similar time periods for similar species and for facilities with similar characteristics and similar monitoring programs, to the extent such data are available.

Case Study Specific Comments

Question 7

How can the success of regulatory action be evaluated if the model cannot be tested and if there is no estimate of the variance of the parameters?

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

The purpose of EPA's benefits analysis was to develop the best estimate possible, given the data available, of national impingement and entrainment losses, the costs of reducing these losses, and the economic benefits to be expected nationwide as a result of reductions in I&E.

EPA believes its analysis was reasonable given the data available and the goals of the ecological analysis. EPA's evaluation of I&E data had four main objectives (1) to develop a national estimate of the magnitude of I&E, (2)to standardize I&E rates using common biological metrics so that rates could be compared across species, years, facilities, and geographical regions, (3)to estimate changes in these metrics as a result of projected reductions in I&E under the Phase II rule, and (4) to estimate the national economic benefits of reduced I&E.

EPA's predictions can be tested if and when reliable data are available on actual I&E reductions resulting from the rule's implementation.

Question 8

How can the model be proposed as a basis for regulatory action given the lack of accuracy, lack of precision, inability to verify output, and unknown habitat carrying capacity?

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

EPA maintains that its analysis is based on sound science and therefore is a reasonable basis for regulatory action. For a discussion of uncertainty in the context of EPA's analysis, please see Chapter A6 of the Regional Analysis Document (DCN #6-0003). See also response to the related Comment 316bEFR.041.845.

Subject Matter Code 10.03.03
Tampa Bay

Question 9

It is not obvious if there were upper limits for the Foregone Production relating to carrying capacity of Hillsborough Bay/Tampa Bay. Why were there no upper limits set based on biology? This is critical. There is a real possibility that the Bay may at present be at some equilibrium capacity and no new fish may be possible without significant habitat restoration.

EPA's response partially answers the question, but see comment under item 2. We request a clarification.

EPA Response

EPA's analysis for the final rule did not evaluate Tampa Bay as a separate case study. Instead, Tampa Bay I&E estimates were included in the regional total for the Gulf Region. Please see Part F of the Regional Analysis Document (DCN # 6-0003) for details.

Carrying capacity is not a variable in the production foregone calculation. Please see Chapter A5 of the Regional Analysis Document for details on the production foregone model.

Question 15

See Page D1-12.
a. What is the relevance of inclusion of some of these sections as related to power plant issues?
B. Are these areas also used in the fishing statistics? For instance the Chassahowitzka National Wildlife Refuge is located in Citrus and Hernando counties and is 65 miles north of St. Petersburg, not an intimate connection to Tampa Bay.

a. EPA's response answers the question.
b. EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

The introductory chapters to the case study reports presented at proposal were intended to provide general background on the study area. This material is not presented in EPA's final benefits analysis for the 316(b) Phase II rule.

Question 16

See Page D2-7. Under section d. F.J. Gannon. The last sentence of this paragraph lists design intake flow of 2465 MGD.
a. Where did this number come from?
b. Was this number used in the model? This does not agree with Table D1-2 which lists 1267 MGD (sum of table numbers). This is a difference of 1198 MGD (95% increase over 1267 MGD). The rated capacity as verified by TECO on May 30, 2002 is 1346MGD (NPDES permit). If the flow value of 2465 MGD was used in the model the values would be overestimated by 95%.

EPA did not answer the questions. UWAG reiterates its request for an answer, and hereby raises it as part of its public record. The question merits a response if the number listed for Gannon (overstatement of design flow by 2x) was used in any of the calculations. The question is restated here: See Page D2-7. Under section d. F.J. Gannon. The last sentence of this paragraph lists design intake flow of 2465 MGD. A. Where did this number come from? B. Was this number used in the model? This does not agree with Table D1-2 which lists 1267 GD (sum of table numbers). This is a difference of 1198 MGD (95% increase over 1267 MGD). The rated capacity as verified by TECO on May 30, 2002 is 1346 MGD (NPDES Permit). If the flow value of 2465 MGD was used in the model the values would be overestimated by 95%.

EPA Response

Tampa Bay

Question 20

See Page D3-15. Section D3-5. What are the data used to maintain that the fish communities and hydrodynamics are similar between Big Bend, Gannon and Hookers Point? This is highly questionable. Hookers Point is located on the dredged channel for the Hillsborough River. Gannon is at the mouth of East Bay which receives the flow of the Palm River (Tampa Bypass Canal). Salinity zonation is pronounced within Hillsborough Bay particularly during the rainy season. The areas around Gannon and Hookers point are highly urbanized and industrial. There are virtually no natural shoreline and the entire area is dredged with shipping channels in excess of 40 foot depths.

EPA's response does not answer the question. UWAG reiterates its request for an answer and hereby raises it as part of the public record.

We would like to rephrase the question: Are there any data used for the analysis illustrating that the fish communities are hydrodynamics are similar between Big Bend, Gannon and Hookers Point?

EPA Response

EPA recognizes that there are physical, chemical, and biological conditions that may vary locally at individual facilities within a watershed. However, EPA's analysis was not concerned with developing precise, facility-specific estimates of I&E. For an explanation of EPA's extrapolation approach and the underlying rationale for the approach, please see Chapter A5 of the Regional Analysis Document (DCN # 6-0003) and response to Comment 316bEFR.041.041.

Question 22

See Page D3-15. Tables D3-16 and D3-17.
a. Was there an upper limit for Foregone Production fisheries estimates?
We have not seen any items that specify the models or that I&E cumulative impacts have an upper limit based on habitat carrying capacity. Habitat carrying capacity operates independently of I&E effects. Under the life history section (page D3-5) it is stated that juvenile mortality of blue crabs is usually the result of exceeding the estuarine carrying capacity. The assumption seems to be that if the I&E organisms were to survive they could reach adult size (within constraints of natural mortality and fishing pressure) and thus increase the fisheries yield.
b. Was there any consideration that populations may be limited by habitat availability for one or more life stages. For instance if lack of seagrass habitat limits the potential of spotted seatrout a reduction of I&E may have no net effect on adult populations.

See comment under item 2. We request a clarification.

EPA Response

The commenter asks about features of EPA's I&E analysis with respect to factors limiting population sizes, including carrying capacity in general and specifically habitat limitations. EPA did not model fish population dynamics as discussed in its response to Comment 316bEFR.005.009.

Question 23

See Page D3-24. Analysis of recent plankton data.
a. Where can we access the Peebles data referenced in this section. TECO does not have and has not reviewed the Peebles data but questions the direct comparisons.
b. Were the Peebles plankton data sorted by depth to use representative bottom water?
c. Were the Peebles data seasonal, representative of every month?
d. What is the magnitude of between-sample variance and how were the averages for Table D3-18 determined? The larval densities of eight of the 15 species listed in Table D3-18 have apparently increased since 1977-79.
e. How is this reconciled with the reported losses of fisheries catches listed in the life history section?
f. Were these new data used in any of the models?

a. EPA's response answers the question.
b. EPA's response answers the question.
c. EPA's response answers the question.
d. EPA's response answers the question.
e. We do not understand the response. The Table D3-18 that we have lists four columns, two are reporting larval densities for different periods (1977 - 1979 and 1988 - 2001) the third list the differences. The larval densities of eight of the 15 species listed in Table D3-18 have apparently increased since 1977-1979. The question was: e. How is this reconciled with the reported losses of fisheries catches listed in the life history section? UWAG reiterates this question for the public record.
f. No additional comment.

EPA Response

These comments refer to material presented at proposal in the report on the Tampa Bay case study (see the Case Study Document, DNC 4-0003). The purpose of this analysis was to examine the potential relationship between ambient larval densities and entrainment rates. The analysis was not used in any way in EPA's 316b benefits analysis and was not included with EPA's materials in support of the final Phase II rule.

Question 25

See page D3-25. The last paragraph. What is the rationale to justify Foregone Production if the item in question 16 (ichthyoplankton levels are similar for the 20 year comparison) is valid?

If as stated the magnitude of larval entrainment has not changed since 1976-1977 the implication is that existing reproductive populations are being maintained within Tampa Bay or that plankton entrainment measures are a poor surrogate for determining adult populations within the bay.

EPA's response does not answer the question. Instead, EPA's response says this question is in the nature of a comment on the record and will be addressed by EPA if it is raised during the public comment period. UWAG hereby raises the question for the public record.

EPA Response

This comment refers to information in the Case Study Document (DCN #4-0003) presented at proposal. EPA did not include this information in its final analysis for the 316b Phase II rule. However, EPA agrees that if the magnitude of larval entrainment has not changed over time, one may infer that populations are relatively stable or that plankton I&E rates are not closely correlated to adult population abundances.

Subject Matter Code 7.01.03

Option 3--Site-specific determination

Author Name Gregg Tieken

Organization City of Public Service

EPA should be complimented for considering a variety of alternative approaches to the regulation. City Public Service is encouraged that the EPA proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that affect the technical practicability of meeting the proposed standards. Specifically, the EPA recognizes that there may be situations where the costs of meeting the proposed standards at a specific facility may be significantly higher than the costs considered by the EPA in establishing these standards. In those instances the proposal provides the facility with the opportunity to justify an alternative technology selection.

EPA Response

Please refer to the response to comment 316bEFR.040.003.

Comment ID 316bEFR.042.004

Author Name Gregg Tieken
Organization City of Public Service

Subject Matter Code 10.07.03
RFC: Test: benefits should justify the costs

The EPA proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific-factors that indicate that the costs of meeting the performance standards are not warranted by the projected benefits at that facility. This is potentially very good. The proposed rule allows facilities to select an alternative level of compliance where the costs of compliance with the EPA's performance levels would be significantly greater than the expected benefits of achieving these levels. This explicitly recognizes the site-specific variations in the waterbodies (with varying ecological conditions) and can help account for controls already in place at many facilities.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.042.005

Author Name Gregg Tieken

Organization City of Public Service

Subject Matter Code 7.01.03

Option 3--Site-specific determination

The EPA has chosen a flexible approach to compliance that allows facilities to meet the performance standards through a number of options, including creation or voluntary restoration of habitats and other non-traditional approaches. This approach allows for continued innovation in addressing the potential adverse environmental impacts associated with impingement and entrainment at power generating facilities. This also leaves significant discretion in determining how best to comply with the standards to state permitting authorities and facilities managers who have developed a great deal of expertise on these issues over the past 25 years. City Public Service has a good working relationship with the state and believes in deferring, where possible, to the state regulators.

EPA Response

Please refer to the response to comment 316bEFR.039.005.

Comment ID 316bEFR.042.006

Author Name Gregg Tieken

Organization City of Public Service

Subject Matter Code 22.06

UMRA/Impacts on local governments

Criticism: the EPA has underestimated the impact on public power systems. City Public Service believes that the EPA should consider these impacts on local government. (See section titled Assessment of Unfunded Mandates Analysis on Public Power in the Comments submitted by the American Public Power Association).

City Public Service agrees with the APPA that the EPA should encourage states to implement the new 316(b) requirements with coordination with states to ensure reliable grid operations.

City Public Service is very concerned with the unintended consequences of downtime in the utility industry when 316(b) requirements are implemented. If the EPA and states attempt to do these too quickly or at the same time, there may be electricity price spikes as public power generators purchase power from IOUs or other public power entities during a one to three month down time. The final rule should encourage state flexibility in setting sensible deadlines for 316(b) retrofits when the utility would have scheduled outage, maintenance or have lower demand. The EPA's proposed rule ignored this potential consequence that could be serious in a region (or watershed) where several utilities face NPDES permit renewal, imposition of 316(b) requirements, and planned outages in the same year. If not timed wisely, the region's customers could face unexpected utility bill increases-particularly during a peak use time such as mid summer or mid winter.

The EPA and states should take a common sense approach to new 316(b) requirements. This common sense approach would minimize potential cost spikes and energy disruptions and would avoid placing too high a demand on the few dozen consulting engineering firms that have considerable expertise in biological studies and the various intake technologies.

EPA Response

For a response to comments on potential impacts on public power systems, please refer to comment 316bEFR.028.008 in subject matter code 22.03.

For a response to comments on implementation of new 316(b) requirements, please refer to comment 316bEFR.028.007 in subject matter code 21.09.

Option 3--Site-specific determination

Section 316(b) requires that the “location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact.” 33 U.S.C. § 1326(b). Through this rulemaking process, EPA is attempting to implement this statutory provision with technology-based performance requirements Under the proposed rule, the facility’s owner or operator gets to choose the technology (or combination of technologies and other measures) the owner/operator believes will meet the performance standards Georgia Power supports leaving it up to the facility owner or operator to determine what technology is most appropriate for its facility and believes the Clean Water Act intends for the facility owner or operator to make that decision.

Performance standards

The proposed rule establishes performance standards for each type of waterbody in which a cooling water intake structure may be located. The proposed rule addresses oceans, estuaries, tidal rivers, freshwater rivers and streams, lakes, and reservoirs. Each standard calls for owners or operators to minimize their impacts to aquatic life by reducing, by a certain percentage, the number of organisms entrained or killed by impingement Georgia Power believes that to the extent EPA continues to choose this regulatory approach, these standards and their implementation can be vastly improved over EPA's current approach.

Submittal of required information

Author Name E. Fitzergerald Veira

Organization Troutman & Sanders obo Georgia Power

To begin the process of complying with the new performance standards, each facility submitting a permit renewal application will need to include a possibly overwhelming amount of information in its application, including waterbody characterization data for the waterbody in the vicinity of the cooling water intake structure and data characterizing the design and operation of the structure itself Proposed 40 CFR § 122 21(r)(2)-(3), (5). Each facility must also submit a Comprehensive Demonstration Study, unless it has or will implement controls which have or will reduce its intake flows to a level commensurate with the use of a closed-cycle, recirculating cooling system Proposed 40 CFR § 125 95(a), (b)

General Statement of Opposition

Georgia Power believes that EPA needs to properly address these comments in Order to improve the Rule's enforceability, make the rule more effective and consistent with the overall NPDES regulatory program, and maximize the overall use of resources. Furthermore, by failing to address these comments, EPA runs a significant risk of having the rule, if finalized as proposed, be held arbitrary and capricious and, for certain aspects, beyond the scope of EPA's delegated authority.

Performance standards

The Proposed Percent Reductions from the Calculation Baseline are too High.

Under the proposed rule, applicability of the performance standards vary, depending primarily on the source waterbody. If a facility withdraws water from a freshwater river or stream and that facility withdraws five percent or less of the river or stream's mean annual flow, then the facility must reduce fish and shellfish impingement mortality by 80 to 95 percent from the baseline. If the facility's design intake flow is more than five percent of the mean annual flow, the facility must lower impingement mortality by 80 to 95 percent and lower entrainment by 60 to 90 percent.

For an entity whose cooling water <FN 2> intake structure withdraws water from a lake or reservoir, the facility must reduce impingement mortality by 80 to 95 percent from the baseline. For entities whose cooling water intake structures withdraw water from the Great Lakes system, tidal rivers, estuaries, or oceans, those facilities must lower impingement mortality by 80 to 95 percent and lower entrainment by 60 to 90 percent. Regardless of the waterbody, however, the entrainment reduction component does not apply if the facility has a capacity utilization rate that is less than 15%.

EPA states that the performance ranges "reflect the uncertainty inherent in predicting the efficacy of a technology on a site-specific basis." In essence, EPA recognizes the inherently variable nature of aquatic environments 67 Fed Reg 17141, Col 3 The low end of the range indicates the minimum level of impingement or entrainment reduction that EPA believes all facilities -- even those operating in the most sensitive environments -- could achieve with the existing technologies on which EPA's assumptions are based. The high end of the range reflects EPA's belief that in some environments the same technology (technology upon which EPA based its proposed performance standards) will be more effective.

While the overall structure of the rule is not the ideal approach, <FN 3> Georgia Power believes it is workable However, in addition to other deficiencies, the percent reductions from the calculation baseline are too high and not justified by the record

Footnotes

2 EPA defines "cooling water" to mean water used for contact or noncontact cooling,including water used for equipment cooling, evaporative cooling tower make up, and dilution of effluent heat content." Proposed CFR 125.83. Georgia Power requests that EPA make it clear that the water is no longer "cooling water" after it has performed its intended cooling function.

3 Georgia Power agrees with UWAG that the site-specific approach is better.

Available I&E technologies

EPA's Places Too Much Confidence in Existing Technology For Which Only Limited Information is Available

The impact reduction levels were set based on limited experiences with certain technologies, which EPA implicitly expects facilities will opt to use. EPA based its impingement mortality reduction performance standards on design and construction technologies like wedge wire screens and aquatic filter bather systems (which EPA believes can achieve a 99% impingement mortality reduction); barrier nets (EPA believes barrier nets are capable of 80-90% mortality reduction); and modified screens and fish return systems, diversion systems, fine mesh traveling screens, and fish return systems. 67 Fed. Reg. 17142, Col. 1.

For reducing entrainment, EPA acknowledges that the performance that can be expected from available technologies is less clear than with impingement mortality reduction 67 Fed Reg 17142 The situation is further complicated by the fact that some of the entrainment reduction technologies cause problems by increasing impingement. Still, EPA believes technologies such as aquatic filter bather systems, fine mesh wedge wire screens, and fine mesh traveling screens with fish returns should reduce entrainment by 80 to 90 percent from the baseline

Notwithstanding EPA's admission that the support for its entrainment reduction technologies is less than ideal, EPA proposes using these impact reduction benchmarks anyway. Georgia Power believes EPA is being hasty in its approach and needs to re-examine the performance standards and make appropriate adjustments so that the standards will be more consistent with the practical realities of the numerous uncertainties that are associated with the regulation of cooling water intake structures and their very site-specific environments.

Performance standards

EPA Needs to Modify its Proposed Performance Standards to Reflect the Uncertainties Related to the Operation and Impact of Cooling Water Intake Structures.

For several reasons, EPA needs to adjust down the ranges of the performance standards. First, the technologies that EPA relies on have not been broadly tested to guarantee the kinds of results EPA identified. Indeed, perhaps with the exception of fine mesh screens, which have their own shortcomings, there is very little reliable data on the technologies EPA identifies.

Second, EPA itself recognizes the inherent variability of aquatic environments. Adding to the complexity of this problem is the fact that the limited evaluation data that is available does not reflect the diversity of aquatic environments in which EPA expects that these technologies will be applied. Accordingly, EPA should create more room in the standards to accommodate the uncertainties and variabilities.

State or Tribal Alternative Requirements

Third, such substantial percentage reductions assume that this issue has been completely overlooked by state agencies. This is simply not the case Many of the facilities have been around for decades with not only significant and proper regulatory oversight, but also noteworthy public scrutiny. With volumes of NPDES-related data generated regarding water bodies and studies conducted under the various state programs, including assessments done by state wildlife resources departments, significant entrainment and impingement would not have gone unnoticed. Moreover, in certain areas, general knowledge about recreational fishing would have helped to identify facilities that are having significant impacts as a result of entrainment or impingement.

A Possible Improvement to the Rule is to Broaden the Range.

There are several approaches EPA should consider to establish more reasonable standards that are workable within EPA's current structure. One option is .to broaden the ranges and allow permit writers to establish the percent reduction for individual facilities based on characteristics of the waterbody, existing aquatic communities, and other site-specific-data. Georgia Power recommends using 50-70% range for impingement reductions and 40-60% range for entrainment reduction. These ranges are much more reasonable in light of the numerous uncertainties associated with the water bodies, the individual intake structures, the water quality of the various waterbodies, the extent of existing aquatic species, the types of aquatic species, the abundance or lack of nuisance species, the potential for endangered species, and the limited information available regarding the technologies identified by EPA..

Performance standards

EPA Could Establish Interim Limits Until More Is Understood About Available Technology.

Another option that Georgia Power would support is the establishment of interim standards (e.g., for the next five years, reduce impingement by 40% and entrainment by 30% compared to the calculation baseline, where applicable). Then, at the end of that five year period, when assessments of both the waterbodies and technologies have been conducted, a permanent, more stringent standard can become effective.

Comprehensive demonstration study (7 parts)

Author Name E. Fitzergerald Veira

Organization Troutman & Sanders obo Georgia Power

EPA Needs to Establish Clear Definitions of the Objectives of an Acceptable Impingement and Entrainment Study, Including Some Guidance Regarding the Calculation Baseline Impingement and Entrainment Rates.

Under the proposed rule, the permittees of those facilities not employing, and not planning to employ, closed-cycle recirculating cooling systems (or their equivalent) will be required to submit an Impingement Mortality and Entrainment Characterization Study Proposed 40 CFR § 125 95(b)(3), 67 Fed Reg at 17175, Col 3 This Study is one of several steps to be undertaken as part of the Comprehensive Demonstration Study This is arguably the heart of a 316(b) Comprehensive Demonstration Study, yet EPA provides very little meaningful guidance as to how to accomplish this component of the demonstration Because clear objectives and guidelines are not established, the permittee is left with very little information as to how, as a practical matter, to scope the Study and how to extrapolate to a "calculation baseline" Compounding the problem is the absence of a definition of adverse environmental impact Establishing clear guidelines for impingement and entrainment studies is important not only in the context of individual facilities that will be subject to the proposed rule, but also for the overall, long-term goal to reduce the effects of impingement and entrainment and improve the effectiveness of protective technologies There is a great deal of information available from previous 316(b) studies However, the scope, objectives, methods, estimation and reporting of these individual studies vary greatly The variability in the studies themselves is one of the largest obstacles to creating a useful 316(b) database that could be used to help predict impingement and entrainment effects, or help predict the potential effectiveness of various protective technologies for a given set of environmental and operational conditions. Requiring facilities to conduct characterization and demonstration studies, without providing clear guidance to standardize those studies, is short-sighted and only promotes additional variability.

Comprehensive demonstration study (7 parts)

Elements of an Impingement Mortality and Entrainment Characterization Study Needs to be Clarified.

The preamble identifies three elements of an Impingement Mortality and Entrainment Characterization Study. First, the preamble states that the characterization would include “taxonomic identifications of those species of fish and shellfish and their life stages that are in the vicinity of the cooling water intake structure and are most susceptible to impingement and entrainment.” 67 Fed. Reg. at 17175, Col. 3. EPA needs to elaborate further and provide more clarity as to what it means with respect to this first element. For example, with respect to “taxonomic identifications” of species in the vicinity-of the cooling water intake structure, to what extent can facilities rely on existing data generated by State natural resource and wildlife agencies or others? We understand from EPA’s language that not every specie needs to be evaluated, just the ones that are “most susceptible” to impingement and entrainment. But what does EPA mean by “most susceptible?” One possible interpretation of this term. is to focus on those species that are noticeably higher than the rest with respect to the frequency and abundance of the extent of entrainment or impingement. Another concern is to what extent can the permittee select, representative species when the species that are being impacted are similar?

The second element EPA mentions is no clearer than the first EPA expects a “characterization of these species of fish and shellfish and life stages, including a description of the abundance and temporal/spatial characteristics in the vicinity of the cooling water intake structure." Id. What does EPA mean by “characterization of these species?”

The third element is the “documentation of the current impingement mortality and entrainment and an estimation of the calculation baseline.” Id. EPA does not explain the extent of the documentation that may be needed. Nor does EPA provide any useful guidance regarding the establishment of the theoretical baseline. As a practical matter, if the facility is once-through cooling with no existing technology, Georgia Power is concerned that EPA may take the position that the facility is itself equal to the baseline. However, there might be other considerations that may have already lowered the extent of any impingement or entrainment that may not be limited to technology. For example, certain operational controls or the location/angle of the cooling water intake- structure may operate to limit the extent of entrainment or impingement. EPA should, therefore, provide facilities with the opportunity to take into account other considerations beyond technology for purposes of determining the calculation baseline.

Case Study Specific Comments

EPA's Case Studies Are of Limited Value.

Georgia Power has some concerns about the case studies that EPA provided. -Because of variabilities in the way the studies were conducted and reported, there is little information that can be transferred in a meaningful way to other facilities. Those case studies, therefore, have limited use In addition, the case studies are repeatedly qualified as out of date and likely to underestimate impingement arid entrainment, suggesting that EPA would like some as yet undefined but better process. Finally, Georgia Power is concerned that a calculated baseline scaled to design MGD is not a defined measure if the underlying impingement and entrainment studies are open to significant criticism. In real operations, actual pumping rates are often significantly less than design MGD, which might put some facilities in a position of trying to reduce a "calculation baseline" that is greatly overestimated.

EPA Response

EPA agrees that the facility studies that are available for estimating the magnitude of I&E have many limitations. However, EPA had no alternative but to use available data, given the effort that would be required to conduct original studies to obtain less uncertain and more current data, including the need for multiple years of intensive monitoring of hundreds of species at representative facilities throughout the country. Nonetheless, EPA made every possible effort to find reasonably accurate I&E data from the best I&E studies available, including studies with similar methodologies. In addition, EPA converted I&E losses to a standard metric (age 1 equivalents) so that losses could be compared and extrapolated among facilities.

See also responses to Comment 316bEFR.072.055 on sample size and representativeness and Comment 316bEFR.041.041 on EPA's extrapolation approach.

Subject Matter Code 21.04
Determination of compliance

Allowances for Unavoidable Episodic Impingement and/or Entrainment Events.

In development of the Final 316(b) Rule for existing facilities, EPA should acknowledge and make allowances for the occurrence of unavoidable episodic impingement and entrainment events that are beyond the control of the cooling water intake structure facility operator. For example: Threadfin shad (Dorosoma petenense) are a temperate freshwater forage fish species that occurs throughout the southern and southwestern United States. (Lee, D.S., C.R. Gilbert, C.H. Hocutt, R.E. Jenkins, D B McAllister, and J R Stauffer, Jr 1980 et seq ,Atlas of North American Freshwater Fishes N C State Mus Nat Hist , Raleigh i - x + 854 pp)

Threadfin shad are very sensitive to water temperatures with significant mortality of young and adults occurring below 7 C (44 6 F), with 5 C (41 F) reported as the lower lethal temperature for the species. Threadfin shad experiencing decreased swimming ability and/or mortality due to cold stress/shock are subject to impingement, and possibly entrainment, as they enter the cooling water intake structure hydraulic Zone of Influence. Winter stress or kill of threadfin shad commonly occurs in the northern portion of the species range and large die-offs have been known to result m excessive cooling water intake structure impingement rates to the point of intake screen collapse and, consequently, facility power curtailment and/or shutdown. King, R.G., GeoSyntec Consultants, personal communication re: Gentleman Station, Nebraska Public Power District (2002).

Similar phenomena can occur in marine environments involving a variety of thermally (cold) sensitive fish (e.g., snook, Centropomidae, and mullet, Mugilidae). Marine invertebrates are also susceptible candidates for unavoidable episodic impingement and entrainment, particularly planktonic species whose movement is subject to the wind, tides, and currents, and whose populations undergo cyclical expansions or “b1ooms (e.g., jellyfish, a group that includes Scyphomedusae, Hydromedusae, Siphonophores, and Ctenophores).

The occurrence of such an unavoidable episodic event during the conduct of the Impingement Mortality and Entrainment Characterization Study, as currently required by the proposed rule, would unfairly bias the results of the study whose objectives are to provide representative data to support development of the Baseline Calculation for evaluating reductions in impingement mortality and entrainment; document current impingement mortality and entrainment; and provide the basis for evaluating the performance of potential technologies, operational measures, and/or restoration measures. Additionally, in the absence of provisions acknowledging unavoidable impingement and/or entrainment, should such an event occur during Compliance Monitoring a facility could face possible regulatory actions ranging from enforcement penalties to unnecessary implementation of more stringent and costly technological controls and/or restoration measures to meet a required reduction in impingement and/or entrainment mortality from the facility Calculation Baseline; a baseline value that, at the time determined, may not have experienced a similar episodic event.

Therefore, the Final 316(b) Rule for existing facilities should: 1) include language defining and recognizing the occurrence of unavoidable episodic impingement and/or entrainment events; 2) allow exclusion of such events during the conduct of the Impingement Mortality and Entrainment Characterization Study and associated Calculation Baseline determination, and 3) provide exemption from any regulatory actions, including enforcement actions, arising from an unavoidable impingement and/or entrainment event that might occur during Compliance Monitoring or otherwise during the life of the facility NPDES permit.

Option: Reduce capacity comm. with closed-cycle

The Use of Off-Stream Lakes or Ponds Should be Viewed m the Context of the Overall Reduction of Water Withdrawn.

Under the proposed rule, existing facilities with intake flow levels “commensurate with” that which can be attained by a closed-cycle recirculating cooling system using minimized makeup and blowdown flows are deemed to be in compliance with the rule as proposed. Georgia Power believes that certain aspects of this section of the rule is arbitrary, legally unsupported, and in need of clarification. Because of EPA’s unclear definition of “closed-cycle recirculating cooling system,” Georgia Power is concerned about the regulatory status of several of its power plants with cooling towers and off-stream ponds or reservoirs.

Definition: Cooling Water Intake Structure

Author Name E. Fitzergerald Veira

Organization Troutman & Sanders obo Georgia Power

Georgia Power recommends a more practical definition of closed-cycle recirculating cooling system as follows: "A system that minimizes the extent of its overall water withdrawal rate and/or use by recirculating its cooling water through any one of several mechanisms that does not involve once-through use of a significant percentage of the cooling water. Such systems can involve the use of a -cooling tower, with a source of make-up water such as an off-stream lake, or a cooling pond."

Special definitions

Use of Off-Stream Ponds is a Practical Component of a Closed-Cycle System

In Georgia Power's case, off-stream ponds were created to ensure compliance with Georgia's water withdrawal regulatory scheme and to provide a reliable, easily accessible source of water for cooling tower make-up. <FN 4> Essentially, an off-stream pond adds a step to the water withdrawal process while at the same time providing a buffer to the original source waterbody Water is pumped from the original source waterbody into the off-stream -pond. -The pumps at the original source waterbody operate on a limited basis to maintain the off-stream pond at a certain level. Water is then pumped from the off-stream pond to serve various plant functions. The pond's primary function, however, is to serve to make-up the cooling tower water when it is reduced, mostly as a result of evaporation or blowdown. Because Georgia's water withdrawal law implemented through water withdrawal permits imposes certain pumping restrictions, off-stream ponds enable Georgia Power to meet the plants' water needs without overburdening the source waterbody or otherwise violate the water withdrawal regulatory scheme.

Georgia Power believes that a determination of whether a system is "commensurate with" a closed-cycle recirculating system should be based on the overall reduction of water use based primarily on the reduction in water withdrawn from the original source waterbody. Whatever definition EPA ultimately uses, however, Georgia Power's main comment here is to make sure that facilities with off-stream ponds are not excluded from the definition of closed-cycle recirculating systems.

Footnotes

4 Georgia Power does not believe that off-stream ponds are waters of the U.S.

Subject Matter Code 3.07

Special definitions

At the Very Least, EPA Needs to Change or Clarify Certain Terms Used in the Current Definition of Closed-Cycle, Recirculating System.

EPA does not explain the meaning of certain key terms included in the proposed rule EPA's failure to define some of these terms and certain related concepts will make the preliminary determination regarding whether the facility's system is "commensurate with" a closed cycle, recirculating system difficult. First, EPA does not define "commensurate with." Webster's dictionary definition of "commensurate" is "equal in measure or extent, corresponding in size, extent, amount, or degree." This being the case, we assume EPA to mean "equal to" or "same as" when it uses the term "commensurate with."

We believe "commensurate with" is too inflexible for situations where a variety of factors can affect the need for make-up water or the extent and frequency of blowdown. These factors include climate differences, the need for certain water quality within cooling towers, differences in water quality standards applicable to the receiving waterbodies, and evaporation. For these reasons, Georgia Power recommends using "similar to" instead of "commensurate with".

Second, EPA does not explain what is meant by "minimized make-up and blowdown flows." Configurations of closed-cycle, recirculating system-s vary. As mentioned, some systems, such as Georgia Power's, use reservoirs or off-stream ponds to -provide make-up water. Depending on the configuration of the system, the amount of make-up water needed may vary, due largely to evaporation. A system should be considered minimized provided that the majority of the water used does not serve a once-through cooling function.

Also, the frequency of blowdown varies depending, in part, on applicable water -quality standards and the quality of the intake water. The quality of the water in the cooling tower must be maintained at a certain level to preserve the system. A system's blowdown should be considered minimized when blowdown is not performed more than is reasonably necessary.

Subject Matter Code 8.01

Proposed standards for FW rivers and streams

EPA Should Increase the Water Withdrawal Threshold Relating to Rivers and Streams.

Under the proposed rule, facilities located on freshwater rivers or streams do not need to address entrainment, provided that the facilities' design intake flow is 5% or less than the source river's mean annual flow. EPA explains that the 5% withdrawal threshold is based on the concept that, "absent any other controls, withdrawal of a unit volume of water from a waterbody will result in the entrainment of an equivalent unit of aquatic life suspended in that volume of the water column." 67 Fed. Reg.17151, Col. 2.

Accordingly, EPA concludes that "if 5% of the mean annual flow is withdrawn, it would generally result in the entrainment of 5% of the aquatic life within the area of hydraulic influence of the intake." Id. Because EPA believes that it is unacceptable to impact more than 5% of the organisms within the area of an intake structure, EPA is choosing to require those facilities that withdraw more than 5% of the mean annual flow of a fresh water river to reduce entrainment by 60-90%. For several reasons, Georgia Power believes that EPA's approach is arbitrary.

First, the 5% criterion uses design intake pumping rate and annual average flow. Operational measures which may be implemented because of the hydrologic regime are ignored but may minimize entrainment and impingement. Also, consideration should be given to use of actual volume pumped and river flow for periods during critical life stages when fish and shellfish would be impacted.

Second, the 5% criterion assumes a uniform distribution of entrainable organisms to derive a conservative estimate of the potential for adverse impact. See EPA 2002, EPA -821-R-02-002, page Al-5. Examination of the case study data EPA provided shows no relationship between design intake pumping rate and total entrainment or impingement. The Ohio River Watershed Case Study, EPA 2002, EPA-821-R-02-002, Part C. This can be seen qualitatively by noting that the facility with the greatest capacity to withdraw water from the Ohio River, the W H Sammis facility, with design intake capacity of 7.46% of annual river discharge, reports lower annual entrainment rates than four other facilities with design intake capacities ranging from 0.36% to 4.75% of mean annual flow. Possible reasons for this include: different habitat preferences for various fish species; orientation of the intake in relation to the source water body; differences in life history including differences in reproductive strategies As far as Georgia Power can tell, EPA has provided no supporting data for the proposition that entrainment is proportional to design pumping capacity as a percent of average annual river flow.

Third; the existing intake structure may be located in a waterbody segment that supports minimal valuable aquatic life. In certain cases, potential impingement or entrainment may be reduced because of the location of the structure relative to the channel, migratory pathways or other desirable microhabitats. The 5% threshold makes no allowance, for example, for situations where nuisance species may be the primary species being entrained or impinged.

EPA's broad-brush approach to the 5% withdrawal threshold ignores these factors that could justify a higher threshold.

Given various considerations that could affect the potential relationship between aquatic organisms present in the water body and the percentage that is likely to be entrained, we recommend a higher threshold with the opportunity for the permit writer to be more stringent if the situation requires it. EPA should use a threshold flow equal tol5% of the spawning season flow.

Regardless of the ultimate threshold EPA decides to apply, Georgia Power believes that at any such threshold, the risk of entrainment and the relative significance of impingement should be sufficiently low to warrant an avoidance of both impingement and entrainment requirements below the threshold.

RFC: Regulating limited capacity facilities

The Utilization Rate Needs to be Increased.

EPA proposes to exempt facilities from entrainment reduction requirements when a facility operates less than 15% of the available operating time (based on historical data.). Proposed Rule 40 CFR § l.25.94(b)(2); 67 Fed. Reg. 17153, Col. 3. EPA explains that "because these facilities operate only a fraction of the time compared to other facilities, such as base-load plants, the peaking plants achieve sizable flow reductions over their maximum design annual intake flows. 67 Fed. Reg. 17153, Col. 3. EPA also explains that the reduced standard is further justified on the basis that these peaking facilities operate during the peak of winter and summer, which are not the most crucial periods for aquatic organisms. Georgia Power agrees that low capacity utilization facilities should be granted certain exemptions. However, EPA's threshold is too low.

EPA needs to increase the utilization rate that triggers entrainment reductions and give permit writers the flexibility to agree to permit conditions regarding the facility's utilization rate that may depart from the facility's historical operation with or without supporting data, provided that the facility can demonstrate future compliance with the utilization rate it chooses.

Georgia Power believes that a 30% utilization threshold is justified on the basis that, compared to 100% utilization, there is an overall reduction in flow of about 70% which puts the facility within range of the proposed reduction in entrainment (60-90%) In addition, Georgia Power believes the impingement requirement should not apply to facilities with capacity utilization rates up to 20% This would also be in line with the performance standard (80-95% reduction) for facilities that have 100% utilization.

Apply 316(b) before a det. of impact/AEI

Adverse Environmental Impact Cannot be Presumed.

To the extent that EPA is using 316(b) to regulate cooling water intake structures that are not having an adverse impact on the environment, EPA is acting beyond the scope of its authority. Consistent with the Clean Water Act, EPA must allow a two step process that enables a utility to show whether there is any adverse environmental impact in the first place. Section 316(b) of the Clean Water Act requires the location, design, construction, and capacity of cooling water intake structures to "reflect best technology available for minimizing adverse environmental impact." 33 U.S.C. §1326(b). On the basis of strict statutory interpretation, if adverse environmental impact is absent, then the question whether the facility has best technology available becomes largely irrelevant.

Under the rule as proposed, EPA assumes that there is adverse environmental impact by virtue of the operation of a cooling water intake structure. Georgia Power disagrees with this position and finds it to be not only arbitrary, but completely at odds with the Clean Water Act. EPA is without delegated authority to require facilities to undertake activities with respect to their cooling water intake structures where there is an absence of adverse environmental impacts.

EPA Response

See preamble to the final rule, particularly sections III, VII, and VIII, and supporting documents.

Subject Matter Code 18.01.01

UWAG definition of "adverse environmental impact"

Georgia Power supports the UWAG definition of "adverse environmental impact" as stated in the proposed rule. 67 Fed. Reg. at 17163. EPA appears to take the position that a definition for "advertise environmental impact" is re1evant only if the Agency adopts a site-specific approach. 67 Fed. Reg. at 17164. Georgia Power disagrees with EPA's approach. Consistent with the Clean Water Act, a determination of adverse environmental impact is a necessary first step. As mentioned earlier, EPA should at least consider employing its Ecological Risk Assessment Guidelines in this context.

EPA Response

Please see the response to comment 316bEFR.002.019 for the discussion on the definitions EPA rejected for adverse environmental impact in this rulemaking.

Subject Matter Code 18.01

RFC: Definition of "adverse environmental impact"

There are many considerations that may factor into the presence or absence of adverse environmental impact. At the very least, those considerations should include the following factors: (1) whether species compensate for or accommodate the impact to an extent that the overall impact is "not adverse" (e.g., the nuisance species are minimized or the impacted species would have otherwise died or that the species otherwise make up for the loss); (2) if the facility is impacting the waterbody to an extent that is less than 75% of the calculation baseline then the facility should be exempt under the theory that a 25% impact relative to the baseline is acceptable unless endangered or threatened species are involved.

Subject Matter Code 20.0

Role of Trading

Expansive Trading Should be Allowed.

Georgia Power believes that the rule should be modified to specifically allow trading To ensure maximum flexibility and to encourage some experimentation among the states, EPA should let individual states develop their own trading programs. States should be allowed to pursue interstate trading if they desire. States should be given the flexibility to have their programs include the potential for source-based controls, receptor-based mitigation, and compensation based mitigation.

A trading program would be especially useful in this area because of the variety of methodologies that can be employed. As examples, a program can be structured to augment current water quality standards schemes or to meet broad biodiversity goals.

One possible way for a state to design a program would be to conduct a survey of facilities located in the state (perhaps on a per watershed basis) and identify a series of mitigation measures each facility can undertake in order to achieve certain biodiversity goals, achievement of water quality standards or some other measurable outcome. The state can then assign a certain value to these measures and relate these measures to units that can be applied toward reduction in impingement and entrainment as compared to the calculation baseline. Ultimately, fashioning the program should be up to the states. However, EPA should provide the regulatory basis and encourage states to develop such programs

Restoration measures in place of technologies

Voluntary Restoration is Consistent with the Clean Water Act.

Georgia Power can find no regulatory or legal reason to limit the use of restoration. In fact, one of the key premises of the Clean Water Act is restoration. 33 U.S.C. §1251. To the extent that EPA is concerned about over-reliance on restoration measures or that industry may avoid practical technological fixes, this reflects a failure on EPA's part to allow permit writers to fulfill their roles. The permit writer is positioned on the ground and can recognize when an owner or operator is proposing deficient restoration measures. In any event, the permit writer will eventually be able to identify if the restoration project is a failure and will be able to require additional compliance measures.

RFC: Proposed use of restoration measures

Voluntary Restoration Ensures Flexibility and the Best Use of Resources.

Under EPA's preferred regulatory approach, EPA has opted not to pursue the site-specific approach. In order to add some level of flexibility to EPA's approach, it is imperative that EPA make restoration completely voluntary. While Georgia Power does not believe that voluntary restoration will provide a complete fix for the proposed rule, it will certainly translate to~ a significant improvement. Because owners and operators are best positioned to determine how to maximize their resources, they will be able to identify the optimum approach (or combination of approaches) to comply with the rules There might be situations where restoration is simply not cost effective. On the other hand, physical limitations may make employment of technical improvements unattractive or impracticable. Giving the owner or operator the regulatory freedom to determine which approach or combination of approaches would be most efficient and effective would produce the best result. Indeed, it may enable the employment of more creative, environmentally beneficial solutions.

EPA Response

Subject Matter Code 18.02

RFC: Use of previous demonstration studies

Author Name E. Fitzergerald Veira

Organization Troutman & Sanders obo Georgia Power

Streamline the Demonstration Study.

First, a 316(b) demonstration should never have to be repeated unless circumstances have so changed to make the original demonstration unreliable. If a utility holds a NPDES permit with an accepted 316(b) demonstration, a re-evaluation of entrainment and impingement should only be required under specific circumstances such as: (1)when there has been material change in the operation of the facility that would increase the extent of impingement or entrainment; (2) when technological improvements are determined to be ineffective, (3) when restoration projects have failed; and (4) when significant changes are made to the cooling water intake structure New and significant information should be evaluated through consultation with state and federal natural resource agencies to determine whether species of concern (threatened and endangered species) may be present or changes in the fishery have occurred which may significantly increase the rate of impingement and entrainment at a facility.

EPA Response

EPA agrees that a comprehensive demonstration study may not need to be conducted each time a permit is renewed. Please see response to 316bEFR 041.126 for a discussion.

Permit applications/implementation schedule

Streamline the Implementation.

EPA is concerned about the potential burden on permitting agencies associated with the implementation of the proposed rule. Georgia Power believes that one of the best opportunities to minimize the impact of the proposed rule on both the responsible agencies and the regulated community is through the permit implementation process. The implementation process needs to be streamlined. Too much information is being required at the permit re-issuance application first step. The responsible agencies are likely to be overwhelmed and the permittees are likely to straggle with having to address so many issues at one time.

Under the proposed rule, owners or operators must submit the following information when applying for a re-issued NPDES Permit: (1) physical data to characterize the source waterbody in the vicinity where the cooling water intake structures are located (proposed 40 CFR § 122.21 (r) (2)); (2) data to characterize the design and operation of the cooling water intake structures (proposed 40 CFR 122 21(r) (3)) which is to be provided in two components, the first being the cooling water intake structure data and, the second being the existing facility cooling water system description; and (3) a Comprehensive Demonstration Study (proposed § 125.95(b)). Only facilities with closed-cycle, recirculating systems (or their equivalent) are not required to provide the Demonstration Study. Georgia Power believes that this amount of information will be overwhelming to the agencies and may have numerous negative results. Georgia Power recommends a more streamlined/Orderly approach as follows:

-All permittees with permits that will expire within two years after the date the rule becomes final shall submit information to the responsible agencies in two steps. In step one, the permittee shall submit the source water physical data, the cooling water intake structure data; and the existing facility cooling water system description to the director within 60 days of the permit expiration date. These permittees should be required to follow the normal permit renewal process(i.e., new permit conditions related to the 316(b) rule will not be imposed in the first renewal process for permits that will expire within the first two years after the date the rule becomes final). This information gathering stage merely gives the agency the ability to determine (1) whether the facility has a closed-cycle recirculating system and is therefore in compliance with the rule, or (2) what performance standard the facility would need to comply with absent a request for a site-specific determination.

-In step two, facilities with permits that will expire within two years after the date the rule becomes final and that do not have closed-cycle recirculating cooling systems (or their equivalent) should be required to submit a Comprehensive Demonstration Study within two years from the day the permit expires. The permitting agency will review the results of the Study and other factors, and shall request any necessary additional information. The permitting agency shall impose all 316(b) related permit conditions when the permit is renewed in the next renewal cycle.

-For those permits with expiration dates beyond the two years after the date of the final rule, steps one and two above are consolidated. The permittee shall submit (1) the physical data to characterize the source waterbody; (2) data to characterize the design and operation of the cooling water intake structure; and (3) a Comprehensive Demonstration Study5 along with the normal permit renewal application.

EPA Response

EPA has added many efficiencies to today's final rule since the proposal and NODA to provide options for streamlining application requirements. Please see response to comment 316bEFR.034.005.

Special definitions

EPA Should Provide a Definition of “Significantly Greater”

Under the proposed rule, the owner or operator of an existing facility may demonstrate to the Director that a site-specific determination of best technology available is appropriate for its facility if the owner or operator can meet one of the two cost tests. 67 Fed. Reg. at 17145. To obtain a site-specific determination, the facility must first demonstrate (1) that its costs of compliance with the applicable performance standards specified in proposed § 125.94(b) would be significantly greater than the costs considered by the Administrator in establishing such performance standards, or (2) that its cost of complying with such standards would be significantly greater than the environmental benefits at the site.

EPA has not provided any meaningful guidance concerning the term “significantly greater.” To begin with, it is not clear why “significantly” is even part of the analysis. From an economic standpoint. Georgia Power believes that it should be enough that the costs~ of compliance are “greater” than the EPA costs or that the costs are greater than the benefits to be able to qualify for a site-specific determination. We fail to see any reason, whether legal or purely economic, to oppose a site-specific determination when the costs outweigh the benefits under the performance standards approach. To the extent EPA’s primary concern and, the reason for its insertion of “greater,” is because of potential administrative costs associated with reviewing the appropriate documentation in support of a site-specific determination, EPA could encourage permit writers and agency experts to consult with the owner or operator as much as needed to make the permit writer’s work as easy as possible. In other words, Georgia Power, and probably most. if not all of industry, would be happy to do as much as possible to ease the permit writer/agency workload.

One thing is for sure, it would certainly ease the burden on both EPA and the regulated community if EPA were to provide clear and precise guidance on the meaning of “significantly greater.” One way to do this is to identify a cap, beyond which a presumption of “significantly greater” would be established (e g, 25% more than EPA’s estimated compliance costs or if the costs exceed the benefits by more than 25%).

EPA Response

RFC: Entrainment vs. entrainment mortality

Entrainment Survival Has Been Documented.

The proposed rule would establish a performance standard for reducing entrainment, not entrainment mortality. In fact, the proposed rule does not account for entrainment survival. EPA does not provide a credible basis for not recognizing entrainment survival. In particular, EPA states that it chose to regulate entrainment because it does not have sufficient data to establish performance standards based on entrainment mortality. Limited data or the absence of data should not preclude a facility from justifying compliance with the performance standard, at least in part, on the basis of credible scientific data that species survive.

RFC: Directors set performance levels for a facility?

Should EPA require the greatest achievable reduction (within the proposed ranges), or leave it to the Director to determine appropriate performance levels? 67 Fed. Reg. at 17142, Col. 1.

EPA should leave it up to the Director (or the states) to determine appropriate performance levels. <FN 5> Further, leaving this determination up to the Director or the states will enable more flexible use of each facility's uniqueness while still within the performance range. In addition, if a trading program is put in place, the market will entice facilities to achieve the greatest possible reduction where they will gain a marketable commodity from doing so. Also, mandating the greatest achievable reduction increases the burden, possibly in a very uneven way, on facilities.

Footnotes

5 As stated earlier in Part IIA of this document, EPA should goeven further and lower the performance ranges.

RFC: Appropriateness of "significantly greater"

Author Name E. Fitzergerald Veira

Organization Troutman & Sanders obo Georgia Power

Should EPA grant exception for an entity whose costs are "significantly greater" rather than "wholly disproportionate to the costs in EPA's record"? 67 Fed. Reg. 17146, 17166.

"Significantly greater" is a more appropriate standard. Georgia Power agrees with EPA 's effort to make the site-specific determinations more available to Phase II facilities, for which complying with new technological standards may be more complicated than for Phase I facilities. Also, site-specific determinations in general are an appropriate way to allocate the burdens of compliance, and the "significantly greater" standard in particular is amore reasonable means for allowing that option to be pursued where merited. Note, however, as discussed in Part II, Georgia Power believes "significantly" should be dropped so that site-specific determinations can be pursued where the cost to the facility is "greater" than EPA's costs.

Subject Matter Code 11.1

RFC: Discretionary restoration approach

Author Name E. Fitzergerald Veira

Organization Troutman & Sanders obo Georgia Power

Which, if any, restoration approach makes the most sense: discretionary, mandatory or restoration banking? 67 Fed. Reg. 17169 - 17170.

Discretionary restoration with the option of restoration banking. Each situation is too different, and facilities and permitting agencies need the discretion to employ appropriate restoration where they make the most sense. As a practical matter, mandatory restoration is unwise as it ignores cost benefit considerations, especially in situations where a technological fix will not only be less costly, but can also be implemented much more rapidly with almost instant results. As a legal matter, the Clean WaterAct does not authorize nor give EPA authority to require restoration in the NPDES permitting context. Still, restoration should be strongly encouraged and made broadly available as an option. Same with restoration banking -- this should be made available, but not mandatory. It is a means for bringing market forces to bear on allocating resources, so the market forces should be left to decide how it works.

What should be the spatial scale on which restoration can take place and be attributable to a facility? Water body, watershed, state...? 67Fed. Reg. 17146, Col. 3.

The largest possible scale on which restoration will, as a biological matter, adequately displace impacts. This may be complicated, but EPA should strive to broaden the availability of restoration if the program is to work.

How do you measure "substantially similar performance" of restoration measures?. What can be done to reduce the uncertainty? How do you measure success or failure9 Should a facility be required to restore more individual species than are being impinged/entrained? 67 Fed. Reg..17147, Col. 2.

Restoration is imprecise, and its success or failure should be measured in terms of whether, over the term of the permit, and beyond, as appropriate, the restoration measure provided a similar level of stability to the overall population of the species in question that other technologies meeting the standards would have provided.

A facility should not be required to restore more species than are impacted. However, for purposes of trading or other state or local reasons, a facility should be allowed to restore more than are impacted. One way to continue to emphasize the need for the broadest parameters for restoration and credit trading is that ~f restoration is encouraged on a larger scale, we will have better and better information about it, and future restoration efforts may not be so uncertain.

Should EPA set specific, minimum monitoring frequency requirements to deal with uncertainty? One suggestion: once a month over 24 hour period for at least 2 years following permit issuance. Would more frequent sampling be needed to accurately assess diel, seasonal and annual variations in impacts? 67 Fed. Reg. 17149.

EPA should not set minimum monitoring frequency, except to state that monitoring data should be generated as long as necessary to provide representative data. The Director should determine what frequency of monitoring would be appropriate, taking into consideration the circumstances unique to the situation. Some facilities will be dealing with very predictable outcomes, and should not be held to the same level of monitoring as a facility dealing with unique problems and stresses on the biotic population.

More Stringent Requirements

Should EPA allow the Director to require more stringent controls where ordinary compliance would slow the recovery of a listed species? 67 Fed. Reg. 17151.

Only where impingement mortality and entrainment at the facility are clearly primarily responsible for the slow recovery. If there are numerous stressors affecting the species' recovery, the Director should be required to consult with the state's natural resources agency and, as appropriate, the US Fish & Wildlife Service to determine whether other factors should be more closely considered than the CWIS.

RFC: State or Tribal alts. achieve comparable perf.

Should EPA allow states and tribes to suggest an alternate regulatory requirement at the watershed level which would achieve comparable reductions in impacts? If so, what should definition of watershed be? Should states be allowed to demonstrate comparable performance at the state level instead? 67 Fed. Reg. 17152.

This is a good idea. This is one potential mechanism for allowing states and tribes to continue with pre-existing, successful state programs.

EPA Response

Today's final rule maintains the prerogative of a permitted State to demonstrate to the Administrator it has adopted alternative requirements that will result in reductions in impingement mortality and entrainment within a watershed comparable to those that would be achieved under § 125.94. This alternative recognizes the successful achievements of many states in regulating environmental impacts associated with cooling water intakes. In today's final rule, EPA has deferred the decision on the appropriate definition of watershed to the permit director, however, the State's alternative regulatory requirements must be submitted to EPA for review and approval.

Role of States and Tribes (alt./equiv. programs)

What criteria should EPA use to determine whether an alternate state or tribal program to reduce impingement and entrainment mortality is “functionally equivalent”? Should restoration and habitat enhancement be part of a functionally equivalent program? 67 Fed. Reg. 17180.

Restoration and enhancements should certainly be part of a functionally equivalent program. The overall goal is protecting populations. Relying on “functionally equivalent’ further emphasizes this point EPA is right to focus on the bottom line of population protection, and all the features EPA has proposed -- trading, restoration, habitat enhancement, etc. - help focus everyone on the primary purpose of reducing overall adverse impacts.

RFC: Watershed boundaries within political?

At what scale should a watershed be defined to reflect the variability of the receptors? Should watershed boundaries lie within political boundaries of a tribe or state? 67 Fed. Reg. 17152.

The watershed should be defined in the broadest possible terms which make sense as a biological matter. If the watershed goes beyond the jurisdiction of the state or Tribe, the state or Tribe should seek cooperation from the neighboring jurisdiction. If that cooperation can be established, comparable performance should go forward. Although this sounds complicated administratively, we believe in the long haul states and Tribes will successfully establish these relationships, and that industry will be able to allocate its resources toward their most effective use.

Option 3--Site-specific determination

Should EPA use minimum standards for comprehensive cost evaluation studies (to qualify for the site-specific option)? EPA also invites comment on the burden reviewing these studies places on permitting agencies 67 Fed Reg 17153.

Only if such minimum standards do not exclude any significant number of facilities from having a fair opportunity to present their case It is reasonable to ask a facility for the information the Director needs, but it is not reasonable to exclude a facility that would otherwise qualify for a site-specific determination from seeking one because it has no way to get the information EPA is looking for. - Any minimum standard should allow for exceptions The important thing is that the standards be designed so no facility that would qualify for a site-specific determination is arbitrarily forced to comply with the proposed standard, and to absorb particularly high costs.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

For more information on the cost-cost test and the cost-benefit test, please refer to the responses to comments 316bEFR.410.001 and 316bEFR.005.020, respectively.

RFC: Should EPA include impingement trading?

Author Name E. Fitzergerald Veira

Organization Troutman & Sanders obo Georgia Power

Should EPA allow impingement trading, as well as entrainment trading? EPA views impingement control as inexpensive, so there is more need for entrainment trading. 67 Fed. Reg. 17170.

If in fact impingement trading is truly unlikely to generate any real interest, then there is not much sense in establishing a program for it. But EPA should not be quick to dismiss it. There may be instances where facilities are located in close proximity and can work together to allocate the impingement mortality reduction more efficiently through credit trading. Again, trading programs -- for impingement mortality, entrainment, restoration -- all serve to make compliance more effective by reducing costs and maximizing benefits.

RFC: Harmonize of permit reissuance with trading

When should permits be reissued to -trading partners? Should timing be harmonized among partners in a trading area? 67 Fed. Reg. 17173-75.

Harmonizing trading could cause more problems than it solves. If a facility has a credit to sell, it should be able to hang on to that credit until it finds a trading partner, even after it receives its permit. The timing issue should be made an issue for purchasers of credits only, since these facilities will need to procure credits to show that they meet the standard. If the system can be designed so that the sellers are under no time pressure to sell their credits, but still have plenty of incentive to create saleable credits even in the absence of an immediate buyer, then there should not be a major timing issue.

EPA Response

Miscellaneous comment

The following comments are in response to the draft regulations the U.S. Environmental Protection Agency (EPA) is developing pursuant to section 316(b) of the Clean Water Act. They are submitted as part of the formal public comment process and we request that they be included in the record. The Clean Water Act requires that the location, design, construction and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact. EPA's analysis in support of the proposed regulations to date has focused exclusively on near-field environmental effects. We are concerned that the proposed regulation adopts a simplistic approach, ignoring the potential benefits associated with use of existing seawater intakes to support the development of environmentally superior water supplies for the coastal regions of the nation.

Poseidon Resources Corporation is working with a number of water agencies to advance the development of several large-scale seawater desalination facilities in the coastal regions of Southern California, Texas and Florida. These projects are co-located with existing seawater-cooled power stations and reuse the cooling water discharge from the power plant as the source water to the desalination facility. Thus, they are effectively recycling an existing wastewater discharge and creating a number of meaningful environmental benefits as a result.

In California alone, over 200,000 acre-feet per year (AFY) are currently under development. These projects would directly offset the water supply needs of more than one million people that would otherwise be exported from environmentally sensitive areas such as the Sacramento-San Joaquin Delta and the Colorado River and they are considered critical elements of CALFED Bay-Delta Program and the Colorado River 4.4 Plan. The desalination
projects in Texas and Florida would offset demands on groundwater and surface water supplies that are already taxed beyond sustainable levels.

Additionally, recent environmental studies in California and Florida indicate that the combination of desalination plant and power plant discharges significantly reduce the impact of power plant thermal discharge on the environment. However, these environmental benefits, along with the water supply benefits, will not be realized if the promulgation of the Section 316 (b) regulation discourages the co-location of desalination facilities with existing power stations. This is because the economic viability of seawater desalination is closely linked to the ability to use the existing intake and outfall associated with a seawater cooled power generating station.

The scope of section 316(b) inquiry is not limited to the area of the environment directly under the influence of the intake. To the contrary, section 316(b) is a broadly worded statute that simply directs EPA to minimize adverse environmental impact, regardless of location. We urge EPA consider the broader implications of the proposed regulation. Specifically,
EPA needs to consider the opportunity to encourage the environmental benefits of co-locating desalination facilities with existing seawater intakes and in the process of doing so, encouraging the development of environmentally sensitive water supplies.

EPA Response

Because there are no flow restrictions under the final Phase II rule, no allowance would need to be made for Phase II facilities co-located with desalinization plants.

If a desalinization plant is a permitted point source and uses some of the water it withdraws for cooling, then the 316(b) regulations (Phase I or Phase III) could apply to it. The Phase II regulations apply only to facilities that generate and transmit or sell power and, therefore, would not apply to desalinization plants unless they share an intake with a power plant. Furthermore, the distillation plants use water for cooling, but they probably also use the cooling water for process water, so these facilities probably would not meet the threshold for national regulation established in Phase I. Under the Phase I rule, facilities are covered by the national rule if they have a design intake flow of more than 2 million gallons per day (MGD) and if 25% of their intake is for cooling, but facilities do not need to count water withdrawn for cooling if it is recycled and used for another process. Facilities that do not meet the threshold requirements regarding the amount of water withdrawn for cooling purposes must meet any requirements established on a case-by-case, best professional judgment basis.

Some desalinization plants share intakes with power plants. In such situations, the 316(b) regulations would apply to the intake flow attributed to a desalinization plant if the intake flow the flow threshold, but the power plant would be the permitted entity. For example, in Tampa, co-location of a 100 MGD intake/50 MGD freshwater output desalinization plant at a large once-through power plant allows the desalinization plant to use power plant cooling water as its intake without increasing overall water withdrawals and impingement and entrainment from Tampa Bay. The desalinization plant discharges 50 MGD brine to the power plant's large discharge flow, which minimizes the salinity impacts on Tampa Bay (no more than 0.1 part per thousand increase at the outfall and no change from background a short distance from the outfall). There may be more situations like this in the future because of the availability of a large piece of waterfront industrial property or an existing intake structure that the desalinization plant can use without having to go through the permitting process and NEPA/SEPA reviews, or because of some other useful feature of the power plant.

Response to Public Comment

The Electric Power Supply Association (EPSA) is pleased to have an opportunity to provide comments on the proposed rulemaking affecting existing sources under Section 316(b) of the Clean Water Act.

EPA Response

EPA appreciates the comments of the Electric Power Supply Association.

Comment ID 316bEFR.045.002

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 17.08

Option: UWAG's recommended approach

EPSA has been actively following the development of rules under 316(b) and has provided comments on previous proposed regulations. In addition, a number of EPSA members are active participants in other industry groups, including the Utility Water Act Group (UWAG), Edison Electric Institute (EEl) and the Electric Power Research Institute (EPRI). Comments being prepared by those industry groups reflect EPSA member concerns about a number of technical issues raised by this rulemaking. The focus of our comments in this letter will be concerns related to the effects of this rulemaking on the competitive power industry.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

No further response is required. EPA notes the commenter's support for these comments.

Comment ID 316bEFR.045.003

Organization Electric Power Supply Assoc

Subject Matter Code 7.01.03

Option 3--Site-specific determination

As competitive suppliers of electricity to a deregulated marketplace, EPSA members support the development of environmental regulatory programs that use market-based mechanisms to the extent possible, ensure equal treatment for all participants, and provide flexibility that enables affected facilities to achieve compliance through cost-effective solutions. EPSA member companies own and/or operate nearly 100 of the 550 facilities estimated by EPA to be affected by this proposed rulemaking. We recognize that EPA has an imposing task ahead in preparing guidance documents for implementation of the 316 (b) regulations for existing sources, and we would welcome the opportunity to work with EPA in developing this guidance.

We believe that the 316(b) rule for existing sources can address the needs of the competitive electricity market, and we offer the following comments in support of that belief.

EPA Response

Please refer to the response to comment 316bEFR.040.003.

Comment ID 316bEFR.045.004

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 7.01.03

Option 3--Site-specific determination

Flexibility

As EPA has noted, there are numerous factors that affect impingement and entrainment potential at a given cooling water intake structure (CWIS). Because of the variety of locations of power plants, it is critical that the regulations allow the affected facilities flexibility in evaluating and implementing compliance measures. EPSA, therefore, supports the provisions in the proposed regulations that would allow flexibility, such as:

-Alternative technologies to meet performance requirements. By not requiring cooling towers, existing facilities will be able to implement effective aquatic life protection technologies at much lower cost, depending on site-specific circumstances.

-Combinations of alternative methods to meet performance requirements. A combination of methods provides more cost-effective approaches to be taken by existing facilities.

-Varying performance requirements based on water body type, since the same level of fish protection is not necessary in all water body types.

-Varying performance requirements based on water withdrawal rate and capacity utilization rate recognizing that reduced flows and seasonal operations may have less potential impact on the environment.

-Use of site-specific standards, based on valid and appropriate cost-cost and cost-benefit tests.

-The voluntary restoration option as an alternative to technologies for compliance. In some cases, this option may result in a greater environmental benefit than if compliance is addressed by meeting the performance standard using technologies whose performance varies with site-specific conditions.

-Use of trading. EPSA supports the adoption of trading as a tool to facilitate compliance among participants. A well-designed trading program promotes flexibility among the permittees while preserving appropriate measures of environmental protection. Trading can be employed in several ways such as regional or localized methodologies, restoration banking, re-establishment of fish migration pathways, and fish stocking. We have additional thoughts on trading and have addressed these in a separate section later in our comments.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

The commenter supports numerous facets of the rule and applicable references for a more detailed discussion for each are:

-Final rule not based exclusively on cooling towers: section VII of the preamble
-Waterbody type-based standards: 316bEFR.061.004 and § 125.94(b)
-Withdrawal rates and capacity utilization: 316bEFR.061.004 and § 125.94(b)
-Cost tests: 316bEFR.005.020 and 316bEFR.410.001
-Restoration: sections VII and VIII of the preamble to the final rule
Trading: sections VII and VIII of the preamble to the final rule

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 21.01.04

Comprehensive demonstration study (7 parts)

Clarification Regarding Need For Subsequent Demonstrations

The requirement for submittal of a Comprehensive Demonstration with every NPDES renewal application is unnecessary and will result in delays in the issuance of NPDES permits for existing facilities. This assessment is based on current experience with permitting authorities and the time needed to review 316(b) documentation and develop facility NPDES permits. EPSA believes that a demonstration at every permit renewal is a burden for state environmental agencies and is not necessary if there are no substantive changes at the facility or water body. After successful demonstration of compliance with the requirements of the final regulation, at each later permit renewal, the permit writer should accept the initial demonstration, unless there are significant changes in plant operations or significant adverse changes to the aquatic populations, in accordance with specific, agreed-upon criteria to be adopted by EPA.

EPSA supports EPA's intention to allow the use of previously conducted relevant and substantive demonstrations studies for initial NPDES permitting under this proposed rule for an existing facility in lieu of the proposed Comprehensive Demonstration Studies. EPSA requests that EPA provide clarification for the definition of significant changes to the water body and/or facility that would have to occur before a revised 316(b) demonstration would be required. Further, EPSA recommends that the primary responsibility for identifying significant changes in water bodies be placed on state natural resource agencies that have the appropriate experience and information available to make such determinations.

EPA Response

EPA agrees that the submittal of a complete Comprehensive Demonstration Study with each permit renewal might not be necessary. Please see EPA's response to comment 316bEFR 041.126 for EPA's discussion on reducing burden associated with permit renewal.

EPA agrees that existing studies may be used as part of the Comprehensive Demonstration Study, so long as the studies are reflective of current conditions, but EPA does not agree that such studies may be used in lieu of the Comprehensive Demonstration Study in its entirety. For EPA's position on the use of existing demonstration studies, please see EPA's response to comment 316bEFR.040.001.

Finally, EPA disagrees that the natural resource agencies should be responsible for identifying significant changes in a facility's source waterbody or at a facility's intake structure. Rather, EPA believes that if a facility wishes to reduce its information collection burden at permit renewal, it must prove to its permitting Director that conditions remain substantially unchanged and therefore no additional information collection is warranted.

Organization Electric Power Supply Assoc

Subject Matter Code 21.09

Permit applications/implementation schedule

Implementation

EPSA requests that EPA clarify implementation of the proposed regulations through the NPDES permitting process. The time between the effective date of the final rule and implementation has not been defined. Since some facilities may have NPDES permits up for renewal soon after the issuance of the final rule, these facilities will require additional time to prepare work plans and conduct studies required for the application EPSA specifically requests that EPA clarify in the final rule what the application requirements will be and how soon applications will need to comply with the final rule.

As proposed, EPA suggests that the permit application process would be the mechanism for submittal of the demonstration study. In order to allow sufficient time for all permittees to be able to comply with the 316(b) study requirements, EPSA believes that the requirement for the preparation and execution of the study plan should be incorporated into the first renewal of NPDES permit following the promulgation of this regulation. The specific requirements for the studies would be accompanied by a compliance schedule for executing the various activities This approach will allow facilities and the regulatory authority to have an agreed-upon scope and timeframe for completing the work plan and allow sufficient time for agency review.

EPA Response

EPA has clarified timing requirements for the submittal of the required studies. See response to comment 316bEFR.034.066. For a discussion of how compliance with the final rule may be determined, see the preamble to the final rule.

Comment ID 316bEFR.045.008

Author Name Lynn Church

Organization Electric Power Supply Assoc

Monitoring requirements

Compliance

EPSA requests that the regulation include language to establish that compliance with the permit conditions associated with the 316(b) regulations is based on proper installation, operation, and maintenance of the selected approach in accordance with the Demonstration Study, rather than on a numeric performance standard. If a facility's post-demonstration monitoring studies indicate that the numeric performance standard has not been met, the facility's liability should be limited to adding technologies, taking necessary operating measures, or using restoration measures to meet the standard. EPSA also requests that the regulation define "compliance monitoring" as the assurance (through record keeping) that the installed technology is being maintained and operated properly.

EPA Response

Please see EPA's response to comment 316bEFR.035.028.

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 10.05

RFC: Cost-benefit in proposed provision 124.95

Economic Analysis

We commend EPA's proposal to include a cost-benefit analysis. In fact, we believe it is essential to make the rule workable due to the uncertainty that the entrainment alternatives suggested by EPA will be feasible for all facilities. EPA focuses on the monetary costs associated with installing BTA controls compared to the benefits of a reduced level of impingement and entrainment (I & E); at this level of simplicity, EPA's proposal is appropriate.

EPA Response

EPA agrees that cost benefit analysis provides a useful discussion of the costs and benefits of a regulation or other action. EPA would also like to point out that regulatory decisions are based on many factors, and that the Agency considered all of the relevant data, including qualitative benefit estimates, in the section 316(b) rulemaking process. See also EPA's response to comment #316bEFR.005.020 on application of the cost-benefit test to assessing the value of alternative CWIS technologies.

RFC: Test: benefits should justify the costs

Author Name Lynn Church

Organization Electric Power Supply Assoc

Cost Benefit Analysis

EPA considers four alternatives for determining the best technology within the proposal. Only one of these, "the benefits should justify the cost test" (FR p. 17165) is consistent with standard economic criteria and is universally accepted in economics and routinely practiced. This alternative should be the only method included in the final rule as it is the only method that reliably results in decisions to select the alternative with highest overall benefits to society.

EPA Response

See the preamble for a discussion of the site-specific compliance alternative.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Comment ID 316bEFR.045.012

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 10.07.01

RFC: Appropriateness of "wholly disproportionate"

Of the other three methods proposed, the wholly disproportionate cost test and the modified wholly disproportionate cost test will routinely lead to results which make society worse off because they often lead to the identification of a set of alternatives, all of which have benefits that are less than the costs. The "significantly greater than cost test" could lead to the selection of an option from a set of alternatives, all of which have no net or even negative net benefits.

EPA Response

See response to 316bEFR.005.018. EPA would add, regarding the significantly greater cost test, that CWA section 316(b) does not establish a standard for environmental protection that requires that EPA maximize net benefits. Rather, Congress requires in section 316(b) application of the best technology available for minimizing adverse environmental impact. Moreover, EPA has long recognized that there should be some reasonable relationship between the cost of cooling water intake technology and the environmental benefits associated with its use. (See, 41 FR 17387; 65 FR 49094). Such a relationship exists where technologies are economically practicable, but does not require that EPA maximize net benefits. The final rule's compliance alternatives, including the site-specific determination of BTA and the significantly greater test, are reasonable when assessed in this context.

RFC: Cost-benefit in proposed provision 124.95

Cost Evaluation

EPA has not adequately addressed all elements that should be included in the cost assessment of new intake technology. Technical feasibility and reliability, adverse environmental and other effects, and possible safety concerns do not seem to be considered. EPSA recommends that these items, along with a full technology effectiveness assessment, be included in the cost-benefit analysis for each BTA alternative technology as follows:

Effectiveness: The potential effectiveness of the alternative technology selected to reduce impingement and entrainment of aquatic organisms should be evaluated with consideration to the overall effect on the aquatic ecosystem, including an estimate of the anticipated change in the aquatic population. EPSA supports EPA's decision to consider survivability of aquatic biota with respect to both entrainment and impingement when performing a cost benefit assessment.

Technical feasibility, reliability, and safety: Technical feasibility involves an analysis of the technical difficulties associated with the construction, operation, and maintenance of the selected BTA alternative. Reliability involves analysis of the alternative's consistent ability to deliver water to the cooling system. The long-term reliability of each alternative depends on reasonable levels of maintenance to clean and repair elements of the technology.

For example, for a fine mesh screen alternative, the extent and frequency of screen clogging would be estimated and facility maintenanc requirements associated with screen clogging would be considered in the analysis. For an aquatic filter barrier system alternative, the ability of the technology to reliably withstand natural forces, such as storm-induced wave activity for power facilities in open coastal environments, should be considered. Also, for certain applications, the required size of an aquatic filter barrier may be large enough to be a potential barrier to navigation.

Reliable water supply is critical to the safe operation of power plants, especially nuclear power facilities. EPSA supports EPA's decision to allow for a site-specific determination of BTA if there are conflicts with Nuclear Regulatory Commission (NRC) safety requirements. Issues regarding plant safety, operating staff and the surrounding community should be considered.

In summary, EPSA believes that selection of intake technologies for a given site should consider site-specific considerations in the feasibility assessment, including the demonstration in practice of a considered technology under equivalent conditions before being considered as required technology for a particular facility.

Net Environmental Impacts: Consideration of net environmental impacts (other than on aquatic ecology) should include water resources, noise, air emissions, aesthetics, safety, navigation, local law compliance and cost. For example, a cost-benefit analysis of a wet cooling tower alternative would include water consumption, noise, fogging and icing, salt deposition, air emissions (directly from the cooling tower and attributable to electricity consumption and unit efficiency), and aesthetic or visual impacts.

Benefit Analysis

EPSA has several concerns regarding EPA's treatment of benefits analysis associated with this rulemaking. In the paragraphs that follow, we will elaborate on our view that EPA overestimated the benefits of the regulation, used inaccurate supporting data, and used invalid methods to estimate benefits. In particular, EPA's use of the Habitat Restoration Cost (HRC) method as a surrogate for real benefit estimation is completely inappropriate.

1. EPSA is concerned that EPA overestimated the benefits of the regulation. One of the assumptions used in the benefits analysis is 100% mortality for all entrained organisms. Several studies (discussed in more detail in EPRI/UWAG comments on the proposed regulation) have shown that for many species there is significant survivability associated with entrainment. EPA has also assumed that there is no compensation for entrainment losses of eggs and larvae. Studies have shown (again, discussed in more detail in EPRI/UWAG comments) that natural systems compensate for such losses in order to maintain an adult population that is in dynamic equilibrium. EPSA believes that adequate data exist to make reasonable estimates of the level of entrainment survivability and compensation for the benefits analysis in the regulation. If such reasonable estimates are not included, EPA should, at a minimum, explain why they are not included and state that the benefits are likely overestimated.

EPA Response

The commenter asserts that EPA has not adequately addressed elements in the cost analysis, and then fails to provide evidence to support this claim.

The commenter asserts that the Agency did not address technology effectiveness. However, the Agency did address technology effectiveness in its evaluation of costs as an integral element in the selection of technologies at model facilities. The Agency's analysis and methodology for applying costs to model facilities is presented in the Technical Development Document, wherein the issue of technology efficacy is further discussed.

The commenter asserts that the Agency did not address technical feasibility, reliability, and safety in its analysis of costs. However, the Agency did address these issues in its evaluation and selection of candidate technologies applied to model facilities. The Agency conducted research on and outreach with state-of-the-art fish protection technologies and integrated technical feasibility, reliability, and safety study into its documentation of the candidate technologies. For more information see the discussion of each of the "technology cost modules" in the Technical Development Document.

The example provided by the commenter of a fine mesh screen alternative is illustrative of the Agency's point. The Agency analyzed and included costs for fine mesh screens reflective of a realization that maintenance requirements associated with screen clogging would be an integral piece of the analysis, so much so that the Agency includes in its technology cost modules the ability to delineate moderate or high debris loading dependent on Site-Specific factors of the model facility. Furthermore, the commenter's example of aquatic filter barrier systems underlines the Agency's commitment to a site-specific analysis of costs. The Agency was aware of the issue of filter barrier nets and questions of its reliability to withstand strong tidal forces. Hence, the Agency did not apply this technology to any model facility cases in which strong tidal forces would jeopardize the technology's effectiveness. Finally, regarding the example of navigation and barrier technologies: the Agency refers the commenter to the Technical Development Document, in which they will find ample discussion of the Agency's approach to incorporating waterbody navigation and technology feasibility into the analysis of costs for the final rule. Suffice it to say, this item is explicitly accounted for by the Agency for every model facility in the final costing analysis.

Because the commenter supports the final rule's provision for the consideration of site-specific determinations based on NRC safety considerations, then no response is necessary to the previous assertion that the Agency failed to account for this item in the final rule, as the commenter explicitly contradicts himself.

EPA agrees that Habitat Restoration Cost (HRC) method estimates costs and not values to society and therefore is not a surrogate for benefits. Therefore, the HRC is not used in the benefit analysis of the final regulation.

Please see the response to comment 316bEFR.306.506 for the discussion on the appropriateness of EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule.

Please see response to comment 316bEFR.025.015 for a discussion on density dependence.

Pilgrim

It should also be noted that there are several errors and inconsistencies in the benefit analysis conducted by EPA. For example, there are large discrepancies in the number of fish impinged at Pilgrim Station that was used in the in the draft regulation and supporting documentation. It is not clear which of these values EPA actually used in the benefit analysis, and the impact on the results of the analysis can be substantial. EPSA recommends that EPA review and verify the accuracy of the data used in all Case Studies given that these results are relied on to demonstrate the benefits of the rule and could result in substantial overestimates of benefits.

EPA Response

The commenter indicates there are errors and inconsistencies in EPA's analysis but does not provide specific examples. However, EPA believes this comment mischaracterizes its analysis and notes that EPA conducted extensive QA/QC on all of its analyses for the final Phase II rule, as discussed in its QA/QC Plan (Docket #6-1002). Please see responses to related comments on the Pilgrim analysis: 316bEFR.029.106 and 316bEFR.029.103.

Subject Matter Code 10.02.03

Use of Replacement Costs (HRC and hatchery-based)

EPA's HRC method is purely a measure of costs, not benefits. The habitat replacement costs are the design, implementation of administration maintenance, and monitoring costs of various identified means of restoring underwater habitats in the hope of producing the same in-situ services and services flows that are associated with the various technological alternatives under consideration. In other words, these are the costs of other alternatives for achieving the functions as targeted by the proposed rule. While voluntary stocking and/or habitat restoration are acceptable alternative approaches as alternatives to the installation of specific technologies in order to offset entrainment and impingement losses, the cost of such alternatives is in no sense whatsoever a reasonable proxy for the value (i.e., benefit) of reducing entrainment and impingement. At best this method yields the cost of yet another alternative, not the benefit of the original alternatives.

EPA has deviated from proper economic analysis through the application of this method in case studies supporting the rulemaking. Virtually any alternative could be justified by this approach. Simply taking the next, more costly, alternative and calling that the benefit will always result in a finding that "benefits" exceed cost. Thus, EPSA believes that the benefits of the rule have been inappropriately determined and EPA has put forward a flawed methodology that cannot be used either in support of the rulemaking itself or in any decisions made on facility-specific basis. EPSA is concerned with the precedent that could be set by this approach, not just for this rulemaking and its application to the industry but in other rulemakings that affect the industry. EPSA requests that the final rule be amended to allow this method to be used only for the purpose of estimating cost of habitat replacement as a restoration measure.

EPA Response

EPA does not use the Habitat-based Replacement Cost (HRC) method in the cost benefit analysis for the final Section 316(b) Phase II rule.

Please see the document entitled "Habitat-based Replacement Cost Method" (Docket # XX) for additional discussion of the HRC method. Please also see EPA's response to comment #316bEFR.005.035.

Subject Matter Code 10.02.05

Valuing CWIS effects on other species

Another issue that has not been addressed by EPA is with regard to the variable “worth” of various aquatic organisms in specific waterways. In some areas of the country, natural resources managers are actively trying to remove certain exotic, nuisance fish species from their waterways. In other instances, the quality of certain indigenous species is low and of minimal importance to both the recreational industry as well as the overall food web in the waterway Allowances should be made for those facilities whose main impact is demonstrated to be primarily on these “low quality” and/or nuisance organisms.

EPA Response

Problem species are not included in EPA's benefits analysis for the final section 316(b) Phase II rule.

Comment ID 316bEFR.045.017

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 9.0

Costs

Estimated Cost of Compliance

EPSA is concerned that EPA's cost estimate for compliance with the proposed regulation underestimates the potential compliance costs. We believe that sufficient data do not exist to estimate the costs for retrofitting existing power plants with technology that can achieve the entrainment reduction requirements in the regulation - 60% to 90% for many facilities. Such reductions can potentially be achieved by aquatic filter barrier systems, fine mesh screens, or cooling towers, but not at all facilities.

EPA Response

The Agency disagrees with the comment. First, the Agency believes that the final regulation reasonably estimates the potential compliance costs, as documented further in the Technical Development Document. Second, the Agency believes that the entrainment reduction standards of 60 to 90% have been well researched and documented for the technologies considered in the costs development of the final rule. For information on the efficacy of the technologies capable of meeting the entrainment reduction targets, see the technology efficacy section of the Technical Development Document. The commenter states that the reductions can "potentially" be achieved by a select set of technologies, but not at all facilities. While the Agency disagrees with the general assertion, it recognizes that the site-specific nature of fish protection may complicate compliance for a subset of facilities (beyond the wide set of conditions analyzed by the Agency in the final rule). The final rule provides for the flexibility that should a facility determine that the cost of meeting the entrainment reduction targets exceed those considered by the Agency that site-specific alternative requirements be provided for that case. Therefore, the commenters concerns have been considered and met.

Subject Matter Code 7.03.01

Sample facilities/technologies

The proposed regulation gives only one example each for applications of aquatic filter barrier systems and fine mesh screens. It is our understanding that each of these applications has required extensive efforts to achieve some level of reliable operation and the target entrainment reductions. The costs associated with implementing these technologies nationwide cannot be extrapolated from these applications. We understand that several pilot and laboratory studies have been performed that indicate that these technologies can achieve the goals. However, until there are more practical applications in the field, the total costs associated with system installation, fine-tuning, optimization, and maintenance for these technologies cannot be estimated with a great degree of confidence. Even then, these technologies will not be applicable to all power plants.

Author Name Lynn Church
Organization Electric Power Supply Assoc

Subject Matter Code 17.03.01
Ex. facilities converted to closed-cycle

In the proposed regulation, EPA has identified three facilities that operated as once-through cooling plants and then converted to closed-cycle plants using cooling towers. We believe that this is an inadequate database to use for the extrapolation of nationwide costs. Two of the three facilities are located in South Carolina, none are located along the coast, and only one is larger than 500 MW. None of the conversions occurred in the last decade. It is unclear how the availability of fresh water and cost of a reliable fresh water supply were considered in the cost estimate. Fresh water allocation and consumption have become increasingly important considerations nationwide with increased competition for water resources in recent years.

EPA Response

The Agency notes that it identified 4 cooling tower retrofit projects, not 3 as the commenter asserts. However, the Agency does not consider cooling tower retrofits as an appropriate basis for the final rule.

The Agency agrees that the small number of cooling tower retrofit projects that have been completed does not present a sufficient data base for extrapolation to national costs because EPA has concerns about how representative these examples are. Of the four retrofit projects, only two were at facilities greater than 500 MW (not one, as the commenter asserts), but this is still a small set.

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 9.01

Facility & firm-level costs/Econ. Practicability

Economic Practicability

EPA claims that the rule will not be damaging to companies that must bear its costs based on a comparison of the annual cost of the rule to the annual revenues of the companies affected by the rule. This comparison is inappropriate, even if compliance costs are a small percentage of annual revenue: such costs may cause some otherwise profitable firms to lose money on an ongoing basis. Additionally, the business structure of a typical EPSA member is not the traditional utility structure that can be looked at in the large firm sense. Individual facilities may need to be profitable on their own in a merchant market. Required installation and maintenance of control technologies at these independent sites could create a considerable financial burden that may not be offset by fixed contract sales, given the other operations/maintenance and capital costs associated with independent power producers.

EPA Response

Please refer to the response to comment 316bEFR.005.021 in subject matter code 9.01 for a discussion on EPA's economic practicability determination.

EPA notes that the energy market model analyses conducted to assess the economic impacts of the proposed rule, the NODA preferred option, and the final rule assess the impacts of compliance costs at the facility level, not the firm level. These analyses have shown that the expected economic impacts of the Phase II rule on complying facilities are generally small (see Chapter B3, DCN 6-0002).

RFC: Proposed use of restoration measures

Restoration

EPSA supports voluntary restoration as an alternative means of addressing adverse environmental impacts. EPSA also supports the appropriate application of the HRC method to estimate the costs when using habitat as a means of addressing impingement or entrainment losses; however, EPA has made errors in the application of this method in the proposed rulemaking. Below are three reasons why restoration should remain voluntary:

1. EPSA supports EPA's inclusion of restoration as a means of achieving compliance under the proposed regulation. In many situations, restoration may provide the most effective, environmentally compatible, cost-effective, and reliable alternative to achieve mitigation for both impingement and entrainment losses. However, restoration may not be appropriate for all facilities; therefore, as is currently the case in the draft rule, restoration measures should remain voluntary. Further, EPSA recommends that EPA allow facilities and States flexibility to implement restoration measures.

For example, in many freshwater reservoirs the gizzard shad species may be the most common species impinged. States should have the flexibility to use restoration measures that enhance populations of more desirable recreational species than gizzard shad as long as gizzard shad populations are not impaired. Similarly, states and facilities should be allowed discretion to allow broad use of restoration on a geographic basis, such as restoring populations in an area or water body such that there would be a greater environmental benefit that focuses on the vicinity of the facility.

EPA Response

For a discussion of the extent to which restoration measures are voluntary in the final rule, see EPA's response to comment 316bEFR.060.022.

The final rule allows permitting authorities the flexibility to make decisions on the appropriate methods of assessing restoration measure performance on a site-specific, case-by-case basis. All restoration measures must meet the requirements described in the final rule, including those in sections 125.94 and 125.95.

EPA agrees with the commenter that restoration measures may not be feasible for every permit applicant.

Restoration measures must take place in the same waterbody or watershed that contains the cooling water intake structure causing the impingement and/or entrainment impacts. For additional discussion of the appropriate spatial scale on which to conduct restoration measures, see the preamble to the final rule.

For a discussion of the extent to which restoration measures may incorporate state program priorities,

see EPA's response to comment 316bEFR.099.029.

Comment ID 316bEFR.045.022

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 10.02.03

Use of Replacement Costs (HRC and hatchery-based)

As previously stated in our comments EPSA believes the HRC method is inappropriate for use in estimating benefits. Additionally, EPA's use of the HRC to estimate restoration costs in the 316(b) Case Studies is flawed.

For example, in the Brayton Point Case Study, the selection of habitat restoration alternatives for several species was cursory and limited. Several species would either not be helped by the selected restoration project, or there would be more appropriate alternatives that would provide more improvement per unit of restoration. In order for the restoration project to help the particular species whose losses are being mitigated, that species needs to be limited in productivity by something provided by the restoration.

For example, if winter flounder I & E losses are to be mitigated by a tidal wetlands restoration project, as proposed in the Brayton Point and Pilgrim Station Case Studies (Chapters F and G, respectively), then that project should help winter flounder productivity and/or provide equivalent services by increasing productivity of another species. Moreover, if there is an alternative project that would be of more use to winter flounder productivity, this should be selected instead. This example is used because winter flounder do not rely on tidal wetlands (salt marshes) for completing their life cycle and, although winter flounder may be found in salt marshes, the productivity of the species would be unlikely to show much benefit from salt marsh restoration. In addition, the size of a restoration (or created) habitat area for a specific species should consider additional production of that species in the restored (or created) habitat. Another item that should be considered, particularly when the restoration requirements and costs are determined by a single species, is stocking. It should be noted that stocking of winter flounder is currently being conducted at Pilgrim Station and the initial results are encouraging.

EPA Response

First, EPA notes that it did not use the Habitat-based Replacement Cost (HRC) method to estimate benefits for the final Section 316(b) Phase II rule. For additional information, on the method and its uses, please see the document entitled “Habitat-based Replacement Cost Method” (DCN 6-1003).

With regard to site-specificity of restoration cost estimates, EPA disagrees with the commenter's assertion that EPA's estimates are "flawed." EPA met with and received information from local experts with experience in the types of restoration under consideration. EPA believes that the information was sufficiently site-specific, and sufficiently reviewed by local experts to prevent any systematic bias of unit costs. For additional discussion of HRC restoration costing, please see response to Comment 316bEFR.029.119.

Regarding the selection of restoration actions, the assignment of each species to a restoration alternative reflected the consensus of the local experts who were requested to indicate what single action would most benefit the species in the general habitat where the I&E losses were being experienced.

For example, for the Brayton Point Station HRC case study referred to by the commenter, the focus was on actions that could be taken in the waters of, and connected to Mt. Hope Bay and Narragansett Bay. These assignments were made recognizing that local fish populations could be experiencing population pressure from other sources (e.g., commercial fishing) and that some species could benefit from a range of actions.

With this focus on incorporating local knowledge and information, it is possible that species assignments may contradict findings from other regional efforts. However, selecting a preferred restoration alternative based on information on local habitat utilization and constraints is entirely appropriate and should be a component of any reasonable restoration efforts that are looking to offset localized impacts with projects that would be implemented in the same general area.

Finally, EPA's disagrees with the concerns expressed about the restoration action selected for winter flounder. Winter flounder show a high degree of variability in the habitat utilization of young-of-the-year, which are found in marsh creeks (Roundtree and Able, 1992, DCN # 6-2092). Marsh creeks are a feature tidal wetlands (personal communication K. Raposa, Narragansett Estuarine Research Reserve, 2001, docket number 4-1763). This information supports that conclusion that tidal wetland restoration will benefit is winter flounder.

Comment ID 316bEFR.045.023

Author Name Lynn Church

Organization Electric Power Supply Assoc

Subject Matter Code 10.02.03

Use of Replacement Costs (HRC and hatchery-based)

We have a number of cautions regarding the application of the HRC approach to validating that Habitat Enhancement/Restoration offsets resource and ecosystem losses. In most cases proving this offset biologically (that is, demonstrating that an equal or commensurate number of larvae or adult fish of same or similar species are replaced by restored or enhanced habitat) is an unreasonable if not impossible task. In most water body situations, particularly estuarine environments, the number and variety of impacts on the water body are far too complex to reasonably correlate habitat modifications with long term and complex species population variations.

For these reasons, we strongly recommend that any true-up mechanisms for demonstrating the success of habitat restoration and its correlation to CWIS effects be confined to physical demonstration achieved by use, for example, of aerial imaging to verify changes in: water quality (clarity), in habitat quality and quantity, and sedimentation as determined by bathymetric measurements. These types of verifications avoid the much more difficult and variable biological demonstrations of species replacement, which are subject to too many other impacts to accurately correlate to CWIS-related changes.

In conclusion, we do not believe reliance on the HRC approach for demonstrating replacement of biological losses is a valid, defensible, or reliable method. However, the Habitat Equivalency Analysis model itself, given adequate availability of species data, may be able to serve some purpose in acting as a “reality check” on general mitigation acreage requirements of the habitat restoration/program.

EPA Response

EPA did not use the Habitat-based Replacement Cost (HRC) method to estimate benefits for the final Section 316(b) Phase II rule. However, for additional information on the method and appropriate uses, please refer to the document entitled "Habitat-based Replacement Cost Method" (DCN 6-1003). As this information makes clear, HRC is a type of HEA, and therefore if the commenter considers HEA a valid methodology, it is unclear why the commenter rejects HRC.

An HRC analysis provides a comparison of the cost of offsetting I&E losses through habitat restoration with the cost of preventing I&E losses through "best technology available" (BTA). This comparison can be useful for determining the efficacy of actually requiring a technology for a facility or type of facility, for determining possible actions to offset residual I&E that will continue with a technology, and for comparing relative costs of technologies and offsets that may be under consideration at a facility or type of facility.

With respect to habitat restoration alternatives included in EPA's HRC analyses presented at proposal, EPA met with and received information from local experts with knowledge about which restoration alternatives would most efficiently address the majority of species being lost to I&E in the vicinity of the facilities. EPA believes that the information was sufficiently site-specific, and sufficiently reviewed by local experts to include the most relevant restoration alternatives that could address the majority of species in a practical, cost-effective approach. EPA deliberately avoided including highly experimental or uncertain restorations for species that had no obvious and practical restoration opportunities.

RFC: Should EPA include impingement trading?

Trading

EPSA supports EPA proposal to develop a trading program to provide more flexibility for implementation. However, the devil is in the details of such programs. EPSA and its members have a great interest in supporting market-based mechanisms and look forward to working with EPA to develop the details. EPA should draw from its experiences with the various air trading programs and previous natural resource trading programs for fisheries, wetlands, and zoning. A well-designed trading program provides greater flexibility to the permittee and so facilitates greater environmental improvements. Some thoughts on general details:

-The spatial scale for trading should be the largest geographic area possible in order to provide maximum flexibility.

-The unit for trading should be determined based on what promotes achieving the goals at the lowest costs.

-The trading program must take into account how new facilities will be treated. New facilities should be included in the program to avoid the creation of a two-level playing field and to improve the fluidity of the market.

-EPA should consider expanding the trading program to include other stressors to relevant water bodies. Expanding the potential participants will increase participation and improve market viability. (Stressors identified by EPA in the proposed rule include: habitat alteration, coastal development, dredging, fishing, industrial pollution, nutrient pollution, and waste water runoff)

EPA Response

Please see response to comment 316bEFR.034.027 regarding the role of trading in today's final rule. Please see response to comment 316bEFR.077.052 regarding the unit of trading, comment 316bEFR.077.051 regarding the spatial scale of trading, comment 316bEFR.005.045 regarding trading among new facilities, and comment 316bEFR.005.046 regarding trading for other stressors.

RFC: Cost-benefit in proposed provision 124.95

EPSA does, however, have concerns regarding EPA's economic analyses of alternatives, especially with regard to errors in the development of costs and benefits, as well as the application of the HRC method for estimating benefits. EPSA also requests the clarification of several implementation considerations, as noted.

EPA Response

EPA disagrees that the benefit cost analysis prepared for the 316(b) regulation is seriously flawed. No methods are available for estimating either costs or benefits with perfect accuracy or without uncertainty. EPA's approach to benefit cost analysis of the final Section 316(b) Phase II rule is consistent with principles outlined in the EPA's Guidelines for Preparing Economic Analyses, United States EPA (EPA 240-R-00-003). The Agency believes that despite its limitations, the benefit cost analysis prepared for the final 316(b) rule provides useful, significant, and sufficient information for rulemaking purposes regulatory decision.

EPA has responded to specific concerns regarding the development of costs in Section 9.0 of the 316(b) Phase II Response to Public Comments document.

EPA has responded to specific concerns regarding the development of benefits in Section 10.02 of the 316(b) Phase II Response to Public Comments document.

The habitat-based replacement cost (HRC) method is not used in the cost benefit analysis for the final Section 316(b) Phase II rule. For EPA's response to comments on the HRC method, please see response to comment # 316bEFR.005.035. For additional information on the HRC, please see the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003).

Comprehensive demonstration study (7 parts)

Facilities which withdraw cooling water from zones that would preclude significant entrainment or impingement of aquatic organisms should be exempted from any requirement to perform a Comprehensive Demonstration Study. For example, South Carolina Electric & Gas Company's McMeekin Station withdraws cooling water from Lake Murray through one of the intakes of the Saluda Hydro facility. This arrangement enables McMeekin Station to withdraw cooling water from an average depth of about 140 feet below the surface of the reservoir. At this depth, the presence of viable larval fish or other planktonic organisms is unlikely. Impingement related to McMeekin Station is also unlikely since Saluda Hydro intakes employ bar racks only to screen large debris. It would also be extremely difficult to implement a sampling plan that would quantitatively sample the biological assemblages at this depth.

EPA Response

In the example given, it is possible that the facility does not cause impingement mortality or entrainment of organisms to a level above that of the performance standards, though EPA has left such determinations to the individual permitting Directors. Please see EPA's response to comment 316bEFR.041.007 for EPA's position on facilities with impingement mortality and entrainment rates lower than today's performance standards.

Implications for nuclear facilities

Retrofit costs for nuclear facilities could be much greater than for fossil facilities. The availability of a cost test that balances the conversion costs from once-through cooling to closed-cycle cooling against the actual environmental benefits is crucial.

EPA Response

The cost to cost and the cost to benefit tests have been retained for the final rule. Cooling tower retrofits do not form the basis of requirements for the final rule. The Agency recognizes that costs at existing nuclear facilities will exceed those of fossil-fuel facilities, see response to comment 316b.EFR.029.027.

Implementation

The final rule will probably cause a flurry of activity in the development and implementation of comprehensive demonstration plans and compliance monitoring. This could put significant strain on the pool of contractors available to perform these activities. The limited availability of qualified contractors could cause delays or sub-standard data quality.

EPA Response

EPA disagrees that the implementation schedule will pose an unreasonable burden on contractors. It is EPA's experience that a sufficient number of qualified contractors will be available to assist facilities and States as needed.

Performance standards

Author Name Shirley M. Ruffin

Organization SCANA Services, Inc.

SCANA has concerns over how "calculation baselines" would be determined. Would the baseline calculation assume a particular flow rate and velocity? Facilities with existing low velocity intakes (< 1 fps approach velocity) and resulting low impingement numbers might be penalized for their good design if they were expected to reduce their impingement by 80 - 95% from what they currently experience. If a higher velocity intake were assumed, the calculation baseline could be much higher. The higher the calculation baseline, the more "improvement" could be shown for any facility modification. In the case of facilities with intake canals, how would they scale their existing impingement numbers for a hypothetical shoreline intake? If the EPA intends to go forward with the "calculation baseline" concept, then it needs to develop detailed guidance on how the baseline would be calculated and ensure that the methodology doesn't unnecessarily penalize plants with good impingement performance.

EPA Response

For discussions on the basis for and implementation of the calculation baseline, please see response to comments 316bEFR.308.014 and 316bEFR.063.022, as well as the preamble to today's rule.

RFC: Alt. thresholds for entrainment (E) controls

SCANA supports the use of spawning season flows rather than mean annual flows in determining thresholds for entrainment controls. Larval fish and shellfish would be expected to be present in the greatest numbers in waterbodies during the spawning season. Five percent of the spawning season flow is a more realistic impact threshold than 5% of the mean annual flow.

EPA Response

EPA believes adopting a seasonal flow based on spawning events would be difficult to incorporate into a permit as seasonal flows, as well as spawning and migration patterns, are rarely consistent year to year. Incorporating a seasonal flow (or other standard) into a permit would introduce unnecessary implementation and monitoring costs on both the permitting authority and the facility. EPA believes the design intake flow standard for riverine facilities affords a level of protection for the source water body acceptable under most, if not all, stream conditions. The 5% threshold provides a consistent metric against which permit requirements can be developed. Today's rule maintains the 5% mean annual flow threshold.

Use of Replacement Costs (HRC and hatchery-based)

Introduction and Summary

On behalf of the owner of the Brayton Point Station, PG&E National Energy Group, I have reviewed the HRC methodology contained in the proposed 316(b) rule, specifically focusing on the application by the EPA to the Brayton Point cooling water intake system Impingement and Entrainment (I&E) losses. I have identified a number of flaws in EPA's use of the HRC methodology and its application to the Brayton Point Station. My comments are summarized here and explicated in detail in the following sections.

Inappropriate Use of Habitat Replacement Costs as Valuation (Benefit) Measure: EPA proposes to use estimates of replacement cost (via habitat restoration) as a substitute for valuation of I&E losses. This is incorrect both conceptually and in result, as the value of resources to humans is unrelated to the costs of restoring or replacing those resources. Common and low value species may be expensive to restore simply because no research has been directed at that effort, while valuable species may be relatively inexpensive to restore. While not an appropriate tool for valuation of I&E losses, in some circumstances habitat replacement may be appropriate to offset or mitigate I&E losses.

Failure to Identify Appropriate Restoration/Enhancement Techniques that Provide Net Gains in Species Productivity: EPA asserts that it has chosen the most effective HRC method to mitigate the loss of each type of species lost to I&E at the Brayton Point Station (p. F5-1). However, this is not in fact the case. In order for a restoration technique to provide a net gain for the particular species whose losses are being mitigated, the productivity of the species needs to be limited by something provided by the restoration project, such that there is a resulting net gain in production. Moreover, if there is an alternative technique that would result more of an increase in a species productivity at the same or less cost, this alternative should be selected instead. The life history of the I&E species needs to be researched carefully to identify the limiting factor(s) for the population during each life stage. The limiting factor is typically very different at different life stages. Thus, the restoration technique needs to be targeted to specific life stages and provide something that is limiting to the growth and survival of that life stage. One problem with EPA's application of HRC to Brayton Point (admitted by EPA) is that for some species the selection of restoration alternatives was cursory and limited. The productivity of several species would not gain by the selected restoration technique selected by EPA. As to other species, there are more appropriate alternatives that would provide more production gain per unit of restoration. No criteria are provided or apparently followed by EPA as to how the preferred alternative was selected.

Failure to Account for the Various Ecological Services Provided by Habitat Restoration/Enhancement Projects: Most of the ecological services provided by I&E losses are as food to the marine food web. The purpose of habitat restoration/enhancement should be to provide a net improvement in fish production and not to offset each individual one-for-one with the same species affected by I&E. EPA has failed to consider or quantify provision of ecologically equivalent services to those provided by the I&E losses. One-for-one replacement would only be warranted if the population is limited by the size of the spawning stock. If abundant eggs are produced by the spawning stock, such that the population is limited by other factors than supply of new eggs to the population, one-for-one replacement of that species is not needed.

Need to Identify Most Cost Effective Method for Restoration: Alternate restoration projects being considered as mitigation should be scaled and costs developed, such that the most cost-effective option may be chosen. Since direct one-for-one species replacement is typically much more costly than the value (economic benefits) of the I&E losses, replacement of ecological services is a much more appropriate approach.

Inappropriate Dismissal of Restocking as a Preferred Restoration Alternative: The EPA has stated that there is considerable uncertainty in the success rate of restocking programs and so has dismissed it as a viable method, choosing instead habitat restoration. However, restocking is the most direct way to replace I&E losses, particularly for those species where an appropriate habitat restoration technique cannot be shown to provide a net gain in production or is not feasible. The uncertainty of the success of the habitat restoration and its ecological effects on the target species is as large or larger than for restocking.

Errors in Methods Used to Estimate Production: EPA has failed properly to calculate the net production gained by habitat restoration/enhancement techniques. EPA incorrectly used abundance as a proxy for production. The correct methodology is to use production foregone on the loss side of the equation, and balance this with production gained by all age groups owing to the restoration. Additionally, discrepancies exist in the methods EPA used in their HRC calculations between the Seabrook/Pilgrim case study and the Brayton Point Station study. EPA utilized results from the same studies to determine the average density of species between the two sites, while using very different survival rates from juvenile to age-1 to convert the juveniles measured on these habitats to age-1 equivalents. Since the same studies were used to derive the densities on each habitat type, it does not follow that the survival of individuals in these habitats would differ. EPA has also made errors in its calculation of production foregone on the loss side of the equation, resulting in inflated estimates of losses.

Errors in Methods Used to Estimate Costs: EPA's estimate for the unit cost of SAV restoration is almost three times higher than that derived by NOAA's Restoration Center (in Guidelines for the Conservation and Restoration of Seagrasses in the U.S and Adjacent Waters). EPA's restoration cost for shallow artificial cobble reef, which is the habitat for which it projects a gain in juvenile tautog productivity, are erroneously based on costs for constructing a deeper artificial reef designed for lobsters and that would be of no use to young-of-the-year tautog. In addition, costs for a 1024 m2 reef are scaled up to a hypothetical 41 km2 reef project, which is both infeasible and inappropriately costed as explained in detail below.

Failure to Identify Most Cost Effective Method for Mitigation: The appropriate decision process is to select alternatives that either (1) provide habitat that is limiting to the population's productivity (i.e., is useful in increasing productivity because the habitat is in limited supply and/or in degraded condition), (2) reduce mortality to fishing and other causes, (3) replace missing individuals using restocking techniques, or (4) provide equivalent ecological services. EPA has decided a priori that habitat restoration should be the method used, regardless of net gains in productivity and reasonableness of costs.

Appropriateness of Using a Mitigation Ratio Greater than 1:1: The purpose of a mitigation ratio (where more mitigation is to be performed than would be needed based on calculations of production lost versus production gained) is to compensate for the uncertainty of the success of the mitigation project. If all of the gains of the mitigation project were in fact estimated in a quantitative fashion, the mitigation ratio might be warranted. However, in the case where all the services gained are not quantified, the scale of the mitigation already over-compensates for the losses. EPA has not accounted for many of the ecological services supplied by restoration projects. In contrast to EPA's conclusions in Chapter F5-9, the case study does not underestimate needed mitigation because EPA failed to consider all ecological services provided by the proposed restoration. Moreover, EPA has not identified the most effective restoration alternatives for several of the species. Thus, habitat restoration scaled in this manner should not be mitigated at a greater than 1:1 ratio.

Each of these points will be explicated in detail below.

Inappropriate Use of Habitat Replacement Costs as Valuation (Benefit) Measure

In its proposed 316(b) rule, EPA proposes to use estimates of replacement cost (via habitat restoration) as a substitute for conceptually sound and empirically valid methods of valuing I&E losses. In essence, EPA claims that the cost to restore resources is a correct measure of their value. This is conceptually incorrect, as the economists have noted. The value of resources to humans is unrelated to the costs of restoring or replacing those resources. For example, it might be quite inexpensive to restock a species that is highly valued for commercial or recreational fishing or non-use (i.e. the value that people may derive simply from knowledge of the species existence in some area), and likewise it may be relatively expensive to restore another species that has been little studied with respect to restoration methods (precisely because of its low commercial, recreational, and non-use value). Using restoration costs as a measure of value would lead to exactly the wrong conclusion: the implication would be that the high-value species has low value because of the low costs required to restore it, and the low-value species has high value simply because it is relatively costly to restore it.

As the economists have pointed out, EPA is committing a fundamental error by confusing costs and benefits in its attempt to substitute an "avoided cost" estimate for a real measure of true benefits to humans.

EPA incorrectly states (Chapter A11-1.3) that the use of HRC as a valuation method is consistent with federal court findings regarding NRDA regulations under the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA) and the Oil Pollution Act of 1990 (OPA). In fact, Congress created a special exemption from the general rule in these two statutes. That exemption is not available in the context of NPDES permits. Moreover, even where the exemption applies, Congress and the courts have required that the cost of restoration be proportionate to the value of the injured resources.

The economists have documented elsewhere the inappropriateness of using habitat replacement or species restoration costs as economic valuation methods. As biologists, we address a different issue in these comments: whether EPA has appropriately laid out the concepts and methods to estimate restoration costs associated with I&E losses in its HRC method. This is itself an important question, because while the cost of restoration/replacement is not a reasonable proxy for the economic value (that is, the benefits) of reducing I&E, habitat restoration and/or restocking may be acceptable approaches as alternatives to the installation of specific technologies in order to mitigate I&E losses. Hence, in the remainder of these comments, we address EPA's recommended methods for mitigation and attempts to estimate its costs, with particular focus on the case study of the Brayton Point Station.

EPA has failed to Identify Appropriate Restoration/Enhancement Techniques that Provide Net Gains in Species Productivity

EPA asserts that it has chosen the most effective HRC method to replace each of the I&E species for the Brayton Point Station (p. F5-1). However, this is not in fact the case. In order for the restoration technique to be of assistance to the particular species whose losses are being mitigated, the productivity of the species needs to be limited by something provided by the restoration project, such that there is a net gain in production. Moreover, if there is an alternative technique that would result more of an increase in a species productivity for the same or less cost, this alternative should be selected instead. For example, if survival is controlled by predation, providing a refuge from predation would improve production. If however, food is more limiting to growth and survival, restoration that provides additional food or feeding habitat would be the appropriate choice to improve production. Thus, the life history of the I&E species needs to be researched carefully to identify the limiting factor(s) for the population during each life stage. The limiting factor(s) are typically very different at different life stages. Thus, the restoration technique needs to be targeted to specific life stages and provide something that is limiting to the growth and survival of that life stage.

One problem with EPA's application of HRC to Brayton Point is that the selection of restoration alternatives was according to EPA itself cursory and limited (Chapters F5-3 and F5-4). EPA also relied heavily on the advise of personnel from environmental groups, who are not restoration experts. The productivity of several species would not be increased by the restoration technique selected by EPA. As to other species, there are more appropriate alternatives that would provide more production gain per unit of restoration. Several species and EPA's selected habitat techniques are examined below to demonstrate the flaws in EPA's selected restoration/enhancement techniques for mitigating the Brayton Point I&E.

The tables in Appendix A (attached) summarize the life history of the species entrained and impinged at the Brayton Point plant. Information was sought on the habitat usage by each life stage and the factors and habitats that are likely limiting to that life stage. This type of analysis should be used in identifying potential restoration alternatives that would in fact provide a net gain to the populations of concern. While EPA briefly summarizes the life history of I&E species (Chapter F3), it fails to identify the likely limiting factors for the species involved. Instead, the use of a habitat by a life stage is implicitly assumed to be indicative that the amount and/or quality of that habitat available is limiting to production. In some cases EPA arbitrarily assumes a habitat restoration technique will produce a net gain in production, even if there is no evidence that it would be beneficial to the species.

Tautog (Tautoga onitis)

Eggs, larvae and juvenile tautog utilize shallow (especially <1m deep) vegetated habitats, such as eelgrass (Zostera marina) and seaweed (macroalgae, e.g. Ulva lactuca, Codium fragile, Enteromorpha sp., Chondris crispus, Fucus sp., Laminara sp.) for development, feeding and refuge from predators. As eelgrass beds are limited in extent in Narragansett and Mount Hope Bays, macroalgal habitat is the dominant benthic cover in shallow waters and is an important nursery area for this species. In her four-year study of the distribution, abundance and habitat characterization of juvenile tautog, Dorf (1994 PhD thesis, University of Rhode Island) found the habitat that produced large numbers of juveniles in all years was characterized by a sandy bottom and consistent density of medium to high (25% to >75%) macroalgal cover. This contrasted with shallow areas with gravel/cobble bottom and little to no macroalgal or eelgrass cover, which supported no more than one juvenile collected in any year. The mean monthly juvenile tautog density for sixteen Narragansett Bay sites in shallow water of varying vegetation cover density ranged from 0.03-8.1 fish per 100 m2. An average of 3.48 " 1.4 tautog per 100 m2 were collected at the station of medium to high macroalgal cover that consistently produced large numbers of juveniles between June and October 1988-1992. This is opposed to the mean density of 0.012 " 0.04 tautog per 100 m2 caught during the same sampling period at the gravel/cobble bottom station with little to no macroalgal or eelgrass cover (Dorf, 1994).

Adult tautog utilize vegetated habitats, as well as natural and artificial reefs and structures. As tautog are considered over-fished, the adult population size is limited primarily by mortality to fishing. Deeper reef structures, such as those in Dutch Harbor used for cost information on artificial reefs (Chapter F.5-7.3), might reduce predation mortality on adults (although evidence for this is lacking), but would be of no use to egg, larval or juvenile stages. The most effective means of replacing adult tautog would be to reduce fishing pressure, an option listed by EPA in Chapter F5-3 but not discussed or considered further. This option should be considered, along with habitat restoration and restocking (see discussion below).

If habitat restoration is to be used for mitigation, rather than creating artificial reef in relatively deep water (used by adults) to offset tautog I&E losses, it would be more beneficial to restore eelgrass and/or macroalgal species in shallow water areas. While macroalgal restoration has not been attempted in the area, macroalgae typically colonize eelgrass beds and shallow rock-boulder areas that are relatively stable (as opposed to continuously shifted by surf). Thus, the addition of substrate in shallow water (eelgrass or possibly other structures) would encourage macroalgal vegetation as well. The restoration of submerged aquatic vegetation (SAV), including eelgrass and macroalgae, would produce more tautog recruits to the population than gravel/cobble bottom, based on the data provided by Dorf (1994).

EPA's extraordinarily high figure for the scale of artificial reef assumed to be needed results in part from inconsistent and incorrect use of data and a lack of clarity on the type of habitat to be restored. While the scaling of the artificial reef was based juvenile production in shallow cobble habitat, the costs were based on deeper artificial reef more suitable to lobster and adult tautog. Either the scaling should have been based on the tautog age classes produced, or (more appropriately) the costing should be for the habitat type to be restored.

Winter and Windowpane Flounder

As EPA itself acknowledges in Appendix A and in Chapter F3, winter flounder do not prefer or rely on tidal wetlands (salt marshes) for completing their life cycle. Although winter flounder may be found in salt marshes, the productivity of the species would be unlikely to exhibit significant changes due to salt marsh restoration. Thus, EPA's choice to restore tidal wetlands in order to mitigate winter flounder is inappropriate.

Similarly, windowpane flounder would not gain significantly from salt marsh restoration. This fact is noted by EPA, and tidal restoration is not selected for that species.

Both these species are limited in production by fishing, predation and other sources of mortality. Fishing pressure has increased substantially over the past few decades, clearly causing a decrease in the populations. Additionally, cormorants, jellyfish, and other predators have increased exponentially throughout the Narragansett Bay system (as well as New England waters) over the last 20 years, which is undoubtedly reflected in higher mortality rates. Potentially, food resources could be limiting, particularly to younger stages. Thus, appropriate restoration techniques would need to decrease mortality, such as further reducing fishing pressure, or improve natural survival rates by changing environmental conditions to be more favorable or by providing food resources to increase growth. Again, EPA has failed to consider further reduction in fishing pressure, which is the most likely method to succeed in increasing flounder production.

The choices of habitat restoration techniques that would increase the productivity of these species are limited. Alternatives for habitat restoration could include:

-Improvement of water quality in waters of low oxygen limiting egg and larval survival

-Reduction of predation losses by creating refugia (possibly by providing alternate food for predators)

-Addition of food to the food web by eelgrass bed restoration, as this is a more productive habitat than open shallow water, and the entire food web (including the flounder) would gain.

In view of the difficulty and uncertainty of habitat restoration, restocking would appear to be the most direct replacement alternative, if it can be performed successfully (see discussion below). EPA is incorrect to rule out restocking as an alternative, only to choose much more uncertain restoration techniques.

Potential Net Gains Resulting from Tidal Restoration by Phragmites Removal

In Chapter F of the proposed rule, the EPA advocates tidal wetland enhancement as the preferred habitat restoration technique to mitigate some I&E losses. The enhancement technique selected involves removal of the common reed Phragmites australis (an invasive reed grass that alters habitat structure) and improvement of tidal flows into the marsh. The goal is to change the common reed marsh to a (native) salt marsh dominated by Spartina spp.

Phragmites australis has expanded rapidly in areal coverage over recent decades in marshlands along the northern and middle Atlantic coasts. The rate and pattern of this increase is perceived as invasive and related to anthropogenic interference either through genetic introductions or disturbance. Thus, the removal of Phragmites is popular and high on the environmental group Save the Bay's list of preferences for restoration. As Save the Bay was a primary organization consulted by EPA (Chapter F5-4), this technique was selected over other possible and more productive wetland restoration options (which don't even appear to have been considered).

There is a general lack of quantitative production data showing that Spartina marshes are more productive than Phragmites marshes. This calls into question the scaling of HRC for marsh alteration from Phragmites to other marsh types to improve productivity.   Thus, the data used to measure net gains needs to be reviewed and selected carefully, to be sure the technique used is in fact one that provides a net increase in ecological services.

EPA did not compare fish production or abundance in Phragmites marshes versus salt marshes in its case study example for Brayton Point. In fact, much of the abundance data used was in not even from wetland habitat (in particular for winter flounder which is supposedly aided by tidal wetland restoration).   Abundance data from a variety of habitats were apparently averaged, and it was assumed that this would be the net gain of a undefined tidal restoration project. Thus, the data used to scale the tidal restoration is entirely unreliable for this use.

Failure to Account for the Various Ecological Services Provided by Habitat Restoration/Enhancement Projects

EPA has failed to account for ecological services provided by the restoration techniques that would be equivalent to the services lost to I&E. Instead, EPA adopted an overly simplistic approach by which it assumes that all individuals need to be replaced in kind. That approach fails to recognize that any given restoration technique may provide equivalent services to I&E losses by increasing productivity of other species of similar ecological role and so mitigate the losses.

Continuing with the winter flounder example: some of the services of winter flounder larvae are to become prey to larger organisms.   Those larger organisms are flexible enough to eat other species of prey, as is the case for most marine predators. Thus, the prey service provided by (age-one) winter flounder can be replaced by production of another or several equivalent prey species. The replacement of winter flounder need only be enough to provide services unique to that species, i.e., larger winter flounder that survive the predation and fishing pressure and contribute to the next generation via reproduction. In order to take this approach, the winter flounder individuals that would otherwise survive would need a refuge from predators and fishing, perhaps by providing predators with alternate food sources or by reducing fishing pressure.

For example, age-one equivalent flounders, which serve primarily as prey for other species, and secondarily as recruits to the fishery, may not themselves be directly aided by the creation of SAV. Yet, SAV produces other species that serve as prey for the fish predators, as well as additional food for flounders and the food web generally. Small fish production in such a habitat should be considered suitable for and taken into account in offsetting the I/E losses of age-one equivalents that would otherwise be taken by predators by virtue of providing the equivalent services. Only the fraction of the age-one equivalents that would otherwise be recruited to the spawning stock and make a difference to the next generation of the species would need to be replaced one-for-one. Moreover, this one-for-one replacement would only be warranted if the population is limited by the size of the spawning stock. If abundant eggs are produced by the spawning stock, such that the population is limited by other factors than supply of new eggs to the population, one-for-one replacement of that species is not needed.

The same point would be made for other species. Some of the services of the species and life stages entrained and impinged are to repopulate the local spawning and fishery stock of that species, while other individuals serve as prey to the food web. As most marine animals are opportunist feeders, replacement of similar sized fish prey would replace those ecological services. Thus, we argue that much (if not all) of the mitigation should be in the form of increased production of similar prey to those lost to I&E. This approach has been used in the restoration of many species injured by the North Cape oil spill (French et al., 2001), and in other NRDA cases, as well as development mitigation projects in development projects.

The basic approach is to select a biological restoration or enhancement activity that will provide a net gain in terms of fish production, such as creating seagrass beds or wetlands (salt marsh) that provide habitat and food services to fish, such that there is a net increase in the total fish production of the ecosystem. Seagrass and wetlands have been shown to be more productive in terms of weight of fish produced per unit area than unstructured habitats. However, because some species prefer open bottom, while others prefer these structured habitats, the net fish production gain may not be of the same species as the losses. It may nonetheless be appropriate if it results in production of similar sized fish which provide ecological services to the food web, as well as other ecological services, and so this is compensatory to the losses (French McCay et al., 2001).

Inappropriate Dismissal of Restocking as a Preferred Restoration Alternative

The EPA has stated that there is considerable uncertainty in the costs and success rate of restocking programs and that there are ecological concerns with stocked animals (Chapter A11-1.1). However, restocking is the most direct way to replace I&E losses, particularly for those species where an appropriate habitat restoration technique cannot be shown to provide a net gain in production or is not feasible. The uncertainty of the success of the habitat restoration and its ecological effects on the target species is as large or larger than for restocking. Restocking directly addresses the lost use as a fishery, which, for example, is a particular concern for winter flounder for which tidal wetland restoration would be of little use.

Despite EPA's concerns associated with hatcheries, such as the idea that propagated fishes might prey on or compete with endangered species or might alter the evolutionary genetics of the native species, there have been numerous success stories for restocking programs. Some species that have increased in productivity from restocking are striped bass, endangered shortnose sturgeon (produced 11,000 fry in South Carolina), rainbow trout, lake trout, and turbot (http://southeast.fws.gov/fisheries/hatcheryindex.html).

There are a number of finfish hatcheries in the northeast United States that are focusing primarily on some of the species that have been listed as being impinged or entrained at Brayton Point CWIS. In particular, these include winter flounder and tautog. For the last three years, winter flounder have been reared at Great Bay Aquafarms in Portsmouth, New Hampshire and Llennoco Inc. in Chatham, Massachusetts, who have been supplying the Plymouth Mass Pilgrim plant, in Plymouth, Massachusetts. Recaptures have been recorded at each location. Great Bay Aquafarms (GBA) specializes in the aquaculture of summer flounder (Paralichthys dentatus), which have a similar life history to the winter flounder (Pleuronectes americanus). The GBA hatchery, alone, has an annual capacity of up to 1 million 5-10 gram juvenile summer flounder for stocking its farm. Once stocked into their on-growing operation, the juvenile flounder then reach a 1.5 kg harvest size in 16-18 months.

Juvenile tautog (Tautoga onitis) are currently being raised and studied at the MIT Sea Grant Fin Fish Hatchery in the historic Navy Yard in Charlestown, Massachusetts. At this site, a relatively new and innovative recirculating system has been constructed. This system requires a tank, from which the water flows out through a particle filter to remove waste and excess feed. A pump is then plumed in to aid in the movement of the water through the rest of the system. The water then gets pumped up through a biological filter that strips the water of toxic forms of ammonia that are dangerous to the animals. Water then passes through a UV treatment to reduce the bacteria and virus growing within the system. The water then returns to the tank. (http://web.mit.edu/seagrant/advisory/hatcheryprojects.html).

Additionally, two sites have been proposed as potential summer flounder hatcheries in Rhode Island (http://www.rilin.state.ri.us/leg_bios/naughton/aqua2/APPB.html). These are AquaFuture and V.G. Sea Farms, which would both be located in the Quonset Point/Davisville Industrial Park in North Kingstown. AquaFuture is proposed to produce approximately 200,000 juvenile summer flounder per year, some of which will then be sold to grow-out facilities such as V.G. Sea Farms and Trio-Algarvio in New Bedford, Massachusetts. At V.G. Sea Farms, shallow raceways and a recirculating system would be used to produce an expected 50 tons of fish per year.

Numerous research projects are ongoing in regards to the proper methods to use in order to get the best net production of these species, especially winter flounder, and to the overall success of restocking programs. In particular, at the University of New Hampshire, Dr. W. Hunting Howell and his PhD candidate, Elizabeth Fairchild, are studying the feasibility of winter flounder stock enhancement, and are attempting to answer some important questions, such as when and where the fish should be released (http://zoology.unh.edu/faculty/howell/grad/efairchild/fairchild.html).

Errors in Methods Used to Estimate Net Gains in Production

EPA improperly used species abundance as a proxy for production

While production is the appropriate scalar for measuring the gains of restoration, as described by EPA in the methodology in Chapter A11, in the Brayton case study (as well as others) EPA has stated that data are lacking and so has used instead abundance estimates, corrected to age-one equivalents, as measures of production (Chapter F5-5). In other words, they have implicitly assumed a production-to-biomass ratio of 1:1 (biomass being the standing stock or abundance at a given instant in time). EPA implicitly assumed that the standing stock is not turned over in time, and that those individuals observed at the sampling time are all the individuals that will be produced that year at that age sampled.

An analogy that illustrates the problem is as follows. If replacement income is sought for a person loosing his job, it is the annual salary that should be replaced. The quantity of dollars present in that person's wallet at any one time (when someone happened to query him) may be larger if their salary is larger, but there is not a one-to-one equivalence between his income and the amount in his wallet on a single day, or even with the average of what is in his wallet on a random sampling of days. If the person is paid his annual salary on one day of the year, and the sampling is made on the day he takes home his money, then perhaps the standing amount in this wallet is equivalent to annual salary.

The assumption of a production-to-biomass ratio of 1:1 is invalid for short-lived species that reproduce multiple times a year or at varying times during the year, such as for many of the forage fishes. Also, if a species has a protracted spawning period, such that individuals pass through a life stage using a particular habitat at varying times, the snap-shot standing abundance at any given time would not capture all the production in the habitat. Only in the limited circumstances when all life stages up to age one year use the same habitat and the species spawns over a limited season, will the standing abundance be indicative of annual production of age-one equivalents.

The details of the data used for estimating production from young-of-the-year (YOY) abundance for Brayton Point I&E species are not provided in the proposed rule documentation. Based on the standard life stage tables for the Brayton Point I&E species, it is apparent that the abundance measure does not measure all the production for most I&E species:

The I&E species spawn over at least three months, and many species have more protracted spawning periods (Appendix A and Chapter F3). Thus, there is turn-over of individuals, with new individuals replacing those moving into older stages. The assumed age of the animals for the abundance data used is not documented, and the uncertainty introduced by error in this assumption, as well as by the mortality rate estimate for the remainder of the first year of life, would be extremely large.

Winter flounder YOY do not preferentially use salt marshes as nursery grounds. Thus, the abundance observed in salt marshes is not indicative of production gained, as animals likely move in and out of the habitat sampled. Certainly the abundance in open water habitat is not indicative of production in tidal wetlands, as erroneously assumed by EPA.

Forage fish such as stickleback, reproduce at varying times of the year, and predation rates are high, making a standing stock abundance at a single time a poor indicator of annual production.

The correct methodology is to use production foregone on the loss side of the equation, and balance this with production gained by all age groups owing to the restoration. If survival is increased from the sampled stage to age-one equivalents, or if production of older age classes is improved, the use of abundance corrected to age-one equivalents using the same survival rate as in less advantageous habitat provides an underestimate of the net gains of the restoration. While data are lacking in the form of production rate per unit area, estimations may be made using population modeling.

If young-of-the-year (YOY) abundance data are used to estimate age-one equivalent production per unit area of habitat, it is important to take into consideration the seasonal pattern of the species of spawning and development. It is not accurate to assume that abundance from any time of the year is indicative of production, because of the sampling of different age cohorts and potential turnover of individual over time. Again, the correct methodology is to estimate production over the life span of the individuals gained by the restoration.

Inconsistency in Assumed Survival Rates for the Same Habitat Restoration Technique

Discrepancies exist in the methods EPA used in its HRC calculations between the Seabrook/Pilgrim case study and the Brayton Point Station study. EPA utilized results from the same studies to determine the average density of species (e.g. number/100m2) for common species between the two sites. However, EPA has used very different survival rates from juvenile to age-1 to convert the juveniles measured on these habitats to age-1 equivalents. Since the same studies were used to derive the densities on each habitat type, it does not follow that the survival of individuals in these habitats would differ. Additionally, the survival rates for threespine stickleback, winter flounder, Atlantic silverside, and tautog for the Pilgrim/Seabrook study are higher than those used by EPA for the Brayton Point study (Table 1). Using these estimates, the same habitat is suggested to provide between 2 times and more than 10 times the number of fish per acre for mitigating the Pilgrim/Seabrook Facilities I&E as compared to the Brayton Point Station. Therefore, costs at Pilgrim are estimated to be half to 1/10 less that of the costs for the same losses at Brayton Point.

For example, EPA uses a survival adjustment for winter flounder of 0.2903 for Pilgrim/Seabrook site but a survival adjustment of 0.1697 for Brayton Point. This translates into an average of 0.09 age-1 flounder per m2 of restored tidal wetland for Pilgrim, but an average of 0.05 age-1 flounder per m2 of restored tidal wetland for Brayton Point (Tables F5-19 and G5-19). Therefore, the loss of each age-1 equivalent flounder would require twice the area of wetland to mitigate losses at Brayton Point than at Pilgrim.

[see hard copy for table]
Table 1: Comparison of the information EPA used for case studies at Brayton Point Station and Seabrook/Pilgrim Facilities to develop life stage adjustment factors (estimated survival rate) for juveniles to age 1 equivalents.

Errors in Calculation of Production Foregone

EPA has also made errors in its calculation of production foregone on the loss side of the equation, resulting in inflated estimates of losses. In the production foregone calculations, EPA used the average weight of individuals in a stage, rather than the initial weight for the stage. This problem was reviewed in detail by LMS, as described in their comments on the Brayton Point case study.

Errors in Methods Used to Estimate Costs

EPA based their costs for restoring SAV (Chapter F5-7.1) on a cost proposal made by Save the Bay for eelgrass planting of a 48-m2 area in RI waters. The final costs EPA derived from these estimates were $71.80/m2 of eelgrass bed. In contrast, in their extensive review of the success and costs of seagrass restoration, Fonseca et al (1998) of NOAA's Restoration Center (in Guidelines for the Conservation and Restoration of Seagrasses in the U.S and Adjacent Waters) estimated eelgrass restoration costs at $25/m2, including a planting guarantee. Thus, EPA's estimate is almost three times higher than that derived by acknowledged restoration experts at the government agency charged with planning and carrying out restoration.

In estimating the construction costs for shallow artificial cobble reef (Chapter F5-7.3), which is the habitat for which data are used to estimate the expected gain in juvenile productivity (Chapter F5-5.3.1), EPA used costs for a project for a deeper reef designed for lobsters, that might be of use to older tautog, but not age one juveniles. It is likely that placement of cobble in very shallow water is less costly than construction a reef with refuge spaces for lobster.

Moreover, total artificial reef construction and monitoring costs were divided by the area of the lobster reef (1024 m2) to obtain an estimate of cost per square meter. This cost was then multiplied by the needed reef area (41 km2) to generate a total project cost. Putting aside the reasonableness of constructing 41 km2 of artificial reef of a type designed for lobsters, restoration costs are not linear with area of the project, particularly over four orders of magnitude. There are unit costs for planning and implementation that are not related to area, and there are economies of scale, making smaller projects much more costly per unit area than larger ones. The example costing methodology is inaccurate and misleading in this regard.

Failure to Identify Most Cost Effective Method for Mitigation

The appropriate decision process is to select alternatives that either (1) provide habitat where the population's productivity is limited by the amount and/or quality of existing habitat, (2) reduce mortality to fishing and other causes, (3) replace missing individuals using restocking techniques, or (4) provide equivalent ecological services. The costs of each alternative need to be compared to the public's values of the gains (i.e., economic benefits). EPA has not used this decision process, instead deciding a priori that habitat restoration should be the method used, regardless of net gains in productivity or reasonableness of costs.

Alternate restoration projects being considered as mitigation should be scaled and costs developed, such that the most cost-effective option may be chosen. The costs need to be compared to economic value of the resource, including consideration of what is and is not captured by the valuation measures, to determine if the costs are reasonable as compared to value (i.e., a cost-benefit analysis needs to be performed for each alternative).

Since direct one-for-one species replacement is likely much more costly than the value (economic benefits) of the I&E losses, replacement of ecological services is a much more appropriate approach. EPA has failed to evaluate sufficient alternatives for Brayton Point, as well as other case studies provided.

Appropriateness of Using a Mitigation Ratio Greater than 1:1

The purpose of a mitigation ratio (where more mitigation is to be performed than would be needed based on calculations of production lost versus production gained) is to compensate for the uncertainty of the success of the mitigation project. If all of the gains of the mitigation project were in fact estimated in a quantitative fashion, the mitigation ratio might be warranted. However, in the case where all the services gained are not quantified, the scale of the mitigation already over-compensates for the losses.

EPA has not accounted for many of the ecological services supplied by restoration projects. In contrast to EPA's conclusions in Chapter F5-9, the case study does not underestimate needed mitigation because all ecological services have not been considered and the most effective restoration alternatives have not been selected. EPA has only quantified (and incorrectly at that) the net gains in the particular species lost in I&E on a one-for-one basis using pre-selected habitat restoration choices. Thus, habitat restoration scaled in this manner should not be mitigated at a greater than 1:1 ratio.

[see hard copy for references and appendices]

EPA Response

EPA agrees with the commenter that the Habitat-based Replacement Cost (HRC) method is not a valuation method. EPA has clarified this point in its response to Comment 316bEFR.005.035 and the document entitled “Habitat-based Replacement Cost Method” (DCN 6-1003). EPA did not use the HRC to estimate benefits for the final Section 316(b) Phase II rule.

With respect to habitat restoration alternatives included in EPA's HRC analyses presented at proposal, EPA met with and received information from local experts with knowledge about which restoration alternatives would most efficiently address the majority of species being lost to I&E in the vicinity of the facilities. EPA believes that the information was sufficiently site-specific, and sufficiently reviewed by local experts, to include the most relevant restoration alternatives that could address the majority of species in a practical, cost-effective approach. EPA deliberately avoided including highly experimental or uncertain restorations for species that had no obvious and practical restoration opportunities.

Regarding the issue of offsetting I&E losses and replacement of ecological services, please see EPA's response to Comment 316bEFR.312.003

Contrary to the commenter's assertion, EPA has not eliminated fish stocking as a restoration alternative. Please see the preamble for the final 316b Phase 2 rule. However, EPA notes that there currently are no hatcheries for most of the fish species that are impinged and entrained.

Regarding EPA's assumption that abundance can be a reasonable proxy for production, please see EPA's response to Comment 316bEFR.029.113. EPA notes that it intentionally used location-specific data when available.

Regarding restoration costing, please see EPA's responses to Comment 316bEFR.029.119 and Comment 316bEFR.029.117.

Regarding EPA's production foregone calculations, please see EPA's response to Comment 316bEFR.305.003.

Regarding the issue of mitigation ratio, EPA notes that the question posed by the HRC analyses presented at proposal was “How much would it cost to offset all of the losses, including the multitude of unique ecological services provided by each life stage of each species, if those losses are not prevented by technology?” Since most ecological services will never be described, the only practical means to offset all of the service losses is to offset all of the organisms, by species. Therefore, if minimizing all I&E is the primary purpose for "best technology available" (BTA), then offsetting each of the same losses, not just the life stages, species, or services that happen to be easiest to measure or monetize, is the appropriate purpose of restoration.

Many species lost to I&E were not included in the HRC analyses because restorations were not available, practical, or known. Furthermore, many conservative assumptions were included to ensure that the type and scale of restorations have a high probability of offsetting known losses. As data become available for more species and more habitat restorations, EPA believes that it is more likely that such analyses will prove to be conservative estimates of the amount of restoration required, rather than over-estimates, as the commenter contends.

Finally, EPA notes that the HRC analyses conducted for proposal are not used to estimate benefits for the final rule. Additional information on the HRC method and its uses is provided in the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003).

Burden on permitting agencies (general)

The TNRCC appreciates the need to minimize the impacts of impingement and entrainment of organisms in cooling water from sensitive aquatic ecosystems. We also understand concerns about compliance costs. Our review indicates that approximately 57 existing industrial facilities in Texas will be subject to the proposed regulations. Therefore, the potential regulatory impacts and administrative burdens are large. In the EPA's economic and benefits analysis, the administrative costs to permitting authorities are estimated to be from $30,043 to $72,405 for each initial permit that is issued after promulgation. The higher cost is incurred when a facility conducts a site-specific demonstration of economic and environmental impacts. Costs of subsequent permitting actions are estimated as $9,311 to $21,996 each. Overall estimates for the maximum state administrative burden were 1,074 staff hours per facility (67 FR 17210).

The TNRCC estimates that an additional six to eight full-time permitting staff (or equivalent effort) would be needed to adequately administer and evaluate the initial round of 10 to 12 permits per year during the first five-year cycle of permit renewals for 57 facilities. This level of effort is commensurate with EPA's estimated costs for permit administration, which in Texas would be about $1,712,451 to $4,127,085 over the first five years -- depending on the number of site-specific demonstrations. Representatives of electrical generating utilities in Texas have indicated that most facilities will choose to conduct site-specific studies if the proposed regulation is promulgated.

Proposed standards for lakes and reservoirs

In the proposed regulation, the EPA established moderately different impingement/entrainment performance standards for different categories of water bodies. The categories were (1) freshwater rivers and streams, (2) lakes and reservoirs, (3) Great Lakes, (4) estuaries and tidal rivers, and (5) oceans. In Texas, approximately 11 affected existing facilities are located on estuaries and tidal rivers, two on freshwater rivers, 11 on multi-use reservoirs, and 33 on smaller reservoirs that were constructed to be cooling water impoundments for a specific facility.

These cooling water impoundments were constructed in the watershed of relatively small streams. They usually provide opportunities for public fishing and aquatic recreation. Fisheries are maintained and manipulated by stocking, and many have been stocked with a variety of non-native fish species. Net evaporation rates are high, and many of them require supplemental sources of water that are piped in from adjacent water bodies. Their regulatory histories, uses, and ecosystems are markedly different from natural lakes and larger mainstream impoundments.

The proposed regulations are inappropriate for cooling water impoundments with the characteristics described above. The EPA should therefore establish separate requirements for cooling water impoundments with respect to performance standards, monitoring, and site-specific demonstrations. This approach could significantly reduce compliance and administrative costs and still protect sensitive aquatic ecosystems from entrainment and impingement impacts in cooling water.

EPA Response

Please refer to the response to comment 316bEFR.041.551 for a discussion of the biology of reservoirs.

UMRA/Impacts on local governments

There are a number of provisions in the EPA's proposed rule on cooling water intake systems for existing facilities that our utility finds particlarly encouraging. However, we remain concerned that the EPA has underestimated the potential impact on public power systems. Public power systems are utilities owned and operated by local government.

Subject Matter Code 7.01.03

Option 3--Site-specific determination

EPA should be complimented for considering a variety of alternative approaches to the regulation. Holland Board of Public Works is encouraged that the EPA proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific factors that affect the technical practicability of meeting the proposed standards. Specifically, the EPA recognizes that there may be situations where the costs of meeting the proposed standards at a specific facility may be significantly higher than the costs considered by the EPA in establishing these standards. In those instances the proposal provides the facility with the opportunity to justify an alternative technology selection.

EPA Response

Comment ID 316bEFR.049.004

Subject Matter Code 10.07.03

RFC: Test: benefits should justify the costs

Author Name Judy Visscher

Organization Holland Board of Public Works

The EPA proposal explicitly recognizes that alternative technology selection may be warranted based on site-specific-factors that indicate that the costs of meeting the performance standards are not warranted by the projected benefits at that facility. This is potentially very good. The proposed rule allows facilities to select an alternative level of compliance where the costs of compliance with the EPA's performance levels would be significantly greater than the expected benefits of achieving these levels. This explicitly recognizes the site-specific variations in the waterbodies (with varying ecological conditions) and can help account for controls already in place at many facilities.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Comment ID 316bEFR.049.005

Author Name Judy Visscher
Organization Holland Board of Public Works

Subject Matter Code 7.01.03
Option 3--Site-specific determination

The EPA has chosen a flexible approach to compliance that allows facilities to meet the performance standards through a number of options, including creation or voluntary restoration of habitats and other non-traditional approaches. This approach allows for continued innovation in addressing the potential adverse environmental impacts associated with impingement and entrainment at power generating facilities. This also leaves significant discretion in determining how best to comply with the standards to state permitting authorities and facilities managers who have developed a great deal of expertise on these issues over the past 25 years. Holland Board of Public Works has a good working relationship with the state and believes in deferring, where possible, to the state regulators.

EPA Response

Subject Matter Code 22.06
UMRA/Impacts on local governments

Author Name Judy Visscher
Organization Holland Board of Public Works

Criticism: the EPA has underestimated the impact on public power systems. Holland Board of Public Works believes that the EPA should consider these impacts on local government. (See section titled Assessment of Unfunded Mandates Analysis on Public Power in the Comments submitted by the American Public Power Association).

Holland Board of Public Works agrees with the APPA that the EPA should encourage states to implement the new 316(b) requirements with coordination with states to ensure reliable grid operations.

Holland Board of Public Works is very concerned with the unintended consequences of downtime in the utility industry when 316(b) requirements are implemented.

If the EPA and states attempt to do these too quickly or at the same time, there may be electricity price spikes as public power generators purchase power from IOUs or other public power entities during a one to three month down time. The final rule should encourage state flexibility in setting sensible deadlines for 316(b) retrofits when the utility would have scheduled outage, maintenance or have lower demand. The EPA's proposed rule ignored this potential consequence that could be serious in a region (or watershed) where several utilities face NPDES permit renewal, imposition of 316(b) requirements, and planned outages in the same year. If not timed wisely, the region's customers could face unexpected utility bill increases-particularly during a peak use time such as mid summer or mid winter.

The EPA and states should take a common sense approach to new 316(b) requirements. This common sense approach would minimize potential cost spikes and energy disruptions and would avoid placing too high a demand on the few dozen consulting engineering firms that have considerable expertise in biological studies and the various intake technologies.

Response to Public Comment

---National Pollutant Discharge Elimination System---
Regulations Addressing Cooling Water Intake Structures
for Phase II Existing Facilities

(40 CFR Parts 9, 122, 123, 124, and 125)

Response to Comments Submitted by:

R.Ken Findley

On Behalf Of:

PPG Industries

Author ID Number:

316bEFR.050

Comment ID 316bEFR.050.001

Author Name R.Ken Findley

Organization PPG Industries

Subject Matter Code 3.01

Definition: Existing Facility

PPG requests that applicability of the Phase II rule be limited to specific SIC codes.

PPG's processes operate under SIC codes 2812, 2816, and 2869, none of which are included in the Major SIC Group of 49 designated for Electric, Gas, and Sanitary Services. Because of the high-energy demands associated with the production units, our power facilities are considered to be part of our chlor/alkali (SIC 2816) plants. It is apparent from references identified throughout the proposed rule that it was the agency's intent to regulate commercial utility units during the current rulemaking. See our comments below for some of these references.

EPA Response

As discussed in Section VIII.A.1. of the preamble to the final rule, EPA considered specifying SIC or NAIC codes to clarify the scope of the rule beyond that proposed in § 125.91(a)(2), but did not do so because it believes the changes in § 125.91(a)(3), which define a facility as a Phase II existing facility only if its primary activity is to generate and transmit or sell for transmission electric power, are sufficient to clarify the scope of the rule and due to concerns that SIC and NAIC codes may change over time, which could unintentionally alter the scope of the rule. Also see response to 316bEFR.050.002.

Comment ID 316bEFR.050.002

Author Name R.Ken Findley
Organization PPG Industries

Subject Matter Code 3.01
Definition: Existing Facility

PPG requests that the proposed rule be clarified to exempt non-commercial utilities from the applicability determination. The definition of "Phase II existing facilities" does not adequately exempt existing manufacturing facilities that may occasionally transfer power offsite during peak load events.

Throughout the preamble to the proposed rule, there are statements that allude to the agencies intent to exempt existing facilities whose primary business is the manufacture of chemical products.

From the April 9, 2002 Federal Register: page 17124:

"Today's proposal would not apply to existing manufacturing facilities,"

In discussing additional (Phase III) regulations on page 17126:

"The decree requires further that EPA propose regulations governing smaller-flow power plants and factories in four industrial sectors (, chemical and allied manufacturing) by June 15, 2003."

On page 17128:

"(e.g., existing power generating facilities with design flows below the 50 MGD threshold, certain existing manufacturing facilities). These facilities are not covered under this proposal because they do not meet the requirements of proposed 125.91."

This language clearly distinguishes between power generating facilities and manufacturing facilities.

At http://www.epa.gov/waterscience/316b/econbenefits/a2.pdf, EPA cites several exemptions to the proposed Phase II rule. In section A2-1 Overview of Regulated Facilities, the publication states:

"The proposed Phase II rule does not cover," and "(4) existing manufacturing facilities." The footnote references a statement that includes "and existing manufacturing facilities will be addressed by a separate rule."

The title of an EPA web publication (Fact Sheet EPA 821-F-02-012) issued in June 2002, appears to further support the applicability of the proposed rule. The title is Cooling Water Intake Structures At Large Existing Power Plants-Extension of Comment Period. PPG interprets "Power Plants" as those that generate electricity for public consumption, not power generation units that supply power to a manufacturing facility.

Based on the above references and exemptions published by the EPA, PPG Industries does not interpret the Lake Charles facility to be an entity subject to regulation under 316b-Phase II.

EPA Response

In § 125.91(a)(3) of the final rule, EPA has changed the rule from proposal and specified that an existing facility is a Phase II existing facility only if its primary activity is to generate and transmit electric power or to generate electric power and sell it to another entity for transmission. EPA believes that this criterion – the primary activity being the generation of electric power and its transmission or sale for transmission – sufficiently clarifies and limits the scope of this rule to existing facilities whose primary business is the generation of power for use by other entities. For additional discussion, see sections II and VIII.A.1. of the preamble to the final rule.

RFC: Three-option framework for determining BTA

The first is support of the flexibility provided by EPA's "preferred option" that includes the use of alternative technologies to demonstrate BTA, the option of developing site specific approaches based on the cost-cost and cost-benefit tests and the voluntary use of restoration/mitigation in lieu of technologies for compliance.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

Comment ID 316bEFR.051.002

Author Name Ron Hix

Organization Florida Power & Light Company

Subject Matter Code 19.0

Dry Cooling

The second is support of EPA's comment that dry cooling technologies are not appropriate for this rule making. FPL does not believe that there is currently a sufficient understanding of the potential operational problems or the environmental "costs" (i.e.; decreased efficiency and greater parasitic load resulting in more power demand and more power plants with more air pollution, etc.) to justify the use (and especially the retrofitting) of this technology in all scenarios. We do know that the capital and operational costs of this technology are extremely high.

EPA Response

The Agency has not based the final rule on dry cooling technologies and does not believe that they are viable technologies at date for retrofit to the vast majority of facilities within scope of this regulation, in part, due to the factors addressed by the commenter.

Comment ID 316bEFR.051.003

Subject Matter Code 17.03.02

RFC: EPA rationale to not require closed-cycle

The third is that retrofitting any existing facilities (regardless of water body type or flow of current once-through cooling system) with wet closed-cycle cooling is also inappropriate not only due to the cost and energy penalties, but also the other environmental "costs" such as consumptive use of water, noise, air pollution, drift, etc.

EPA Response

Retrofitting of existing cooling systems with cooling towers is not a basis of the final national rule.

Comment ID 316bEFR.051.004

Subject Matter Code 21.06.01

Implications for nuclear facilities

EPA should exempt emergency intakes.

FPL suggests that EPA exempt “emergency” intakes from the coverage of the Phase II rule. Nuclear power plants generally have emergency intakes in case the primary intake that supplies safety related cooling water is not available. These intakes are only used under emergency conditions and the amount of flow would be minimal (only enough to cool emergency equipment as the unit would be shut down). They would only be used for the period of time necessary to ensure a safe shut down of the unit or until the main intake is available again.

The emergency intakes are also periodically tested in accordance with the requirements of the Nuclear Regulatory Commission (NRC) operating license.

EPA Response

Today's final rule allows for a site-specific determination of best technology available if requirements conflict with Nuclear Regulatory Commission safety requirements (see § 125.94(f)).

Organization Florida Power & Light Company

Subject Matter Code 18.02

RFC: Use of previous demonstration studies

If a facility has already been determined to employ BTA, that determination should be adequate

If a facility has previously conducted a detailed, Comprehensive 316 (b) Demonstration study that resulted in the Cooling Water Intake Structure (CWIS) being determined to reflect Best Technology Available (BTA), that determination should stand and no further work should be required under Phase II.

If a detailed demonstration study was not conducted, any information collected in the past, such as a 316 (b) screening study, should be able to be used, assuming no major changes to the intake structure or the water body have occurred since the study was conducted.

EPA Response

EPA has disallowed the use of historical determinations of BTA in today's final rule; however, existing data that is reflective of current conditions may be used to support the required studies. Please see response to comment 316bEFR.040.001 for details.

Organization Florida Power & Light Company

Subject Matter Code 3.06.01

Withdrawal threshold of 50 MGD

Option of meeting an actual flow threshold in lieu of the 50-MGD design flow threshold.

Permittees should have the option of meeting an actual flow threshold in lieu of the 50 million-gallon per day (50-MGD) design flow threshold.

The proposed rule lists a design intake flow of 50-MGD as one of the criteria for applicability of the proposed Phase II regulations. In many cases, however, actual intake flow is below the design capacity. If a permittee is willing to accept permit limitations that restrict its actual water use to some level below 50 MGD, and thereby not be subject to the Phase II regulations, EPA should encourage such actions as a means of reducing the potential for entrainment and impingement.

EPA Response

Please see response to comment 316bEFR.019.003.

RFC: Effects of re-powering on intake flow

Author Name Ron Hix

Organization Florida Power & Light Company

Repowering of Steam Electric Power Generating Facilities (Utility and Non-utility)

In the preamble for the draft 316 (b) rule, EPA asked for "information from facilities that have enacted repowering changes and the degree to which these changes have changed their design flow."

FPL has repowered three facilities to date, converting them from conventional (full-stream) to combined-cycle plants. Two of these facilities were on tidal rivers. The flows were not changed for the repowered facilities as the existing condensers and circulating water pumps were used. This would likely be the case at any facility that FPL repowers that has a once-through cooling water system.

For this reason, we disagree with EPA's statement that,

"The Agency determined that projected compliance costs for facilities withdrawing from estuaries could be lower after incorporating the repowering changes. The primary reason for this fact is the majority of estuary repowering facilities would change from a full-stream cycle to combined cycle, thereby maintaining or decreasing their cooling water withdrawals (note that a combined-cycle facility generally will withdraw one-third of the cooling water of a comparably sized full-steam facility). Therefore the portion of compliance costs for regulatory options that included flow reduction requirements or technologies would significantly decrease if the Agency incorporated repowering changes into the analysis."

As mentioned above, in the type of repowering undertaken by FPL, the CWIS and condensers remained unchanged; only the heat source was different. It is true that on a megawatt/circulating water-used basis, combined cycle facilities have a much lower use rate. However, in both FPL cases (as well as any future cases), the repowered facility produced substantially more megawatts for the same amount of cooling water flow. The steam turbine is generating the same number of megawatts as it did prior to repowering plus approximately 170 additional megawatts from each gas turbine. Thus, the repowering of a unit would have no effect on the cost for 316 (b) compliance.

The real potential benefit of repowering from a reduced flow standpoint lies in more megawatts being produced by a more efficient power plant meaning that a less efficient power plant somewhere, that may have a once-through cooling water system, is operating less.

The third FPL facility that was recently repowered utilizes an off-stream cooling pond. This facility will require more cooling water (cooling pond make-up water) than was previously used because the heat-load to the cooling pond will be greater, resulting in more evaporation and therefore more make-up water being required. FPL does not believe this facility is within the scope of the Phase II rule.

EPA Response

EPA appreciates the information provided by the commenter. See Comment ID 316EFR.087.014 for response on repowering and compliance costs.

Subject Matter Code 11.03

RFC: Appropriate spatial scale for restoration

Restoration/Mitigation

Should restoration measures be limited to the waterbody at which a facility's intakes are sited, or should they be implemented on a broader scale, such as at the watershed or State boundary level?

FPL believes that restoration measures should be expanded to the largest extent possible and should make sense from an ecosystem standpoint and not be inhibited by political boundaries. For instance, mitigation or restoration that could be conducted in an estuary impacts numerous types of fish and shellfish that spend portions of their lives there. Many of these organisms later move to open ocean waters and can move up and down along the coastline.

EPA Response

For a discussion of the appropriate scale on which to conduct restoration measures, see EPA's response to comment 316bEFR.212.001.

Comment ID 316bEFR.051.009

Author Name Ron Hix

Organization Florida Power & Light Company

Subject Matter Code 11.08

RFC: Habitat conservation as part of restoration

EPA seeks comment on whether habitat conservation would be an appropriate component of a facility's restoration efforts.

FPL agrees that activities such as habitat conservation are an appropriate component of a facility's restoration efforts. Other appropriate components are activities such as stormwater management or connecting facilities using septic tanks located near a water body to a POTW. These activities don't directly replace organisms (like stocking) or sea grass (like restoration) but could play a major part in the recovery of an ecosystem.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority in determining the appropriate level of performance to meet the requirements of the final, see EPA's response to comment 316bEFR.060.026.

For a discussion of ancillary benefits associated with restoration measures, see EPA's response to comment 316bEFR.032.011.

Comment ID 316bEFR.051.010

Author Name Ron Hix

Organization Florida Power & Light Company

Subject Matter Code 11.12

RFC: Restoration banking

EPA is also inviting comments on other restoration approaches that it is considering. These include discretionary and mandatory regulatory approaches involving restoration measures as well as restoration banking, which are discussed below.

FPL believes that innovation should be the driver and all reasonable approaches should be considered. For instance, the development of mitigation banks, such as those allowed by the 404 program, could have a major positive impact on an ecosystem located next to them. This additional value could result in more banks being developed and therefore more restored habitat for all types of aquatic as well as terrestrial creatures.

EPA Response

In the final rule, EPA allows use of restoration to minimize or to help to minimize adverse environmental impacts that derive from impingement and entrainment of aquatic organisms. Restoration measures must meet the requirements described in the final rule.

For a discussion of trading programs, see the preamble to the final rule.

Subject Matter Code 17.01

RFC: Other proposed provisions

Other Technology-Based Options Under Consideration

-Intake Capacity Commensurate with Closed-Cycle, Recirculating Cooling System for All Facilities

-Intake Capacity Commensurate with Closed-Cycle, Recirculating Cooling Systems Based on Waterbody Type

-Intake Capacity Commensurate with Closed-Cycle, Recirculating Cooling System Based on Waterbody Type and Proportion of Waterbody Flow

FPL strongly opposes all of the "Technology-Based Options Under Consideration" that would result in mandatory installation of retrofitted cooling towers for any facilities. These options are extremely expensive (far beyond EPA's estimates) and are not warranted.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161). Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

Author Name Ron Hix
Organization Florida Power & Light Company

Subject Matter Code 9.04
Cooling system costs (e.g., dry, wet, recirculating)

Technical Problems with Retrofitting Cooling Towers

In addition to cost, the are many technical problems associated with retrofitting plants with cooling towers. As an example, consider the St. Lucie Nuclear Plant. Its Final Safety Analysis Report states that St. Lucie Units 1 and 2 use two independent water sources and a common discharge canal for the ultimate heat sink (UHS). The design of the UHS complies with Regulatory Guide 1.27, "Ultimate Heat Sink for Nuclear Power Plants." In the unlikely event of a loss of the intake, a second independent source of water is available from the Indian River Lagoon. By NRC Technical Specification requirements, the UHS must be operable at all times.

Cooling towers would increase the probability that the ocean intake would be lost, thereby creating a challenge to the UHS that currently does not exist.

EPA Response

See responses to comment 316b.EFR.041.023 and 316b.EFR.208.002.

Organization Florida Power & Light Company

Environmentally Sensitive Areas Increase Cooling tower retrofit costs

Some possible locations for cooling towers are in environmentally sensitive areas. For example, an area that is otherwise feasible for towers at the St. Lucie Nuclear Plant is a protected mangrove swamp. Since the NRC has concluded that the entrainment and impingement of fish and shellfish at St. Lucie has an insignificant impact on the fisheries near the site, <FN 1> there would be no net environmental benefit in destroying acres of mangroves to accommodate cooling towers. Facts such as these support the need for a site-specific analysis to determine BTA under § 316(b).

Footnotes

1 U.S. Nuclear Regulatory Commission. Final Environmental Statement Related to the Operation of St. Lucie Plant, Unit No. 2; Florida Power & Light Company, Orlando Utilities Commission of the City of Orlando, Florida. Docket No. 50-389. NUREG-0842. Office of Nuclear Reactor Regulation. Washington, D.C. April 1982.

EPA Response

The final rule is not based on cooling towers. Therefore, the commenter's assessment of the net benefits in the hypothetical analysis is moot as pertains the final rule.

The Agency has included site-specific alternative provisions in the final rule requirements, which to a certain degree would assess the net benefits of a site-specific BTA determination. However, the Agency notes that the NRC is not the final judge for the significance of impact that impingement and entrainment has on a fishery.

See Sections V, the Rule, and section IX, Implementation, of the preamble on a site-specific determination of best technology available for minimizing adverse environmental impact.

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Author Name Ron Hix

Organization Florida Power & Light Company

Subject Matter Code 6.08

Non-aquatic impacts

Sea Turtles Could be at Greater Risk

At the St. Lucie Plant, sea turtles could be at greater risk if flows were low in the intake pipes (between the velocity caps in the ocean and the headwall). This condition could exist if, for example, the St. Lucie intake structures were used to support wet saltwater cooling towers. With a weak current, the turtles could enter the velocity cap and not be carried along. If they loiter in the pipe too long (as may occur with reduced flow with a cooling tower) they may drown, because they cannot surface for air.

Some analysis would be necessary before deciding how best to use the existing velocity caps at St. Lucie if cooling towers were required. Flow rates required for make-up water and the discharge from a wet saltwater cooling tower would need to be studied. Harm to sea turtles could be an unintended consequence of requiring cooling towers.

EPA Response

Cooling towers are not included as a basis for the final rule requirements. Additionally, intake velocity is not regulated through the existing facility phase II rule. Therefore, the commenter's concerns have been met.

Permit applications/implementation schedule

Comments on execution time line

The preferred alternative for the 316 (b) rule for existing facilities, as proposed, requires an extensive amount of work to be done before an adequate application could be completed. It would be unreasonable to require a completed application less than three (3) years after the rule became final. Therefore, we feel the rule should only apply to facilities that have an NPDES (or SPDES) permit that expires more than three (3) years after the rule becomes final.

EPA Response

EPA agrees with the comment and has clarified timing requirements for the submittal of the required studies. See response to comment 316bEFR.034.066 for a discussion.

Comment ID 316bEFR.051.016

Subject Matter Code 6.08

Non-aquatic impacts

Author Name Ron Hix

Organization Florida Power & Light Company

Manatees and Sea Turtles

In addition to fish and shellfish, the rule should consider effects on other wildlife. A facility should be able to take mitigation credit for sheltering manatees and releasing sea turtles.

Manatee Protection Plans

The SPDES permits for five FPL facilities have permit conditions that require them to draft and follow "manatee protection plans". These plans, which are enforced by the Florida Fish and Wildlife Conservation Commission, require the facility to provide an adequate quantity and quality of warm water during cold weather to be effective refuges for the endangered manatees.

Relocating Sea Turtles

Approximately 600 sea turtles entered the intake canal at the St. Lucie Plant in 2001, and over 99% were successfully returned to the Atlantic Ocean. Prior to release the turtles are examined, weighed, measured, etc. The result is an enormous amount of scientific information (which the scientific community considers to be very valuable) on sea turtles being generated. Also, any turtles that are injured or ill (generally these conditions are not related operation of the plant) are taken to a nearby facility for rehabilitation and then released. FPL is constantly modifying and improving this program.

FPL also is permitted to collect fish that have entered the intake canal at the St. Lucie Plant. Many of these fish are released back to the natural environment. Some of these fish are sent to aquariums all over the world, which reduces the number of specimens the aquariums would otherwise have to acquire from the natural environment.

EPA Response

The sea turtles the author refers to are taken into the intake canal which must then be rescued. The goal should be to not take these animals into their cooling water system at all. The manatees the author refers to have grown dependent on the artificial environment created by the facility's warm water discharge. This is a section 316(a) issue. Today's final rule does not require wet cooling towers, and therefore, will not change thermal discharges.

Organization Florida Power & Light Company

Subject Matter Code 3.03

Definition: Waters of the U.S.

Cooling Ponds and Cooling Canals

EPA's proposal indicates it has to apply § 316(b) to cooling ponds if they otherwise would qualify as "waters of the United States" (WUS) under EPA's current definition. EPA has long exercised discretion to define WUS and to include and exclude waters from that definition, where necessary to achieve the purposes (or intent) of the CWA. EPA should exercise that discretion here. Cooling ponds built for the purpose of supplying cooling water should be treated as closed-cycle cooling systems that achieve the requirements of any final rule that ends up being promulgated.

It makes little or no sense for EPA to open existing facilities with cooling ponds up to the possibility that they will be required to install additional fish protection technologies on impoundments that were in the first place designed and constructed to provide cooling water.

EPA Response

See response to 316bEFR.006.001.

Comment ID 316bEFR.051.018

Author Name Ron Hix

Organization Florida Power & Light Company

Subject Matter Code 7.02

Performance standards

Calculation baseline

The rule must be revised so the "calculation baseline" is not the only available method to determine the extent of adverse environmental impact. Alternative methods must be allowed to demonstrate that an existing CWIS is not adversely impacting populations of aquatic life in an area.

The "calculation baseline" is used in the proposed rule as a method of determining when adverse environmental impact begins. It calls for an "estimate of impingement mortality and entrainment that would occur at a site assuming it had a shoreline cooling water intake structure with an intake capacity commensurate with a once-though cooling water system and with no impingement and/or entrainment reduction controls." (Section 125.93). It would be extremely difficult to make this estimate in a scientifically supportable manner as most of these facilities have been in existence for 30 or more years and the ecosystem has equilibrated to the presence of the CWIS. Performance standards based on the calculation baseline are essentially reducing the performance standard to a volume reduction requirement based on reducing intake capacity to that of a cooling tower system.

EPA Response

For discussions on the basis for and implementation of the calculation baseline, please see response to comments 316bEFR.308.014 and 316bEFR.063.022, as well as the preamble to today's rule.

Organization Florida Power & Light Company

Subject Matter Code 8.05

Proposed standards for oceans

Difficulty with technologies in an open ocean environment

For a facility with an open-ocean intake, it is even more imperative that the site-specific approach for compliance with 316 (b) be maintained. None of the technologies, such as fine mesh screens, wedgewire screens or aquatic filter barriers would work in conjunction with velocity caps already installed offshore to minimize entrainment. The fact that a facility is located in sub-tropical waters further exacerbates the problem of rapid and heavy biofouling that would be expected to impede the operation of wedgewire screens and aquatic filter barriers.

EPA Response

Please refer to the response to comment 316bEFR.032.014 for more information about oceans as sensitive waterbodies.

EPA acknowledges that some technologies will not be feasible at some facilities. A facility such as the one described by the commenter could elect to seek a site-specific determination of BTA under § 125.94.(a)(5).

Mkt-level impacts/Reliability/EO 13211: Energy Effects

Compliance with Executive Order 13211

In "316(b) Phase II EBA (EPA-821-821-02--001), Part B: Costs and Economic Impacts, Chapter B6 ; Other Administrative Requirements ", EPA states in Paragraph B6-1, "Pursuant to the terms of Executive Order 12866, EPA determined that this proposed rule is a "significant regulatory action."

EPA states in Paragraph B6-7, "For the purposes of Executive Order 13211, "significant energy action" means: any action..... (1)(i) that is a significant regulatory action under Executive Order 12866 or any successor order , and (ii) is likely to have a significant adverse effect on the supply, distribution, or use of energy ;"

EPA goes on to state in Paragraph B6-7, " This proposed rule does not qualify as a "significant energy action" as defined in Executive Order 13211 because it is not likely to have a significant adverse effect on the supply, distribution, or use of energy. The proposed rule does not contain any compliance requirements that would directly reduce the installed capacity or the electricity production of U.S. electric power generators.

In Paragraph B6-1 EPA has characterized this proposed rule as a "significant regulatory action". Based on the current understanding of the Proposed Rule, it will have a significant adverse effect on the supply of energy. Some generators would be forced to cease operations while others would suffer the consequences of higher generation costs without the provision of a valid cost benefit analysis. For certain, somebody will have to pay for these extraordinary costs. A valid economic analysis must be performed and a Statement of Energy Effects be furnished as required by Executive Order 13211.

The EPA has brushed off this important requirement without offering any valid analysis. We must insist that EPA revisit this issue and justify this flawed conclusion.

EPA Response

Please refer to the response to comment 316bEFR.041.131 in subject matter code 9.03.

Subject Matter Code 7.03

Available I&E technologies

Author Name Ron Hix

Organization Florida Power & Light Company

Unintended consequences of impingement reductions

As fine mesh and wedgewire screens are used to reduce impingement, one of the effects can be that entrainment is increased. Certain eggs and planktonic forms, which some research indicates are not killed in their trip through a once-through cooling water system, can be entrained and lost to the environment due to the use of these devices. Care must be taken in requiring technologies that shift the problem from one area to another, rather than solve it.

EPA Response

EPA agrees that care must be taken to ensure that the measures adopted to reduce impingement mortality do not consequently result in an increase in entrainment, or vice versa, and should be considered during the permitting phase. Wedgewire screens have demonstrated significant promise in reducing both entrainment and impingement under certain circumstances. If properly deployed, EPA does not believe that wedgewire screens will result in the type of impacts described by the commenter. Fine mesh screens, whether as part of a wedgewire system or traditional traveling screen system, can significantly reduce entrainment of eggs and larvae. Although the potential exists for a corresponding increase in impingement, EPA believes that proper maintenance of the screens (i.e. maintaining through-screen velocities) as well as the incorporation of other design and construction technologies can often mitigate any resulting increase in impingement.

RFC: Three-option framework for determining BTA

Author Name R. Michael Hartman

Organization Stewards of the St. Johns River

It would appear that existing steam electric units larger than about 100 MWe operating with once through cooling systems located in estuaries will either need to install closed cycle cooling or demonstrate an alternative site specific performance standard of Best Technology Available (BTA) in accordance with 125.94 (a) (3). These comments apply to such a situation.

If the facility, for cost, land availability, and other environmental impact reasons, feel they can not install closed cycle cooling and wish to use that site specific performance standard approach under 125.94 (c) based on "restoration measures in addition to those already in place are not justified because of significantly greater costs." What constitutes "restoration measures" and "significantly greater costs"? Furthermore, are the regulations flexible so they can be implemented by systems ecologists trying to achieve a net improvement in any affected ecosystem beyond any potential harm that existing facilities without the proposed BTA may be having to that ecosystem? These are the main concerns I have with the proposed regulations.

EPA Response

EPA disagrees with the commenter's interpretation of the rule. The final rule contains five compliance alternatives from which a permittee (including a facility on an estuary or tidal river) may choose. Please refer to the preamble for a discussion of the framework of the final rule.

For a discussion of the role of restoration, please refer to sections VII and VIII in the preamble for the final rule. Also, please refer to the response to comments 316bEFR.410.001 and 316bEFR.005.020 for a discussion of the implementation of the cost-cost and cost-benefit tests.

Comment ID 316bEFR.052.002

Subject Matter Code 17.03.01
Ex. facilities converted to closed-cycle

At the western boundary of the Preserve begins a series of three different steam electric power facilities along about a 3-4 mile stretch of the river. Two of these facilities are two unit coal fired plants that utilize closed cycle cooling. The third is a facility called the Northside Generating Station run by Jacksonville Electric Authority (JEA). That facility originally had three oil fired units. One of those units has been re-powered utilizing fluidized bed combustion technology to burn a mixture of coal and petroleum coke. Another unit is in the process of being similarly re-powered. All of these units use once through cooling systems. A 316 (a) and (b) demonstration was apparently submitted in the late 1970s and subsequently granted by the Florida Department of Environmental Protection allowing the units to keep operating with once through cooling systems up to the present time.

EPA Response

This is an introductory paragraph for comment 316b.efr.052.003. Therefore, no response is necessary to this specific comment. See response to comment 316b.efr.052.003.

Comment ID 316bEFR.052.003

Subject Matter Code 6.08
Non-aquatic impacts

Author Name R. Michael Hartman
Organization Stewards of the St. Johns River

Please bear in mind that the Stewards of the St. Johns think JEA is one of the best and most professionally managed municipal utilities in the country. They have a strong policy for doing great things to benefit the community. Our comments should not be interpreted as concern about JEA or how they may implement these proposed regulations. Rather, we are concerned about the general health of the estuarine ecosystem that some of their existing plants happen to utilize. We believe that this aquatic ecosystem has been in general decline due to many other factors. We hope regulations are finalized and implemented in such a way as to allow the most net improvement in that whole ecosystem for any dollars spent. We are not convinced that the utilization of closed cycle cooling on some of their units would return benefits to that ecosystem in proportion to the costs that they would need to spend to make such a change. Instead, we see other general ecosystem restoration and preservation measures that could yield much greater benefits to that ecosystem. We believe that restoration and preservation efforts of the estuarine section of the St. Johns River is a topic that the whole community in Northeast Florida has a stake in and thus should be consulted in how any regulations are implemented once finalized.

EPA Response

The final rule is not based on and does not require installation of cooling towers. Restoration and preservation efforts can be used to comply with the requirements of the final rule. Therefore, the commenter's concerns have been met.

Comment ID 316bEFR.052.004

Author Name R. Michael Hartman

Organization Stewards of the St. Johns River

Performance standards

How does one quantify and measure economic benefits through deduction by 60-90% of all stages of fish and shellfish larvae due to the existing entrainment at a facility on an ecologically impaired estuary? Is such a question capable of being calculated with any degree of precision? If regulatory action under the TMDL program (CWA section 303 (d)) cleans up an estuary that exceeds several water quality standards, that estuary will likely begin to return to more normal ecological conditions. This means in theory there will be greater benefits from reduction of entrainment as the estuary ecological conditions improve. Would the regulations estimate the benefits now when the river is impaired or after the estuary is improved? How could such a theoretical estimate be done?

It may be more cost effective in making improvements to the overall health of an impaired estuary if a portion of the economic costs for back-fitting closed cycle cooling were instead allowed to be spent on ecosystem studies of the whole ecosystem aimed at finding the best restoration measures. In theory, this means the restoration may not necessarily be directly correlatable to relieving ecosystem impacts due to entrainment or impingement for a facility using once through cooling on that estuary. The health of the whole ecosystem needs to be considered before determining the best restoration measures.

As a biologist familiar with ecological conditions in the St. Johns River, I realize how difficult it is to judge how the St. Johns is being impacted by a wide range of human activity and variable natural conditions around our river. There are no good bio-assessment tools for judging the health condition of habitats in an estuary or for determining what may be causing decline in those ecological conditions. The background noise due to natural changes such as climate, flow rates, temperature and introduction of new species has a tendency to mask changes due to human origin. Suppose the river was like a human patient that had a systemic disease like diabetes. Now suppose that patient had a hyperglycemic episode and fell down breaking an arm. In this case the broken arm is like an estuary with a power plant with a once through cooling system on it. Would not the doctor want to treat the whole patient with diabetes not just the broken arm? In a sense the broken arm is related to the diabetes so evaluation and correcting blood sugar levels may be more important for the long-term health of the individual.

This is how I see applying EPA's proposed regulations for existing once through power plants on impaired estuaries. The best answer is not necessarily a rush to back fit closed cycle cooling or to jump on building fish hatcheries that replace larval fish being entrained. The solution may be to understand and then restore the whole ecosystem slowly over time. We need to apply the right treatment after making the correct diagnosis. The diagnosis varies according to the unique physical, chemical and biological properties of the ecosystem the facility is in. Hopefully EPA and the states will have the flexibility under these regulations to adopt a customized approach that is based on scientific facts not short term political or economic gain.

EPA Response

For discussions on the basis for and implementation of the calculation baseline, please see response to comments 316bEFR.308.014 and 316bEFR.063.022, as well as the preamble to today's rule.

EPA recognizes that improvement of impaired waters is a goal of the Clean Water Act and will continue to be achieved over time. EPA also acknowledges that improvements to waterbodies are the result of concerted efforts involving numerous factors, the results of which manifest themselves over time. NPDES permits are valid for five years to allow the permitting authority to revisit issues and circumstances that may not have been present during the previous permit issuance. Improved water quality is one such issue that can be addressed during a permit reissuance.

EPA believes today's final rule maintains a desired flexibility for both the permittee and the Director to determine the most appropriate and cost effective strategy for meeting the requirements of the rule.

RFC: Proposed use of restoration measures

These proposed regulations are difficult for me to clearly foresee how they may be implemented. I was not able to find a definition of what a definition of “restoration measures” or “significantly greater costs” were. I only read sections 125.94, 125.95, 125.96, and 125.97. Are definitions of those terms found in other parts of EPA regulations? If they are not, I suggest such definitions be added for greater clarity in understanding the regulations.

EPA Response

EPA did not provide a definition of restoration measures in the final rule. There are a wide variety of techniques that can restore fish and shellfish in aquatic ecosystems. In the final rule, permitting authorities have the flexibility to determine the precise, appropriate nature of a restoration measure on a site-specific, case-by-case basis. EPA has, however, provided specific requirements for restoration measures in the final rule that guide the determination of an appropriate restoration measure.

For a discussion of "significantly greater costs", see EPA's response to comment 316bEFR.006.003.

Option 3--Site-specific determination

Section 125.94 (c) paragraphs (2) and (3) sound essentially the same. These provisions lay out the basic grounds for using a site-specific determination of BTA. In essence they both allow site specific BTA to come into play when site specific factors cause the costs for BTA (closed cycle cooling) to be higher than the environmental benefits. When this happens then the facility can reduce adverse environmental impacts by employing a combination of design and construction technologies, operational measures and restoration measures in addition to those already in place. Therefore, I do not understand having two separate provisions that appear to say the same thing. Is there a subtle difference that I may have missed?

EPA Response

The final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

The difference between the two subsections is that the first is a cost-cost test based upon the cost of a particular facility's expected compliance costs versus those costs estimated by EPA in the rulemaking. The second is a cost-benefit test which compares the cost of compliance against the expected benefits of compliance. For more information, please refer to 316bEFR.410.001 and 316bEFR.005.020, respectively.

RFC: Proposed use of restoration measures

The wording of paragraph 125.94 (d) lays out a requirement to allow an alternative site specific alternative for meeting BTA. It states that the facility must show that the fish and shellfish within the waterbody, including community structure and function, are maintained at a level comparable to what would result if the facility were to employ technology (closed cycle cooling) that meets BTA. This proof will not be possible to produce. The waterbody will likely have many natural and other man made stresses all of which vary over time. Against such fluctuation of variables superimposed over a complex ecosystem like an estuary, it is impossible to predict what level of community structure, and function might have existed if EPA’s current definition of BTA would have been applied when the facility first went into operation. The test should be one that does not worry about quantifying ahead of time what exact benefits might equate to using some guess about what closed cycle cooling might do to improve the whole ecosystem. Instead the approach should be to demonstrate that by first studying what the major stresses are in a specific ecosystem, by employing restoration measures, those stresses have a reasonable potential to be overcome. What is needed here is restoration of the whole ecosystem at a cost much less than applying technologies that meet the general definition of BTA. Do not worry if you are dealing with a stress that comes from impingement or entrainment and alleviating that stress.

EPA Response

EPA is not requiring closed cycle cooling in the final rule.

EPA agrees with the commenter that there are uncertainties associated with the implementation and assessment of restoration measures, and that these can pose a challenge in the assessment, design, and implementation of a restoration measure. For additional discussion of these uncertainties, see EPA's response to comment 316bEFR.206.055. In some cases, restoration measure performance may be uncertain enough to render a restoration project infeasible for a particular site.

All restoration measures must meet the performance and implementation requirements described in the final rule.

Comprehensive demonstration study (7 parts)

Section 125.95 (a) (1) (iii) asks for written comments from consultation with certain government agencies over the Comprehensive Demonstration Study required by this section. I would suggest that the applicant also be encouraged to seek written comments on their proposed study from any public interest firms and affected industry groups that has an interest in the waterbody the facility discharges into.

EPA Response

EPA believes that a facility may consult with public interest firms or any other interested party regarding its 316(b) obligations, but EPA disagrees that such consultations should be mandated by law or may be used in place of consultations with the appropriate fish and wildlife agencies.

Comment ID 316bEFR.052.009

Author Name R. Michael Hartman

Organization Stewards of the St. Johns River

Subject Matter Code 21.01.04

Comprehensive demonstration study (7 parts)

I would also suggest the sampling plan referenced in 125.95 (a) (1) (iv) not be limited to estimating impacts due to impingement and entrainment at the site but to also assessing the general health of the ecosystem near the site. In this case one needs to look broader than just fishes and shellfish by the site but also benthic and epibenthos macroinvertibrates and even bacteria and plants in the general aquatic ecosystem by the site.

I also suggest that impingement mortality and entrainment characterization studies specified in section 125.95 (a) (2), include a broad study of the general health of the aquatic ecosystem in the area of the site. As stated before, the first step is to diagnose what the general condition of the aquatic ecosystem is. One can not evaluate any impacts from entrainment and impingement are having on the ecosystem without first understanding the health and general characteristics of the ecosystem the facility discharges to.

EPA Response

Please refer to the final rule preamble section VIII. B. Environmental Impact Associated with Cooling Water Intake Structures, for EPA's position on the need to consider environmental impacts beyond impingement mortality and entrainment in today's final rule.

Section 125.95 (a) (4), asks for information to support proposed restoration measures in the Comprehensive Demonstration Study. I submit that the restoration plans needs to follow after information is gleamed from the other biological studies required by this section. How can a facility guess at site specific restoration measures before the results of some of those biological studies are in?

EPA Response

EPA agrees that a Director cannot confirm the appropriate compliance option for a facility without first reviewing data on the facility's intake structure and source waterbody conditions, among other factors. For this reason, EPA has designed the rule such that a facility must first submit a Proposal for Information Collection (see requirements at § 125.95(b)(1)), conduct approximately one year of studies, and submit the results of those studies before the Director determines which compliance option best suits the facility. For additional information on the timing of EPA's submittal requirements, please refer to EPA's response to comment 316bEFR.034.066.

Comment ID 316bEFR.052.011

Monitoring requirements

I support the "Verification Monitoring Plan" provisions of Section 125.95 (a) (6). I point out, however, how difficult it will be to differentiate reduction in levels of impacts from entrainment and impingement in an ecosystem with many natural and man made factors impacting it. I suggest this monitoring be directed more at measuring the benefits of improvement in general health conditions of the river ecosystem near the facility.

EPA Response

For the purpose of today's final rule, EPA has chosen to evaluate compliance based upon (1) reduced impingement mortality and entrainment rates; (2) increase in the production of fish and shellfish; and/or (3) compliance with the Technology Installation and Operation Plan discussed in the final rule preamble. EPA believes that today's final rule does take overall ecosystem health into account, by attempting to protect aquatic life in the waterbodies.

Miscellaneous comment

Author Name R. Michael Hartman

Organization Stewards of the St. Johns River

Lastly I would like to suggest something novel. Most EPA regulations create a set of requirements that are hoped will benefit the environment while adding only a little to the costs of the facility being regulated. Sometimes what happens is some marginal environmental improvements are made but the commercial consultants that get involved in helping the facility comply are the main ones enriched by the experience. They are enriched with knowledge and with cash. How great it would be if local universities could benefit from this experience the way commercial consulting firms often do. In this case the knowledge gain stays in the area to be passed on to students and people in the community. The costs are generally less and benefit the university instead of business investors. The difficulty with university studies, as seen by commercial clients, is that they take longer and the results are less controllable. From a public policy standpoint the later problem should be seen as a benefit. Is there anything that EPA could do in these regulations to encourage utilities to consider the public benefits of using local universities (or a consortium of local colleges and universities) to do some of the studies mandated by the regulations where the right expertise exists at those institutions?

EPA Response

EPA does not take a position on whether facilities should employ colleges or universities to assist with conducting studies required under today’s final rule. However, the studies required in today's final rule may be conducted by any qualified professional. Facilities may choose to have such activities conducted by educational institutions, and there is nothing preventing universities or colleges from soliciting work from facilities.

Definition: Existing Facility

Author Name Bernie Sullivan

Organization PPG Industries

PPG believes that more detail is needed in the applicability section specifying that the rule does not apply to facilities whose primary business activity is not power generation.

The proposed Phase II regulation applicability would include a facility that "both generates and transmits electric power, or generates electric power but sells it to another entity for transmission." Section IV of the preamble clarifies the above applicability by stating; "today's rule does not apply to facilities whose primary business activity is not power generation, such as manufacturing facilities that produce electricity by co-generation."

PPG supports this statement and recommends that EPA include this in the regulations to provide clarity on the applicability of the Phase II Rule.

EPA Response

See response to 316bEFR.050.002. In the final rule, EPA also has not adopted proposed 125.91(b), which would have addressed a co-generation facility that shares an intake with another existing facility. Rather, EPA replaced this with a provision that clarifies how the rule applies to a Phase II existing facility co-located with a manufacturing facility. See 125.91(b)in the final rule.

PROCEDURAL PERMITTING ISSUES

The Proposed Rule 40 CFR Part 125.92, Subpart J "When must I comply with this subpart?" states, “You must comply with this subpart when an NPDES permit containing requirements consistent with this subpart is issued to you.”

The language in this subparagraph does not clearly indicate when the Permittee must comply and when the Permitting Authority must require compliance with the rule for the specific regulated community, which consists of existing facilities. The majority of these facilities have held NPDES permits for many years. They are mostly Once-Through Cooling Water (OTCW) systems, and therefore are mostly older facilities. Thus, the overwhelming majority of the NPDES permits in question will be renewals. Does EPA intend that compliance with the rule must be achieved when the next renewal permit is issued following the effective date of the final Phase II rule?

We are concerned that this rule language may lead to inconsistent implementation among the delegated states and EPA Regions, as permit writers and Permittees struggle to understand the intent of the rule. A number of situations which can realistically occur would make the permitting process confusing and uncertain. What if a renewal application is received before the effective date of the final rule, but a permit is not issued by the effective date? What if a Draft Permit is issued just before the effective date, but not a Proposed Permit? What about a Proposed Permit just before the effective date but not a Final Permit? Such cases boil down to a general concern: Permittees need sufficient time to adequately evaluate and implement the means by which they will comply with the rule, and Permit Writers need sufficient guidance from the rule to determine when compliance must be achieved. Each of these cases obviously has the potential to create a situation in which the Permittee (who may have been operating in good faith and in compliance for many years) can be set at odds with the State and with EPA, potentially delaying renewal and compliance to the detriment of the environment.

Several mechanisms, perhaps in combination, could reduce this sort of implementation crisis. EPA could revise the proposed rule clarifying that facilities which apply for renewal or for their initial permit before the effective date of the Final rule will not be subject to the rule until a specified subsequent date or the next renewal. EPA could revise the proposed rule incorporating a fixed period of time over which facilities can evaluate how they will meet the performance standards or develop site-specific performance standards. Alternatively, a compliance schedule could be incorporated into permits allowing the permittee enough time to come into compliance. In any event, clarification should provide a framework of consistency to guide both Permittees and Permit Writers nationwide.

Non-aquatic impacts

ENDANGERED SPECIES ISSUES

The Proposed Draft Rule seeks to protect endangered aquatic species by reducing losses due to impingement and entrainment from cooling water intake structures (CWIS) regulated under Phase II. To the extent that this beneficial effect will result from limitations on warm water discharges at once-through cooling water systems, serious harm may result for the Florida manatee, a very important endangered aquatic species in our State's waters. Unlike many other aquatic species, manatees are not impacted by impingement or entrainment from CWIS. On the contrary, manatees find refuge in the warm water discharge areas of some of Florida's steam electric power plants during cold days in the winter. It is estimated that two-thirds of the Florida manatee population uses these man-made warm water refuges on the coldest days. The situation presents a difficult case study in competing environmental benefits and impacts.

Within the proposed rule, as currently written, we do not find a mechanism for the protection of species that may be adversely impacted by the significant reductions in warm water discharges that will result from implementation of the proposed rule. It is easy to understand how this oversight could have occurred, given the rule's mandated focus on intake structures rather than discharge, the magnitude of EPA's task, and the fact that manatees are uniquely Floridian and Caribbean animals living nowhere else in the United States. Nevertheless, we believe that the proposed rule should be revised to incorporate the flexibility to protect the endangered Florida manatee.

Delaware

As recognized in EPA's case studies document, there are numerous facilities operating with cooling water intake structures within the Delaware River Basin, including (according to EPA's Figure B1-l) over a dozen facilities that would be impacted by the proposed regulation. Among these facilities is the Salem Nuclear Generating Station, located along the Delaware River in Salem County, New Jersey. Salem has one of the largest cooling water intakes in the country and is implementing the controversial mitigation approach which is being promoted in the current regulatory draft.

EPA Response

This general statement about the Salem facility does not require a response from EPA.

Define BTA as anything less than closed cycle

Author Name Maya K.van Rossum

Organization Delaware Riverkeeper

Every day, cooling water intake structures (CWISs) kill billions of aquatic organisms, including plankton, eggs, larvae, fish and other aquatic life. When Congress amended the Federal Water Pollution Control Act ("Clean Water Act" or "CWA") in 1972, it attempted to address the harms associated with cooling water intake structures by including section 316(b). Section 316(b) requires that "the location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact." The proposed 316(b) regulations for existing facilities fail to carry out the mandate of this provision of the law. Of particular concern are the provisions that allow a facility to continue to inflict tremendous impingement and entrainment impacts simply because the owner/operator commits to undertaking some other "mitigation" project they claim and/or deem to be beneficial to the environment and community.

EPA Response

See preamble to the final rule, particularly sections III, VII, and VIII, and supporting documents.

Comment ID 316bEFR.056.003

Author Name Maya K.van Rossum
Organization Delaware Riverkeeper

Subject Matter Code 2.04.06
Restoration measures in place of technologies

The Clean Water Act Requires BTA on a Facility's Cooling Water Intake Structure--Mitigation does not fulfill the requirements of the law.

The requirements of section 316(b) are clear on the face of the statute - it requires power plants to apply BTA with regard to their CWISs in order to minimize the adverse environmental impacts they cause. Only technologies that will reduce the impingement and entrainment impacts and deaths caused by CWISs can be used to fulfill 316(b)'s mandate. Fish hatcheries, fish restocking programs, programs for removing impediments to fish migration, and implementation of programs for enhancing and/or creating wetlands (examples of "Mitigation Proposals") which are wholly unrelated to cooling water intake structures cannot be used to fulfill the requirements of 316(b). Mitigation Proposals being proposed in the 316(b) context all have common goals: they seek to allow cooling water intake facilities to continue to indiscriminately kill aquatic life rather than make attempts to curb, or stop, the damage they are inflicting; and they all fail to fulfill the mandates of section 316(b) of the Clean Water Act.

EPA Response

For a discussion of EPA's authority to include restoration measures in the final rule, see the preamble to the final rule.

EPA has defined adverse environmental impact in terms of impingement and entrainment caused by cooling water intake structures. In order to reduce the occurrence of impingement and entrainment caused by cooling water intake structures, EPA examined a variety of design and construction technologies and operational measures. As discussed in the preamble to the final rule in Section VIII.B, EPA ultimately developed national performance standards expressed in terms of ranges, which EPA concluded could generally be achieved by application of some combination of the model technologies. EPA recognized, however, that a facility's choice of how to achieve those standards would depend on a host of site-specific factors. Therefore, in addition to authorizing facilities to choose their own suite of design and construction technologies and/or operational measures to reach the performance standards, EPA is also authorizing facilities to use restoration technologies under certain circumstances and still in relation to the applicable performance goal. As noted elsewhere, the ultimate objective of today's rule is to minimize the impact of impingement and entrainment on the waters from which cooling water is withdrawn. Restoration is one way of minimizing that impact.

Subject Matter Code 11.11

RFC: Mandatory restoration approach

Author Name Maya K.van Rossum

Organization Delaware Riverkeeper

Mitigation cannot play a role in meeting the requirements of section 316(b) -- but should be required in addition to 316(b) technology requirements in order to remediate for the past damage inflicted by facilities' CWIS. For many years existing facilities with CWIS have been indiscriminately killing fish. Requiring remediation/mitigation to make up for these historical impacts is justified but it does not fulfill 316(b)'s technology requirements.

EPA Response

For a discussion of EPA's authority to include restoration measures in the final rule, see the preamble to the final rule and EPA's response to comment 316bEFR.056.003.

For a discussion of the use of restoration measures to compensate for past damages from cooling water intake structures, see EPA's response to comment 316bEFR.206.055.

Comment ID 316bEFR.056.005

Author Name Maya K.van Rossum

Organization Delaware Riverkeeper

Subject Matter Code 11.01

RFC: Proposed use of restoration measures

Simply put, mitigation does not fulfill the plain language of the CWA because mitigation is not BTA for the location, design construction or capacity of a CWIS. Mitigation does not minimize the impingement and entrainment harms being inflicted on an aquatic system by CWIS as required by the law. Mitigation projects or proposals are often unproven and unprovable -- there is no guarantee of success.

EPA Response

For a discussion of EPA's authority to include restoration measures in the final rule, see EPA's response to comment 316bEFR.056.003 and the preamble to the final rule.

EPA agrees with the commenter that there are uncertainties associated with restoration measures. For additional discussion of these uncertainties, see EPA's response to comment 316bEFR.206.055.

Delaware

PSE&G has been working on the Delaware River on a mitigation experiment in response to 316(b) requirements for its Salem Nuclear Generating Station. To date, that mitigation experiment is failing. PSE&G has been unable to demonstrate that its mitigation effort for the fish kills at its Salem plant is benefiting the fish populations of the Delaware Estuary. PSE&G cannot demonstrate that its mitigation effort at Salem is in any way minimizing the impingement and entrainment of over 3 billion Delaware River fish. It's not likely that PSE&G could demonstrate that its wetlands mitigation efforts have contributed back, in a long-term, sustainable, and successful way to the River's aquatic populations. Further, it can't even demonstrate that if it were successful in eradicating and/or controlling phragmites in designated areas as mandated by its currently permitted mitigation project (an outcome that is itself questionable), that this success would be sustainable without continuous intervening action. In fact, the primary result of PSE&G's mitigation effort is that the Salem facility continues to kill over 3 billion Delaware River fish a year while PSE&G is also harming thousands of acres of marshland by spraying it with glyphosate only to have the targeted phragmites return. There has been no minimization of adverse impact as required by section 316(b).

EPA Response

Under the final rule, EPA allows use of restoration to minimize or help to minimize the adverse environmental impacts deriving from impingement and entrainment of aquatic organisms. For a discussion of EPA's authority to include restoration measures as a compliance option in the final rule, see the preamble to the final rule.

EPA is aware of the uncertainties associated with the performance of restoration measures (see 67 FR 17146-17148 and 68 FR 13541-13543). However, EPA believes that implementation of the requirements in the final rule, as described in sections 125.94 and 125.95, will help reduce uncertainties associated with restoration projects and enhance their performance.

RFC: Performance/effectiveness of restoration

The Adverse Environmental Impacts 316(b) BTA Must Address

The theory behind the Mitigation Proposals is that they will result in the utilities replacing the aquatic organisms their cooling water intake structures kill. The utilities claim that by replacing the organisms they kill, the adverse environmental impact their CWISs are having will be minimized. When arguing that Mitigation Proposals can be used to fulfill the requirements of section 316(b), the utilities fail to show how the Mitigation Proposals will address the specific adverse environmental impact section 316(b) is seeking to minimize -- they do not reduce impingement and entrainment. Essentially, supporters of mitigation are arguing that replacing dead aquatic organisms equates avoiding killing those aquatic organisms—an argument that is not based in reality, science or the law.

EPA Response

For a discussion of EPA's authority to include restoration measures in the final rule, see EPA's response to comment 316bEFR.056.003 and the preamble to the final rule.

Subject Matter Code 2.04.03

Define BTA as anything less than closed cycle

The plain meaning of the statute and decisions rendered concerning BTA and section 316(b) make clear that 316(b) BTA must address the specific harms being caused by CWISs (impingement and entrainment). Section 316(b) cannot be fulfilled by a technology or project, which seeks only to address man-made after-the-fact injury to the natural environment and the overall fish losses caused to a source waterbody. Congress, by enacting 316(b), and EPA in its historic interpretation of it clearly intend for the overall harm to the natural environment to be avoided by utilizing technology designed to prevent the specific harms CWISs cause. The impacts the CWIS is having on a waterway's overall health and fishery as a result of its water withdrawals and impingement and entrainment of aquatic organisms is addressed through direct reduction of the impingement and entrainment of aquatic organisms.

EPA Response

Organization Delaware Riverkeeper

When considering the impacts of the Salem Nuclear Generating Station for purposes of section 316(b) of the Clean Water Act, Dr. Goodyear, in a report made for the Delaware Department of Natural Resources and Environmental Control, makes clear that the existence of a balanced-indigenous community is not a proper gauge for whether or not Salem and its CWIS is having an effect. He notes that the “suite of species present, and the relative magnitudes of those species could shift m important ways and there would still be a balanced indigenous community.“ Dr. Goodyear joins with ESSA Technologies (who conducted a study of the Salem facility for NJDEP) and the case law in concluding that the focus of decision making must be on minimizing the impingement and entrainment impacts. <FN 1> Dr Goodyear supports this interpretation of the law by pointing out scientific problems with PSE&G’s suggested approach. <FN 2>

Footnotes

1 Dr. Goodyear et. al., comments on Appendix F. of the PSE&G Permit Application for Salem 4 March 1999, 12/13/99. (“Dr. Goodyear 12/13/99”)

EPA Response

EPA agrees that ecological impacts can occur on many levels and many serious impacts can occur without causing a change in or an impact on a "balanced indigenous community" which, in any case is the statutory test for section 316 (a), not section 316(b). EPA believes it is important to evaluate all levels of impacts that are possible beginning with accurate I&E monitoring and appropriate annualization of losses.

Restoration measures in place of technologies

Mitigation does not “Minimize” impingement and entrainment.

Section 316(b) requires that power plants use BTA to “minimize” their adverse environmental impacts. The term “minimize” means to reduce to the smallest possible amount or degree. <FN 3> Minimization of adverse environmental impacts is required regardless of whether the adverse environmental impact a cooling water intake structure is having is significant or not - “[a]ll environmental harm should be avoided.” <FN 4> Therefore, a facility, which is having an adverse environmental impact that can be reduced, should be reduced as much as is possible by using BTA. It is not permissible to allow a facility to continue to inflict its impingement and entrainment impacts largely unchecked simply because a facility promises to undertake some other environmental project (i.e. mitigation) it claims will be beneficial to the impacted waterway or communities (human and nonhuman communities).

316(b) Requires Action on Intake Structures

Section 316(b) mandates that the “location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact.” Because the language of section 316(b) is clear, its plain meaning controls its construction. <FN 5> The plain language of the statute clearly requires implementation of technologies on cooling water intake structures. The language cannot be read to permit action wholly unrelated to cooling water intake structures.

The Clean Water Act, when reviewed as a whole, is a technology forcing statute -- through regulation industry is encouraged and required to develop the technologies needed to attain the requirements of the law. Assertions by industry that there are no viable alternatives for complying with the law does not alleviate them from the responsibility for identifying and creating, new technologies that do comply with the law. Industry has had 30 years to create technologies which comply with the requirements of 316(b) and which satisfies industry concerns — the fact that they have chosen instead to fight this statutory requirement should not be rewarded with a weakened standard.

Prior EPA guidance, regulatory and court decisions make clear that the a CWIS includes all structures and components of the intake system which are an integral component of the CWIS and associated with the withdrawal of cooling water including dikes, dredged channel, intake canals, etc. In order to fulfill the definition of the term “cooling water intake structure” there must be an intimate connection between the structure at issue and the cooling water intake structure. <FN 6> Technology proposed for use to fulfill section 316(b) requirements should be affiliated with the cooling water intake system in terms of bringing water into the cooling system.

Mitigation Proposals do not impact the location, design, construction or capacity of a CWIS. They are merely an attempt to address the overall harm caused by CWIS’s, i.e. the overall loss of fish and aquatic organisms in the source waterbody, they are not seeking to address the specific impingement and entrainment harms caused by the CWISs. Creation of wetlands, removal of impediments to fish migration, and fish hatcheries are in no way linked to, or associated with, CWISs or the process of drawing water into the cooling system and cannot be used to fulfill the requirements of section 316(b). Technologies/activities which do not specifically focus on the CWIS, such as non-CWIS mitigation efforts, cannot be said to fulfill the requirements of the law.

Use cost-benefit tests

Mitigation and the 316b Cost Test.

As the result of interpretive agency and judicial decisions, 316(b) has been subject to a cost test —technologies cannot be required pursuant to 316(b) if their costs are wholly disproportionate to the environmental benefit to be gained.

We note at the outset that the plain language of 316(b) does not provide for implementation of a cost test. As a result, we do not believe that an appropriate application of 316(b) would include such a test. But, to the extent that past decisions have included, and continue to rely upon, application of the wholly disproportionate cost test, and provided the cost test will continue to be utilized, it is important that 316(b) decisions and rulemaking include an appropriate application of this test.

A widely used argument against closed cycle cooling and in support of the use of Mitigation to fulfill the requirements of section 316(b) is that the cost of implementing technologies (particularly closed-cycle cooling systems) that would meet the requirement of section 316(b) is so high that it is wholly disproportionate to the environmental benefits which would be obtained. Utilities argue heavily that they cannot afford the technologies needed to meet the 316(b) standard. These arguments tend to focus on the total cost of implementing a required 316(b) technology, as opposed to the incremental costs to the ratepayers.

These cost arguments are faulty and inconsistent with the requirements of section 316(b) and EPA's interpretation thereof. It is important that the proposed rules clearly establish that to the extent the wholly disproportionate test is applied, that it is focused on the incremental cost to the ratepayer and that it must, in order to support thorough and informed decision making, include a thorough analysis of all of the economic and environmental benefits that the technologies and/or mitigation proposals under consideration would achieve.

It is essential that a facility's ability to pay for a required 316(b) technology not be used to absolve them from the requirements of the law. Ability to pay is not a proper part of any cost consideration. The Clean Water Act was designed as a technology-forcing statute— as such it is incumbent on the industry to find cost-effective ways to meet the requirements of the law.

Consideration of the economic impact on an individual facility should not be part of the analysis -- ability to comply with regulations, provide service and remain economically viable is an accepted part of the free market process. Society cannot be made to subsidize the inability of a facility to comply with the law by allowing it to continue to adversely impact our public trust resources -- our waterways, our fisheries, our aquatic systems.

In applying the 316(b) cost test, past decisions closely link the acceptable cost level with the level of environmental benefit to be achieved. The decisions regarding consideration of costs pursuant to section 316(b) have not required a specific cost-benefit analysis nor have they focused upon the ability of a facility to pay for intake technologies; they have required that the cost of the technology not be wholly disproportionate to the environmental benefit to be gained. <FN 7> Therefore, it is clear that a consideration of costs pursuant to section 316(b) should focus on the amount of environmental benefit to be obtained from the technology considered, not whether or not the facility can afford the technology.

The 316(b) cost analysis requires a careful analysis of the costs of a proposed technology in conjunction with an analysis of the environmental benefits to be achieved. Under proper application of this test, as the environmental benefits associated with proposed technology increases so to does the acceptable cost level pursuant to 316(b), i.e. a high level of environmental benefit warrants a high level of cost.

RFC: Proposed use of restoration measures

When Could Mitigation be an Appropriate Option Under the Regs?

Section 316(b) is, under the plain meaning of the statute, technology driven. As discussed to this point, if there are CWIS technologies available to minimize the impingement and entrainment impacts of the facility, then that is what the law requires be implemented. Mitigation can be an option, can only be an option, in those circumstances when there are no CWIS technologies available that can accomplish the minimization goal. This reading of the law is supported by previous 316(b) decisions.

EPA Response

For a discussion of EPA's authority to include restoration measures in the final rule, see the preamble to the final rule.

Documented facility examples of CWIS impacts

The Crystal River Power Plant, owned by Florida Power Corporation, CWIS is located in an estuarine nursery. The facility has five generating units, two of which employ closed-cycle cooling and three of which use once-through cooling. <FN 8> The three once-through cooling units intake 1,889 MGD of cooling water from the estuary <FN 9> and in so doing annually impinge and entrain more than 40 tons of finfish and shellfish. <FN 10> In issuing a NPDES permit for the Crystal Rivers Plant, EPA determined that the location, design and capacity of its three once-through cooling water intake structures did not reflect the best technology available for minimizing adverse impacts as required by section 316(b). <FN 11> After determining that fine mesh screens were not a technically feasible technology for the cooling water intake structures because of associated siltation problems, <FN 12> and that the cost of installing closed-cycle cooling towers, which would reduce entrainment damage by approximately 85 percent, <FN 13> were wholly disproportionate, EPA determined that the plant could fulfill the mandate of 316(b) via a combined capacity reduction and Mitigation Proposal <FN 14> EPA required that the Crystal River Plant reduce its flow by 15 percent during the months of November through April, and that it construct and operate a fish hatchery “in an attempt to replace fish and shellfish eggs, larvae, and juveniles entrained by the plant.” <FN 15> EPA explicitly stated that implementation of this plan “constituted minimization of the environmental impacts of the cooling water intake as required by section 316(b) of the Clean Water Act for the Crystal River Power Plant” once-through cooling units. <FN 16>

In reading this decision it is clear that while cooling towers were not required, the flow reductions were clearly the major means by which EPA intended to achieve compliance with 316(b). Operation of the fish hatchery was merely a supplemental requirement to try and replenish fish to the source waterbody. The fish hatchery was used only as “an attempt” to replace the lost aquatic organisms--not to meet the requirements of 316(b).

Documented facility examples of CWIS impacts

The Tennessee Valley Authority's John Sevier Steam Plant used a detention dam to form a cooling water intake pool for the powerplant's cooling system. <FN 17> Because the primary purpose of the dam was to provide an adequate supply of condenser cooling water to the plant, it was determined to be an "integral component of the intake structure and subject to the provisions of Section 316(b). <FN 18> The existence of the dam was contributing to adverse impacts in the Cherokee Reservoir and the Holston River upstream from the plant. <FN 19> Because the dam interrupted spawning runs of indigenous migratory fish species and was responsible at least partly, if not completely, for the depletion of these species in the local waterbodies, and because the dam did not allow far successful use of tailwater areas for spawning by reservoir fish, the plant's cooling water intake structure was determined to have had a significant adverse environmental impact and did not fulfill the BTA requirements of section 3l6b. <FN 20> Initially, while making its Tentative 316 Determination, EPA determined that removal of the dam was not necessary because other mitigative measures existed for reestablishing the migratory pathway for spawning. Of significance was EPA's determination that the fish and removal of the dam "would probably result in additional severe adverse environmental impact." <FN 21> Subsequently EPA determined that many of the technologies originally thought to be available were in fact not feasible technologies for the plant. <FN 22> Additionally, EPA determined that the construction of a new intake system, removal and disposal of sediments, and the modification that would result to flow release patterns from upstream impoundments, which would all occur if the dam were removed, would result in the costs of removing the dam to be wholly disproportionate to the environmental benefits to be obtained. <FN 23> As a result, EPA did not find removal of the dam to be BTA pursuant to section 316(b). Ultimately, EPA required TVA to conduct a stocking program in order to assure replacement of fish populations which. have been extirpated or depleted "until such time as technology becomes available to modify the dam;" that it annually assess available technologies for fish passage and implement such technologies if they become available at a cost that is not wholly disproportionate to the anticipated benefits; conduct or support research and development of fish passage technology, in addition to other monitoring requirements. <FN 24> The Agency then stated "at this time" these conditions constitute minimization within the meaning of 316(b). <FN 25>

The key to the John Sevier decision is the fact that the Agency was unable to find any technologies which were feasible at the John Sevier Plant for minimization of adverse environmental impacts. Therefore, rather than not do anything, it seemed that EPA was attempting to place some requirements on the plant to address the concerns embodied in 316(b) as nearly as possible. Primarily it is important to note that while EPA was apparently, at the time of the decision, unable to find any technologies that would fulfill 316(b), it clearly required that TVA continue to assess possible technologies, attempt to create them, and that it implement them as soon as they became feasible, the costs test was met, and they would not further harm the already degraded environment. Additionally, in conjunction with its statement concerning the costs of the dam removal, EPA explicitly stated that if the environmental benefits associated with dam removal increased, then the cost of removing the dam may, in light of this information, no longer be wholly disproportionate thereby leaving this option open for future 316(b) determinations. <FN 26> Therefore, this case was a special situation in which no feasible technologies existed for addressing the adverse environmental impacts, yet EPA was attempting to implement 316(b) to the best of its ability with specific conditions that feasible technologies be sought out and implemented as soon as available.

EPA Response

Because of the uncertainties associated with the performance of restoration measures (see 67 FR 17146-17148 and 68 FR 13541-13543), EPA believes it is important for a facility to assess the range of design and construction technologies and operational measures available to it before requesting approval from the Director to pursue restoration. EPA believes it is also important that a facility explain why it believes that restoration is the most feasible, cost-effective, or environmentally desirable option. Therefore, EPA has established requirements at sections 125.94 and 125.95 to ensure that restoration measures are used only when appropriate.

RFC: Performance/effectiveness of restoration

A settlement made in 1980 between five utilities, EPA, the New York Department of Environmental Conservation and local environmental groups regarding several powerplants located on the Hudson River <FN 27> was meant to settle a challenge the environmental groups brought concerning permitting of the powerplants at issue. As part of the settlement, the utilities were to use their best efforts to keep the volumes of water they drew in for cooling purposes to a minimum, they were to construct, lease or contract for the operation of a hatchery for the stocking of the river with striped bass fingerlings, <FN 28> they were to engage in a biological monitoring program, <FN 29> and they were to provide an endowment to fund research to advance the scientific understanding and management of the Hudson River fishery. <FN 30> Of primary importance, and the major reason why utility reliance on this settlement is unfounded, is the fact that the fish hatchery program has been unsuccessful. By all accounts, the Hudson River is no better off in terms of its fishery than it was when the settlement was reached; therefore it cannot be said that the settlement in any way minimized the adverse environmental impacts the utilities were having on the Hudson River and its fish. Furthermore, the provisions regarding the fish hatchery stated that "[n]one of the Utilities shall be liable in any way for the results of the operation of the hatchery or the stocking of the fingerlings....' <FN 31> This statement clearly indicates that there was no intention by the parties to the document that this requirement fulfill the mandate of section 316(b) of the CWA, it was merely an attempt to get the utilities to mitigate past environmental damage they had inflicted on the Hudson River with their CWISs.

Even along the Delaware River, the recently reissued permit to PSE&G for operation of the Salem Nuclear Generating Station stated that use of mitigation was not intended to fulfill the requirements of section 316(b), but merely as a supplement to technology requirements provided for in the permit. While challengers to this permit question the accuracy of that position — it seems clear from the terms of the permit and public agency statements that the mitigation was in fact part of the 316(b) mandates imposed in the Salem permit — it is NJDEP's stated position, and the stated position that EPA signed off on when it did not challenge the permit in its draft and/or final stages.

Require closed cycle cooling

Author Name Maya K.van Rossum

Organization Delaware Riverkeeper

The Terms of the Clean Water Act require a focus on capacity and therefore must necessarily focus on use of closed cycle cooling.

Reducing a facilities' intake capacity (the quantity of water withdrawn) via closed cycle cooling is clearly the most effective technology available for reducing impingement and entrainment impacts. The proposed regulations fail to require this most effective technology in all necessary an appropriate circumstances. As a result, these regulations fail to fulfill the requirements of the law and fails to provide the protection needed by our aquatic ecosystems and populations.

EPA Response

See preamble to the final rule, particularly sections III, VII, and VIII, and supporting documents.

Comment ID 316bEFR.056.017

Author Name Maya K.van Rossum

Organization Delaware Riverkeeper

Subject Matter Code 6.02

Impacts of multiple intake structures on watersheds

Consideration of the existence of other power plants in the area.

316(b) “location” decisions should include consideration of the existence of other powerplants in the area. The need for consideration of the cumulative impacts of surrounding CWIS has been well stated by EPA in the past. <FN 32> According to a 1980 EPA decision, the Brunswick Memo, it is impossible to determine the impact a single powerplant located in an estuary is having on that estuary and the aquatic life which inhabits it. <FN 33> The Brunswick Memo suggests that it is possible that an intake located within an estuary may have an inconsequential impact. <FN 34> Yet, the memorandum notes that the number of powerplants in a single estuary, as well as in estuaries nationwide, is continuing to expand and that this state of affairs “must eventually spell doom for important marine resources.” <FN 35> The Brunswick Memo concludes this analysis by stating: “[t]he environmental decision to be made by the regulatory agency is -- at what point do we draw the line -- at this power plant; or the next, or the next? It appears that Congress has answered this question by requiring best technology to minimize impact at all, plants” <FN 36> Thus, EPA Regional Counsel has suggested that BTA requirements, including location decisions, must look beyond the immediate universe and impacts of a single powerplant, and must include consideration of all the powerplants within an area, and the impacts their cooling water intake structures are having on the source waterbody. To the extent that the regulations fail to mandate consideration of cumulative impacts in its 316(b) decision making, they are not in accordance with law.

Footnotes

34 Id.

35 Id. at 3.

36 Id. (emphasis in original.)

EPA Response

EPA agrees with this commenter that cumulative impacts can be important. Multiple facilities located in a watershed are more likely to be affecting the same population of a particular species. EPA disagrees, however, that today's rule must require consideration of such impacts. Section 316(b) applies to individual point sources and their cooling water intake structures; therefore, the inquiry can focus on the facility alone. EPA believes that the permitting authority has the discretion to consider the cumulative impacts of multiple intakes in a watershed as part of its section 316(b) decisionmaking process because stricter controls may be necessary when more than one facility kills large numbers of individual of the same species in the same watershed.

Subject Matter Code 10.03.01.01

Salem

Mitigation on the Delaware is a Growing Failure — And Cannot Justify Use of Mitigation For Purposes of 316(b) Elsewhere.

The Mitigation experiment permitted by the NJDEP at PSE&G's Salem Nuclear Generating Station for achieving 316(b) requirements has failed. Salem still kills over 3 billion fish and aquatic organisms a year through impingement and entrainment. Species killed include:

Over 59 million Blueback Herring
Over 77 million Weakfish
Over 134 million Atlantic Croaker
Over 412 million White Perch
Over 448 million Striped Bass
Over 2 billion Bay Anchovy

Additionally, sea turtles and shortnose sturgeon, threatened and endangered species, are killed at Salem. Precise figures on these kills have not been provided, but they have been acknowledged and documented on the public record. In fact, PSE&G used to have a special turtle resuscitation program, long since cancelled, especially to address their turtle kills. All of the sea turtles in Delaware Bay are either threatened or endangered.

EPA Response

Past performance of restoration measures is not necessarily indicative of future performance elsewhere. Restoration measures allowed under today's final rule must meet the requirements of the rule, including those described in sections 125.94 and 125.95 of the final rule.

EPA notes the commenter's concern that threatened and endangered sea turtles may be killed at Salem. Potential I&E of these species was not considered in EPA's analysis of the mid-Atlantic region because EPA was unable to locate I&E data for these species.

For a discussion of EPA's authority to include restoration measures in the final rule, see the preamble to the final rule.

Comment ID 316bEFR.056.019

Author Name Maya K.van Rossum

Organization Delaware Riverkeeper

Subject Matter Code 11.06

RFC: Performance/effectiveness of restoration

PSE&G was permitted to fulfill the requirements of section 316(b) by installing alterations to their intake screens, testing experimental sound technology (this is simply a test and results to date are not proving significant reductions in impingement and entrainment and for some species these tests have actually increased the number of organisms killed) and reducing their cooling water intake capacity from a permitted 3.2 billion gallons per day to the 3.024 they were only ever actually using — in other words their permitted capacity was reduced to actual capacity resulting in no actual reduction in capacity at all. In addition PSE&G was permitted to implement a wetlands restoration experiment.

While NJDEP stated that the mitigation was not required to fulfill the BTA requirements of 316(b), it is clear that the mitigation was in fact an integral part of the 316(b) decision and outcome. Without the mitigation experiment NJDEP would not have settled for zero capacity reduction, an unproven and experimental sound deterrence and bubble effort, alterations to existing intake screens and biological monitoring in the Delaware Bay and Estuary. Throughout the process the mitigation was clearly an integral and necessary part of the 316(b) decision.

PSE&G's Wetlands Experiment involves restoring, enhancing and/or preserving 10,000 acres of what PSE&G characterizes as degraded wetlands. The original argument supporting this program was that restoration/enhancement of these wetlands would increase fish production in the Delaware Estuary. In addition to the legal problems with use of this program for fulfilling the requirements of section 316(b), there are other, fundamental scientific problems with this approach for addressing the fish kills imposed on the Delaware Estuary by PSE&G's Salem plant.

First, PSE&G never provided scientific data indicating that food or habitat were limiting factors for the fish populations in the Delaware Estuary — and there is in fact no data or information that would indicate that this is in fact the case. Therefore, altering wetlands to increase food and habitat availability for fish is likely not to have any effect on fish populations in the estuary.

Second, PSE&G's success criteria and evaluation methodology for its wetlands enhancement efforts do not include determining whether the fish populations of the River are benefiting from the wetlands restoration efforts. Instead their success criteria focus on change in vegetation coverage, algal productivity, macrophyte productivity, etc... PSE&G excluded impacts to fish populations because PSE&G is unable to provide this kind of information. Mitigation is problematic in this regard in that science is limited in its capability to quantify these kinds of benefits, at least to the extent necessary to demonstrate any population benefits such as PSE&G is claiming. PSE&G simply cannot establish that its wetlands mitigation has improved the fish population.

Third, PSE&G's own data is confirming studies by other scientists, that the foundation upon which their entire mitigation project is predicated is not true. PSE&G has always asserted that phragmites is inferior at producing food and/or habitat for fish populations. But forage studies within three sections of their own Alloway Creek site as well as studies by the New Jersey Marine Sciences Consortium indicate that phragmites-dominated marshes on the Delaware Bay contribute just as much basic nutrient material into the food web as spartina-dominated marshes.

Another fundamental and flawed underpinning of the PSE&G Mitigation justification, is the false premise that phragmites is inferior to other species, particularly spartina, at providing food and habitat to aquatic species. According to emerging research, Phragmites is not less beneficial as food and habitat for fish, wildlife and other organisms as compared to Spartina. Therefore, the entire underlying basis for PSE&G's marsh experiment is debunked and no longer sustains the asserted goals of the program. "As new data are generated, the general perception that regularly flooded phragmites marshes are less functional than the spartina marshes they replace does not appear to be upheld." <FN 37> "Efforts to restore salt marsh areas by replacing the undesired Phragmites with the desired Spartina are often justified by the assumption that the productivity of animal populations will be enhanced. However, evidence from the studies reported here as well as those of others (e.g. Fell et al, 1998; Wainright et al., 2000) does not support the general assumption that Phragmites leaf detritus is of poorer nutritional quality for estuarine consumers than that of Spartina." <FN 38> Phragmites is native to North America and has been found to be a component of Eastern U.S. marshes for 2000 to 4000 years at least. <FN 39> Multiple studies document that "Phragmites production is equivalent to the role of S. alternaflora production in the diet of key estuarine species" <FN 40> and that it is consumed by fish in the marsh. Phragmites has also been found beneficial in other ways with benefits beyond those provided by Spartina. For example they release less contaminants back into the environment than Spartina. "In comparison to a Spartina community, Phragmites enhances both mineral and organic decomposition, basically doubling the accretion potential of the marsh." <FN 41> "Phragmites function may actually exceed that of other wetland plants in ameliorating certain estuarine dilemmas like eutrophication and marsh loss." <FN 42>

The statement by NJDEP during its most recent permit decision making with regards to the Salem facility, that "Phragmites eradication is generally looked upon favorably by natural resources agencies such as the Department" is not a fair representation of new and emerging science on the issue. Today there is significant information regarding the benefits of Phragmites to aquatic species as well as terrestrial species. PSE&G has not provided any information to support a contention that the overall quality of benefits provided by spartina are greater than those of phragmites and will be of greater value to aquatic populations. In addition, PSE&G and NJDEP discussions of the Cohansey, Alloway and other sites that are dependent on herbicide and marsh manipulations fail to reflect the adverse impacts that loss of this habitat is inflicting on animal populations. In many instances the marsh is devoid of vegetation, or has only low growing vegetation, over extended periods of time depriving the wildlife of shelter, habitat and food. The discussions and decisions to allow this program to continue fail to characterize or consider this damage.

Considering the reality that the efforts of PSE&G are largely being held up as a model for using mitigation to achieve 316(b) requirements it is important to understand why mitigation at Salem is not, and cannot, address the concerns that 316(b) is intended to address - i.e. impingement and entrainment of fish. As a legal matter, mitigation does not satisfy the requirements of 316(b) BTA; as a practical matter PSE&G is unable to demonstrate that its mitigation experiment actually provides benefits to the estuary ecosystem. The problems with PSE&G's mitigation experiment include, inter alia, the following:

-PSE&G failed to conduct any baseline data that would demonstrate whether or not food and habitat were limiting factors for the aquatic communities of the Delaware River system and therefore whether or not wetlands restoration could have contributed positively to their numbers.

-PSE&G is unable to demonstrate that the wetlands it is seeking to restore on these sites are superior, in terms of food and habitat for fish and other aquatic populations, than phragmites-dominated wetlands.

-PSE&G has failed to conduct the baseline data on the contributions of the phragmites stands to the food chain in order to make the necessary comparisons. It is very possible that the fish used the phragmites-dominated marshes in the same way and to the same degree as they would spartina-dominated marshes and therefore nothing has been truly gained by PSE&G's efforts, or would be lost if they were discontinued.

-PSE&G has failed to demonstrate that even if it is successful at replacing the existing phragmites in these areas with, other species of plants, that this change in vegetation is sustainable and will not be overrun by neighboring stands of phragmites within a matter of years.

-The draft permit fails to consider the unsustainability of the phragmites-dominated site (e.g. the Cohansey and Alloway sites). Without continued human intervention, the thousands of acres of phragmites located in Delaware Bay region will reinvade, and thus the alterations secured by PSE&G will be lost with no net or long-term change to the region from these areas.

-As noted by NJDEP, PSE&G cannot document the number of fish benefited by, or resulting from, the wetlands effort and so cannot demonstrate any benefit or lack thereof. Without this kind of information there can be no support to the suggestion that the wetlands are benefiting the fish populations of the River more-so than prior to PSE&G intervention or than would have been provided naturally (i.e. In the case of the salt hay farms, PSE&G merely mimicked a process that nature had already begun undertaking).

The PSE&G mitigation experiment, rather than being an example of why mitigation should be allowed, is actually a prime example of why it shouldn't - the project does not have the scientific baseline data necessary to justify it, the project is not providing data that will demonstrate its impacts on fish, the project does not fulfill the plain language and meaning of 316(b), and the mitigation project which must extend beyond the 5 years of PSE&G's NPDES permit is for all practical purposes unenforceable in terms of 316(b). And, as a result, opening the door to mitigation as a requirement of 316(b) pushes the door wide open and invites in abuse.

As the EPA case study points out, there are limits in the Delaware, today and in the past, on commercial and recreational takes of striped bass, Atlantic menhaden and others. These limits notwithstanding the Salem Nuclear generating Station has been permitted to continue its fish kills indiscriminately, unchecked by regulation. Salem's continued operation has helped create the need for catch limits, and lengthen the term of these limits, and has contributed to an overall sense of unfairness in the local commercial and recreational fishing industry that big business is not subject to the same rules as the rest of the community. Commercial and recreational fishing along the Delaware River are critically important to the local economy and these catch limits impact local community livelihood.

The EPA case study makes the same arguments as PSE&G regarding Salem, essentially that because improvements in water quality and catch limits have helped restore our fisheries to a certain extent that Salem should be allowed its indiscriminate killing. This argument cannot be allowed to continue. I also point out that while on Page B1-9 of the case study EPA asserts that the numbers of American shad have increased more than a thousand-fold since the early 1980s, on page B 1-13 EPA states “Although improved water quality and development of a fishery management plan led to some recovery after 1975, shad remain well below pre-1990 levels.” The case study states further that there are concerns about the extent to which the shad populations have actually recovered. These statements show that EPA’s conclusions regarding the value of mitigation are based on flawed interpretations and data. It also demonstrates one of the problems with a mitigation approach— it is difficult to get an accurate assessment of the health of a fishery, both pre and post mitigation. Efforts to minimize unnecessary and excessive takes of fish species are the best way to work to protect their populations and numbers -- 316(b) required BTA may require capacity reduction at PSE&G’s Salem plant as well as BAT in the CWIS.

It must be noted that EPA asserts in the Delaware Estuary case study that “The non-native common reed (Phragmites australis) ... has reduced the overall biological value” of the tidal marsh in the Delaware Estuary. “by eliminating feeding and nesting areas for waterfowl and wading birds.” EPA also states “This has led to a significant drop in available food resources, habitat diversity, and open water space and affects of number of species, including ducks, which are excluded from these infested areas.” EPA’s claims about wetland benefits to bird populations are unfounded and irrelevant. First, this is irrelevant from a 316(b) perspective. The cooling water intake structures ate harming fish, not birds. Second, PSE&G failed to conduct a scientific comparison of bird use of the marsh both pre-and post- their efforts, And finally, the wetlands experiment sites in the Alloway and Cohansey Creek Watersheds have turned into tremendous “dead zones,” areas devoid of healthy vegetation either because it had been herbicided, burned, disced or mowed. During these extensive periods, often occurring during the critical spring or fall, the vast areas disturbed by this project cannot be accurately said to be providing ecological benefits to birds or other marsh dependent critters.

EPA Response

For a discussion of EPA's authority to include restoration measures as a compliance option in the final rule, see EPA's response to comment 316bEFER.056.003 and the preamble to the final rule.

EPA believes that there are uncertainties associated with the design, implementation, performance, and assessment of restoration measures. For a discussion of these uncertainties, see EPA's responses to comments 316bEFR.206.055 and 316bEFR.077.013. The requirements in the final rule are intended to help reduce uncertainties associated with restoration measures and enhance their overall performance.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

All restoration measures used to comply with the performance requirements of the final rule must meet the requirements described in sections 125.94 and 125.95 of the final rule.

Salem

Impingement and Entrainment Impacts of Salem have Been Undercounted.

The Delaware Estuary relies heavily on studies and findings by PSE&G. Not only were these studies and findings used to establish impacts on the Estuary by Salem, but they were also used, by extrapolation, to identify impingement and entrainment impacts from other facilities in the study area. While it is true that there is more information regarding the impingement and entrainment impacts of Salem than at most other facilities, and therefore it may be appropriate to use data on the impacts of Salem to help quantify impacts at other facilities, the impacts of Salem have themselves been undercounted and need upward adjustment in order to give a truly accurate representation of the impingement and entrainment of cooling water intake structures nationwide.

ESSA Technologies, hired by NJDEP to review PSE&G's most recent studies and data regarding its Salem facility, found that PSE&G had underestimated their impingement and entrainment impacts. And, as a result, not only does EPA's case study undercount the impacts of Salem, but it also undercounts the impacts of the other facilities for which it relied upon PSE&G's data.

Throughout the course of its 154-page analysis, ESSA Technologies identified problems with the studies, data and conclusions contained in PSE&G's permit application. Examples of ESSA findings include (but are certainly not limited to):

-According to ESSA, PSE&G "underestimates biomass lost from the ecosystem by perhaps greater than 2-fold." <FN 43> "... the actual total biomass of fish lost to the ecosystem (including fisheries, station losses, and losses of food to predators, summed over all species) is at least 2.2 times greater than that listed in the Application." <FN 44> PSE&G's estimates exclude "a) actual biomass of fish lost at the station for all species including bay anchovy; b) lost prey production other than bay anchovy thereby underestimating catch foregone; and c) the projected increases in RIS abundance in the Application that should be included in estimates of catch and production foregone. The largest under-estimates are for bay anchovy, spot, striped bass, Atlantic croaker and weakfish. Problems with the estimates of natural mortality rates contribute to the underestimation of lost biomass. The difficulties with production foregone imply redoing all dependent and related analyses." <FN 45>

-". . .natural mortality rates were overestimated for at least the 7 RIS species that are increasing and therefore the actual total biomass of fish lost to the ecosystem should increase further than the 2.2 fold amount..." <FN 46>

-ESSA notes specifically, and repeatedly, the importance of the entrainment and impingement loss estimates and conditional mortality rates, to the other calculations made in the application. They then recognize, discover and point out many shortcomings in the entrainment and impingement estimates. They discuss the "extensive interpolation and extrapolation of entrainment data" and the "high degree of process error (bias) in the sampling methodology." <FN 47> And ESSA states "It is judged, however, that the estimated impingement mortality rates are not representative of actual mortality rates of impinged fishes after they are returned to the Delaware river via the fish return system of the station.” <FN 48> These shortcomings are critical because they underpin any of the other calculations upon which NJDEP is basing its decisions, including the ever-important cost/benefit analysis.

-ESSA Technologies determined that PSE&G has not provided an accurate assessment of the impingement and entrainment impacts of Salem. ESSA found that the sampling provided by PSE&G failed to characterize a number of data uncertainties. ESSA concluded that “documentation of the uncertainty and potential bias associated with the impingement and entrainment loss estimates, and with the CMR estimates, is important because the results of these analyses provide key input to subsequent analyses of the effects of the station, such as fish stock jeopardy, lost fish production and biomass, assessment of the Base Case Future station operations scenario, and ultimately, the cost/benefit analyses of BTA to reduce entrainment and inipingement.” <FN 49>

-“In summary, all the natural mortalities (M) for young fishes are likely overestimated, which has direct implications to CMRs if estimated with the EEIM. The CMRs of pre-juvenile 1 stages would be underestimated. The elevated Ms would result in underestimation of production foregone of growing populations, which would directly affect the fisheries benefit analyses of the cost/benefit assessment of alternative technologies to reduce entrainment and, impingement. <FN 50>

-ESSA pointed out that there were often adjustments made to data sets and analyses. ESSA at times expressed concern about the “magnitude of the correction necessary.” <FN 51> It noted that entrainment sampling in some instances required use of a multiplier -- the result was that “if only one larvae were caught and not extruded it would be counted as 9. At the other extreme, it is possible that during periods of low larval density as many as 8 larvae (and possibly more due to random process error) could be extruded through the net resulting in an observation of zero entrainment.” <FN 52>

EPA Response

EPA recognizes the potential importance of the data issues raised by the commenter, and agrees that the extrapolation methods used at proposal were not ideal. Therefore, in response to this concern, EPA revised its final analysis by adding additional facilities (a total of 46) and extrapolating on a regional, rather than a national basis. For its analysis of the mid-Atlantic region, Salem was only one of many facilities with I&E data that were used to estimate regional I&E. I&E rates were averaged across multiple facilities, lessening the impact of Salem's data on EPA's I&E estimate for the mid-Atlantic.

In addition to ESSA Technologies, the State of Delaware and USF&WS both conducted independent expert review of the permit application materials. The USF&W characterizes the impingement and entrainment impacts at Salem as “high”, <FN 53> as “substantial and potentially significant”, <FN 54> and as “ecologically significant”, <FN 55> and the “conditional mortality rates for some representative important fish species are high enough to be of serious concern.” <FN 56>

With regards to PSE&G assertions that Weakfish in Delaware Bay are subject to shrimp bycatch mortality, Dr. Desmond of the Delaware Division of Fish and Wildlife has stated unequivocally that the Bay's Weakfish are not subject to shrimp bycatch. <FN 57> If PSE&G had not included bycatch mortality in its calculations then there would have been a 12% increase in weakfish equivalent recruits -- there would be 12% more weakfish surviving than PSE&G estimated. This amounts to a 256,000 <FN 58> understatement by PSE&G. As a result, PSE&G's calculations yield lower harvest benefit figures and other costs and benefits, attributable to Weakfish reports and therefore they skew the cost/benefit calculations against technologies that would reduce the impacts to Weakfish in Delaware Bay.

PSE&G's response that ASMFC's recent adjustment yield per fish figures balance out this 12% understatement is inaccurate. While it is true that with regards to pounds harvested by commercial fishermen the changed numbers might balance each other out, this is not the case with regards to impacts to the recreational fisheries. Recreational fishermen are not interested in pounds of fish, they are interested in individual quantities. The 12% undercount by PSE&G impacts the quantity of fish available for recreational fishermen. This 12% figure is not cancelled out by the ASMFC change. The result is that there are more individual fish for fishermen to catch. This translates into more fishing days for recreational fishermen. The result is an increase in the economic benefits that accompany increased number of recreational fishing days.

57 September 26,2000 memo from Dr. Kahn to Andrews Manus

58 Response to Memorandum dated September 26, 2000 from Desmond Kahn to Andrew Manus, December 7, 2000, p. 8

EPA Response

EPA is unclear about the commenter's point about the ASMFC adjustment and recreational catch of weakfish. While it is true that recreational fishing is considered in terms of numbers of fish, not pounds, pounds of fish are readily converted to numbers. In any case, EPA notes that for its final analysis Salem was only one of many facilities with I&E data that were used to estimate I&E for the mid-Atlantic region. Because I&E rates for weakfish were averaged across multiple facilities, EPA believes that estimates of Salem weakfish losses did not significantly influence EPA's I&E estimate for weakfish in the mid-Atlantic region.

According to Dr. Desmond Kahn, Delaware Division of Fish and Wildlife, PSE&G's permit application did not include an estimate of conditional mortality rate (CMR; "The proportion of fish killed by the plant if no other sources of mortality are operating") from entrainment of striped bass, although CMRs were estimated for other RIS species. <FN 59> The result is to seriously understate striped bass mortality caused by Salem, and therefore to skew both the analyses of adverse environmental impact as well as cost-benefit analyses and the wholly disproportionate test. According to Dr. Kahn, the CMR caused by Salem for striped bass averaged 32% to 37%. In some years, CMR estimates were over 50%. Dr. Kahn disagrees with PSE&G's assessment that the cause of such high figures (as the over 50% figures) is the result of the Chesapeake Bay striped bass entering the Delaware. Ultimately, the origin of the fish is irrelevant, we are still killing millions of fish, presenting an adverse environmental impact.

Footnotes

59 Mortality of Delaware River Striped Bass from entrainment and impingement by the Salem Nuclear Generation Station, Dr. Desmond M. Kahn, Delaware Division of Fish and Wildlife, March 30, 2000.

EPA Response

EPA's analysis for the 316(b) rulemaking did not estimate conditional mortality rates, so this comment does not apply to EPA's benefits estimates for the mid-Atlantic region. Most facilities in scope of the Phase II rule have not collected the data needed to estimate conditional mortality rates.

Organization Delaware Riverkeeper

Subject Matter Code 10.03.01.01

Salem

In addition to the ecological loss of the striped bass, which was not reflected in the cost-benefit analysis, by virtue of the fact that the figures were not presented, the costs to the fisheries and fishing industry were therefore not represented. According to Dr. Kahn, the level of conditional mortality to striped bass by Salem "is high enough to be of serious concern, since it must be considered in addition to fishing mortality in stock management and may be a major impediment to stock productivity. <FN 60> The result of this high level of mortality "is equivalent to lowering the maximum reproductive rate of the stock by one third." <FN 61> "With this mortality, the accumulation of sufficient spawning biomass will require a marked reduction in exportation compared to a stock without this high mortality." <FN 62> Dr. Goodyear, reporting to and for the State of Delaware, joined in Dr. Kahn's concern about PSE&G's failure to more vigorously attempt to obtain entrainment estimates for striped bass. <FN 63> The figures in the materials suggest this value is, in reality, high.

Footnotes

60 Mortality of Delaware River Striped Bass from entrainment and impingement by the Salem Nuclear Generation Station, Dr. Desmond M. Kahn, Delaware Division of Fish and Wildlife, March 30, 2000.

61 Mortality of Delaware River Striped Bass from entrainment and impingement by the Salem Nuclear Generation Station, Dr. Desmond M. Kahn, Delaware Division of Fish and Wildlife, March 30, 2000.

62 Mortality of Delaware River Striped Bass from entrainment and impingement by the Salem Nuclear Generation Station, Dr. Desmond M. Kahn, Delaware Division of Fish and Wildlife, March 30, 2000.

EPA Response

Conditional mortality rates were not evaluated as part of EPA's benefits analysis. Most facilities in scope of the Phase II rule have not collected the data needed to estimate conditional mortality rates.

EPA recognizes the commenter's concern about striped bass. However, EPA had no alternative but to rely on facility-generated data. However, EPA notes that for the final rule the Delaware analysis was replaced by an analysis of the entire mid-Atlantic region, which included many more facilities in addition to Salem. Because the analysis was based on many facilities, EPA believes that the Salem estimates of losses did not significantly influence EPA's I&E estimate for the mid-Atlantic region.

Comment ID 316bEFR.056.025

Salem

Author Name Maya K.van Rossum

Organization Delaware Riverkeeper

Based on the significant level of undercounting identified by ESSA Technologies, the US Fish and Wildlife Service, and experts working for the State of Delaware regarding the impacts of Salem, EPA must adjust upward the figures representing the impingement, entrainment and population impacts of Salem. The more conservative assumptions that EPA has already applied to account for some of this error simply do not go far enough to remedy the self-serving underrepresentation of impacts provided by PSE&G.

While EPA has clearly not undertaken enough steps and adjustments to remedy all of the problems with PSE&G's studies and assertions which resulted in their dramatic and tremendous understatement of their ecological impacts in terms of impingement and entrainment at Salem, it is clear that EPA was absolutely correct in its recognition that they had to correct many of the assumptions, bias, errors and misstatements made by PSE&G and its scientists. EPA adjustments to PSE&G's studies, data and calculations were and are necessary in order to obtain and provide a more accurate determination of the impingement and entrainment impacts Salem has on the aquatic species that live in the Delaware Estuary. (Attached find copies of the various reports concerning the many shortcomings, bias and inaccurate assertions made by PSE&G in their studies and resulting 316(b) materials.)

EPA Response

EPA notes these concerns of the commenter about PSEG's impingement and entrainment analyses for the Salem facility. However, EPA's analysis was dependent upon the available data. Nonetheless, to make its analysis more robust, EPA's evaluation of the mid-Atlantic region for the final rule included many more facilities in addition to Salem. For this analysis, EPA's goal was to develop a regional estimate of impingement and entrainment, rather than facility-specific estimates. Please refer to EPA's response to Comment 316bEFR.041.041 concerning EPA's extrapolation approach.

The Delaware River Case Study Understates Impacts to Threatened and Endangered Species.

We are very concerned that EPA failed to evaluate the potential impacts of CWIS' on federally listed threatened and endangered species because they lacked any data. Failure to locate data is no excuse for ignoring the impacts to species that are already at risk. The Delaware Estuary Case Study essentially concluded that because there is no data regarding impacts on threatened and endangered species that there is no impact. Because Salem is used as a model for 35 facilities across the country the magnitude of this error is significant, is magnified, and has far-reaching negative implications for the natural environment, including for threatened and endangered species.

In a December 1998 report prepared by the National Marine Fisheries Service it is stated that Salem does impact the federally endangered shortnose sturgeon that live in the Delaware River. While this is not a comprehensive study on the impacts, the report states that 8 shortnose sturgeon were discovered in trash bars at Salem. Based on their reviews they guestimate that between 0 and 11 fish are impinged at Salem each year. There were no findings regarding entrainment but clearly sturgeon are killed at Salem, if adults are getting caught on trash racks it is highly likely that juveniles, and younger, are also getting killed there.

We also know that Sea Turtles have been injured and killed at Salem. The New Jersey permit record has information about the impacts to the federally threatened turtle populations injured and killed at Salem, and even for a period required a turtle resuscitation program at Salem.

So there is some data available which has not been taken into account regarding impacts to threatened and endangered species by the Salem facility. And more importantly, a lack of data cannot be used to conclude that there is no impact —this is bad science and bad logic. Data regarding impacts to threatened and endangered species needs to be identified and or collected before such a significant and far reaching decision (in light of the use of Salem as a model for so many facilities across the country) is made.

EPA Response

EPA agrees that a lack of data cannot be used to conclude that there is no impact, and in fact did not conclude that there are no impacts to sea turtles from operation of Salem's cooling water intake structures. However, EPA was unable to locate data for sea turtles impinged and entrained at Salem.

Unfortunately, the lack of data on sea turtle I&E rates in general meant that EPA could not include these species in its analysis. This does not mean that EPA concluded that I&E of sea turtles does not occur, only that it's extent is unknown. More information on this issue is needed.

Please see Chapter A13 of Part A of EPA's Regional Analysis Document (DCN #6-0003)for a discussion of T&E species and approaches for analysis of potential I&E impacts.

RFC: Three-option framework for determining BTA

The proposed rule would implement section 316(b) of the Clean Water Act <FN 2> for certain existing power producing facilities that employ a cooling water intake structure and that withdraw 50 million gallons per day or more of water from waters of the U.S. and use at least 25% of water withdrawn solely for cooling purposes. The proposed rule constitutes Phase II in EPA's development of section 316(b) regulations and would establish national requirements applicable to the location, design, construction, and capacity of cooling water intake structures that reflect the best technology available for minimizing adverse environmental impact at these facilities.

Subject Matter Code 10.07.02

RFC: Appropriateness of "significantly greater"

Cost - Benefit Test

A facility may qualify for a site-specific determination of best technology available ("BTA"), if the costs of implementing the performance standards in § 125.94(b) are significantly greater than the costs considered in establishing them or in the benefits of compliance. in such case, a facility may receive alternative performance standards if it can meet one of the two cost tests in proposed § 125 .94(c)(1). Therefore, the cost-benefit test is key to the successful implementation of this rule. As such, assuming that EPA will adopt the Phase II rules under the current proposed framework, it is essential that this test be included in the final rule and given the same significance it has in the proposed rule.

EPA Response

The final rule includes a compliance alternative that allows a site specific determination of BTA. See section VII of the preamble to the final rule, 40 CFR 125.94(a)(5), and response to 316bEFR.006.003.

Author Name Douglas J. Fulle

Organization Oglethorpe Power

Subject Matter Code 10.07.02

RFC: Appropriateness of “significantly greater”

“Significantly Greater”

The proposal provides for a site-specific determination of the BTA, if the costs of compliance at a site would be “significantly greater” than either the benefits of meeting the performance standards or the costs the Agency considered in establishing such standards. EPA must provide a clear definition of what is meant by “significantly greater.” To maximize net benefits to society, economic theory dictates that “significantly greater” should be interpreted to mean any cost benefit ratio greater that 1:1.

RFC: Use of previous demonstration studies

Application to Existing Facilities

In addition to the performance standards set forth in the proposal, a process for approving existing intake technologies as “best available” should be included, where it can be shown that the facility is not causing adverse environmental impact or that the technologies have already been deemed “best available” by the state where the facility is located. Such a process is reasonable, since § 316(b) of the CWA has been in effect since 1972, and has already been implemented on a case-by-case basis at many sites. A such, there are numerous electric generating facilities for which there is already a high degree of confidence that the facility is not causing adverse environmental impact, or that BTA has already been installed. In addition, if the facility has data indicating that the amount of entrainment and impingement is so small that there is no significant harm to the aquatic community or if the environmental impact is of so little economic and environmental significance that the costs of a comprehensive 316(b) study would be significantly greater than its benefits, then there should be no need for further studies or additional intake technology.

EPA Response

EPA has disallowed the use of historical determinations of BTA in today’s final rule; however, existing data that is reflective of current conditions may be used to support the required studies. Please see response to comment 316bEFR.040.001 for details.

Additionally, under compliance alternative 2 (see 125.94(a)(2)), a facility may demonstrate that it already meets rule requirements if its existing design and construction technologies, operational measures, and/or restoration measures meet the performance standards at 125.94(b) and/or the restoration requirements in 125.94(c).

Option 1--Demonstrate existing BTA

In § 125.94(a) of the proposed rule, EPA offers three alternatives for establishing BTA requirements at covered facilities. Under the first option, a facility may demonstrate to EPA that it already employs technologies or measures nee4ed to meet the performance requirements set forth in the proposal. See § 125.94(a)(l). If a facility chooses to establish compliance under this first option, the facility must then meet the performance standards set forth in § 125.94(b). To adequately demonstrate the efficacy of such existing technologies and/or measures, a facility must conduct a Comprehensive Demonstration Study (a “Study”) under § 125.95(b), unless, using the performance standards listed in § 125.94(b)(1), a facility reduces its intake capacity to a level commensurate with the use of a closed-cycle, recirculating cooling system. If a facility can demonstrate to EPA that it meets the performance standard in § 125.94(b)(1), then the facility is not required to conduct and submit a Study. However, the rule does not state what such a facility would have to show in order to establish that it meets the performance standards in § 125.94(b)(1). EPA should consider, therefore, providing specific criteria within the rule for satisfying this performance standard.

EPA Response

The commenter has characterized the proposed rule; therefore no response is required for this part of the comment. Please refer to the preamble for a discussion of the framework of the final rule.

EPA assumes that the commenter is referring to what criteria a closed-cycle facility must meet in order to satisfy the performance standards. EPA notes that facilities with closed-cycle recirculating cooling systems are considered to be in compliance with the performance standards and are not required to submit a Comprehensive Demonstration Study. Please refer to § 124.94(a)(1) for further information.

Performance standards

Compliance Assessment

Since there is such variability in biological systems, it is not practical to require the permittee to meet a specific numerical reduction in affected organisms. The proposed performance criteria should not be directly implemented as enforceable permit limitations. Rather, when the existing technology is not the "best available", the permit should require the installation of technology identified collaboratively by the permittee and the state. Then compliance with the permit would be based on installation, operation and maintenance of the selected technology.

EPA Response

General statement of support

The Commission strongly supports the EPA's decision to establish consistent national standards that outline minimum requirements of location, flow, and velocity for existing facilities. This will remove the uncertainty in the existing case-by-case basis approach while still allowing the state permitting authorities to provide additional site-specific measures when the resource requires them.

EPA Response

EPA notes the comment. No response necessary.

Organization Atlantic States Marine Fisheries

Subject Matter Code 7.01.03

Option 3--Site-specific determination

Although the Commission supports the overall approach to these proposed regulations, we have some significant concerns. The EPA has proposed three options for establishing the best technology available for minimizing adverse environmental impacts in the proposed rule. The ASMFC supports the first two but opposes the third option of the facility owner demonstrating that the cost of compliance would be significantly greater than the EPA estimate or value of the benefits. We do not believe that there is enough data available on all of the fish species to fully estimate the cost of impingement and entrainment at each individual facility, nor do we believe that the methods currently proposed fully estimate the value of the key commercial and recreational fisheries or their forage base.

EPA Response

The final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA agrees with the commenter that developing a complete estimate of benefits of alternative CWIS may not be feasible. See EPA's response to comment #316bEFR.206.047 on benefit categories omitted from EPA's analysis of the benefits of reduced cooling water intake. Also see EPA's response to comment #316bEFR.005.020 on application of the cost-benefit analysis to assessing the value of alternative CWIS technologies. See also sections V and IX of the preamble on site-specific determination of BTA.

Burden on permitting agencies (general)

Currently, most of the state permitting agencies do not have the appropriate staff to properly evaluate these proposals, and it would increase the permitting workloads and timeframes substantially to necessitate the review of comprehensive cost-benefit analyses.

EPA Response

EPA appreciates the lack of resources at some State agencies and plans to provide guidance concerning implementation of today's final rule. Due to the multiple compliance alternatives available in today's final rule, EPA expects that most facilities will not seek a site specific determination of BTA based on the costs of compliance with today's rule being significantly greater than the benefits of complying with the national performance requirements. Therefore, the ensuing burden under this compliance alternative should be minimal.

Comment ID 316bEFR.059.006

Organization Atlantic States Marine Fisheries

Subject Matter Code 10.07.02

RFC: Appropriateness of "significantly greater"

If the EPA does choose to go forward allowing this option the ASMIFC urges you to require costs to be "wholly disproportionate" to the costs EPA has considered as you did with the new facilities rule rather that "significantly greater" as has been proposed for this rule.

EPA Response

The comment includes no reasoning for its request. See response to 316bEFR.006.003.

Comment ID 316bEFR.059.007

Subject Matter Code 11.01

RFC: Proposed use of restoration measures

Author Name John V. O'Shea

Organization Atlantic States Marine Fisheries

We also have concerns with allowing restoration measures by a facility in lieu of reductions in impingement mortality and entrainment. While many of the restoration efforts taking place along the Atlantic Coast are beneficial to the species we manage, restoration should not be used in place of technology to reduce impacts. Restoration should only be used when these impacts cannot be avoided or have already occurred. Restoration science is not currently able to recreate the full functional equivalency (the full range, sequence and timing of interdependent life cycle stages that make up a productive, functioning, aquatic community) destroyed through impingement and entrainment.

EPA Response

For discussion of the consideration of design and construction technologies and operational measures before the use of restoration measures, see EPA's response to comment 316bEFR.033.005.

Comment ID 316bEFR.059.008

Author Name John V. O'Shea

Organization Atlantic States Marine Fisheries

Subject Matter Code 11.03

RFC: Appropriate spatial scale for restoration

If the EPA does choose to go forward with allowing restoration in lieu of reductions, the ASMFC urges you to require restoration efforts in the same local waterbody where impacts are occurring.

EPA Response

For a discussion of the appropriate scale on which to conduct restoration measures, see EPA's response to comment 316bEFR.212.001.

EPA does not want to preclude use of restoration measures on a watershed scale that can accomplish the environmental objectives of the final rule while providing additional flexibility to permit applicants and permitting authorities. For example, EPA believes there are some populations of migratory fish that move on a scale larger than the local waterbody surrounding a cooling water intake structure. Restoration measures can sometimes be implemented to produce and result in increases of these types of fish in the watershed containing the impacted waterbody. Because of the migratory nature of the fish, benefits can still accrue to the impacted waterbody despite the restoration measure taking place elsewhere in the watershed.

Comment ID 316bEFR.059.009

Author Name John V. O'Shea

Organization Atlantic States Marine Fisheries

Subject Matter Code 11.06

RFC: Performance/effectiveness of restoration

In addition facilities should be required to demonstrate that their restoration efforts would achieve a high level of functional equivalency before it is considered as an alternative to reductions in impingement and entrainment.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

RFC: Test: benefits should justify the costs

Author Name Mark V. Carney

Organization PG & E National Energy Group

We also support the use of sound economic analysis in selecting appropriate alternatives for effectively addressing I&E impacts associated with cooling water intake structures. Of the decision criteria presented by EPA in the proposed rule, only one, “a test based on the concept that benefits should justify costs”, will result in the selection of an alternative for reducing I&E that maximizes net benefits to society. The same is not true for a “wholly disproportionate” or “significantly greater cost to benefit” tests.

EPA Response

EPA agrees with the comment that sound economic analysis should be used to select appropriate alternatives. However, EPA does not agree that only a strict benefit-cost criterion is appropriate in this case. For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

For EPA's response to comments on application of a “wholly disproportionate” or “significantly greater cost to benefit” tests please see comment #316bEFR.060.002. See also the preamble to final rule.

Subject Matter Code 10.02.03

Use of Replacement Costs (HRC and hatchery-based)

Unfortunately, sound economics was abandoned in EPA'S decision to use the Habitat Replacement Cost (HRC) Method for estimating benefits associated with reductions in I&E. Even more unfortunate was EPA's decision to use HRC in the Brayton Point case study. As concluded by Dr. Robert N. Stavins, an economist at Harvard University who assisted PG&E NEG in evaluating the proposed rule and case study (see attached comments), HRC is not a method of valuation or benefit estimation at all, but a method of assessing costs. While mitigation, restocking, and/or habitat restoration are acceptable alternatives to the installation of specific technologies in order to offset I&E losses, the cost of such alternatives is in no sense whatsoever a reasonable proxy for the value (i.e. benefits) of reducing I&E. This assessment of the HRC method is shared by other economists, including Drs. David Harrison, Jr., and William Desvousges who assisted the Utility Water Act Group and the Edison Electric Institute's assessment of the proposed rule.

Therefore, we strongly object to EPA's use of HRC for valuing benefits. Its use and results should be removed from the documentation (i.e. case studies, the proposed rule and all supporting documentation), and the "values" calculated should be subtracted from all benefit estimates, including those carried out for the Brayton Point Station. Further, HRC should not be used to support the final rule or NPDES permits at any PG&E NEG stations.

EPA Response

EPA does not use the Habitat-based Replacement Cost (HRC) method in the cost benefit analysis for the final Section 316(b) Phase II rule. Please see the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003) for additional discussion of the HRC method. Please also see EPA's response to comment #316bEFR.005.035.

In the analyses for the NODA and the final rule, EPA no longer uses hatchery costs to estimate impacts on forage species. Instead EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule (DCN #6-0003_. See Chapter A5: Methods Used to Evaluate I&E.

Subject Matter Code 10.03.05

Brayton Point

The Brayton Point case study, noted above, is premised on numerous faulty assumptions, erroneous analytical methods, and flawed calculations. It places undue, but substantial, reliance on several reports prepared by Mark Gibson of the Rhode Department of Environmental Management which, among other flaws, use and present data in a misleading way that distort the impacts of Brayton Point Station, misrepresents the actual conditions of Mount Hope Bay, and mischaracterizes the recovery of winter flounder in Narragansett Bay. The cumulative effect of EPA's errors is to produce a grossly excessive estimate of the benefits of the proposed rule for Mount Hope Bay that has no basis in sound science.

EPA Response

EPA disagrees with the commenter's conclusion that EPA's analysis is based on "faulty assumptions, erroneous analytical methods, and flawed calculations." Without details to support these accusations, EPA is unable to respond further. However, EPA wishes to note that EPA Region 1's 2002 NPDES permitting determinations for BPS provide multiple lines of evidence indicating that the BPS is having an adverse impact on finfish in Mt. Hope Bay. This information is provided in EPA Region 1's 2002 NPDES permit determinations for BPS and the related Responses to Comments document (available at http://www.epa.gov/region1/braytonpoint/index.html)

Performance standards

We are also troubled by EPA's proposed mandatory performance standards for reducing I&E. The three PG&E NEG stations affected by the proposed rule withdraw cooling water from three very different types of water bodies - an ocean, an estuary and a tidal river. Each ecosystem is quite different yet EPA, under the proposed performance standards, is proposing a one-size-fits-all requirement for reducing entrainment and impingement mortality. The only way to accurately and appropriately select BTA is on a site-specific basis.

EPA Response

Please see response to comment 316bEFR.311.002 and the preamble to today's final rule.

Comment ID 316bEFR.060.006

Subject Matter Code 21.09

Permit applications/implementation schedule

Author Name Mark V. Carney

Organization PG & E National Energy Group

Finally, each facility with an NPDES permit renewal pending should have the option of complying with either the existing site-specific process or the new rule. Providing such an option is particularly important given the significant changes EPA is making to its interpretation of the substantive requirements of 316(b).

EPA Response

In today's final rule, EPA offers five compliance alternatives including a site-specific determination of BTA. Please see the preamble to the final rule and response to comment 316bEFR.034.005 for additional discussion.

Comment ID 316bEFR.060.007

Subject Matter Code SUP

General statement of support

Author Name Mark V. Carney

Organization PG & E National Energy Group

EPA's proposed rule contains several elements with which PG&E NEG, in principle, agrees. PG&E NEG agrees with EPA's conclusion that closed-cycle cooling does not represent the "best technology available for minimizing adverse environmental impact" at existing facilities. PG&E NEG also agrees with EPA's inclusion of a site-specific alternative to its proposed national performance standards and supports EPA's abandonment of the "wholly disproportionate" cost test. PG&E NEG welcomes EPA's consideration of several proposals that would provide new flexibility in complying with Section 316(b), including voluntary mitigation measures, mitigation banking and mitigation trading. Each of the foregoing elements should be included in EPA's final Phase II regulation.

EPA Response

Today's final rule maintains the desired flexibility for both the permittee and the Director to determine the most appropriate and cost-effective means for meeting the requirements of today's rule. EPA also notes that compliance alternative 5 allows a site-specific determination to be made based on cost-cost and cost-benefit considerations.

Comment ID 316bEFR.060.008

Author Name Mark V. Carney

Organization PG & E National Energy Group

Subject Matter Code OPP

General Statement of Opposition

Although EPA's inclusion of these elements is laudable, PG&E NEG believes that EPA's Phase II proposal as a whole is fatally flawed. EPA's approach is premised on fundamental misconceptions concerning the scope and purpose of Section 316(b) of the Clean Water Act. As a result, the proposed rule contains a number of provisions which are inconsistent with Congress' grant of authority under Section 316(b) and should be altered or eliminated. In addition, EPA has failed to provide an adequate scientific and technical justification for its proposal. EPA's supporting documents include critical factual and analytical errors and provide no rational basis for the regulatory conclusions EPA has reached.

For these reasons, EPA's current proposal is not a permissible implementation of Section 316(b). It should be modified significantly prior to promulgation of the final rule.

EPA Response

Please refer to the response to comment 316bEFR.034.002.

Comment ID 316bEFR.060.009

Author Name Mark V. Carney

Organization PG & E National Energy Group

Subject Matter Code 2.04

EPA's legal authority to:

Misinterpretation of EPA's Statutory Authority

Section 316(b) states that:

Any standard established pursuant to Section 301 of this title or Section 306 of this title and applicable to a point source shall require that the location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact.

In PG&E NEG's view, the language, legislative history, and contemporaneous agency interpretations of this provision compel two conclusions concerning its proper scope and method of application:

-First, that the scope of authority delegated to EPA by Section 316(b) is limited to regulation of the four enumerated physical aspects of cooling water intake structures. Congress has granted EPA no broader authority to regulate cooling water systems or to consider environmental stresses or effects not related to the specific cooling water intake structure in question;

-Second, that determinations of "best technology available for minimizing adverse impact" must be made on a case-by-case basis, taking into account the unique circumstances of a particular facility affecting the feasibility, cost, and effectiveness of technology to reduce entrainment and impingement impacts. This determination requires a threshold finding by EPA that an adverse environmental impact exists at the facility which requires minimization and also requires EPA to demonstrate that there is a particular technology for use at the site which is "available" at an economically practicable cost.

EPA's proposal is inconsistent in critical respects with these principles.

In the proposed rule, EPA improperly seeks to expand the limited scope of Congress' authorization under Section 316(b). EPA asserts authority under Section 316(b) to impose closed cycle cooling and operational measures through an illogical interpretation of the word "capacity" and to require mitigation measures as aspects of cooling water intake structure "design." EPA also incorrectly claims authority under Section 316(b) to consider cumulative intake structure impacts and other outside environmental stressors in determining the "best technology available."

These interpretations are inconsistent with the plain language of the statute and at odds with settled principles of statutory construction. EPA may not use illogical and unjustified interpretations of single words to assume an authority over aspects of a facility and its environment that Congress did not grant. Provisions of the proposed rule that rely on EPA's authority to impose closed-cycle cooling, operational measures and mitigation and that would require consideration of the cumulative effect of environmental stressors, including other intake structures, exceed the scope of Section 316(b) and should be eliminated from the final rule.

Although EPA correctly recognizes that a site-specific determination of BTA is required, EPA's proposed rule restricts the ability of many, if not most, facilities to obtain a set-specific determination of BTA. Instead, EPA proposes presumptively applicable performance standards that would provide facilities only a limited opportunity to obtain a site-specific determination, based on either the cost-cost or cost-benefit tests. In addition to impermissibly limiting access to a site-specific determination of BTA, EPA's performance standards approach ignores EPA's obligation to show, for each individual case, that there is adverse environmental impact requiring minimization. It also ignores EPA's obligation to demonstrate that any identified technology is "available" at an economically practicable cost.

The mandatory performance standard limited site-specific alternative is inconsistent with Section 316(b) and should not be contained in the final rule without substantial modification. At the very least, EPA should make the site-specific alternative available to any facility that requests it and ensure that a Section 316(b) determination under the site-specific alternative requires on a threshold finding of adverse impact and a determination that the technology chosen is available at an economically practicable cost.

EPA Response

See preamble to the final rule, particularly sections III, VII, and VIII, and supporting documents.

Comment ID 316bEFR.060.010

Subject Matter Code 7.02
Performance standards

Author Name Mark V. Carney
Organization PG & E National Energy Group

Lack of Scientific and Technical Justification

In addition to its erroneous legal premises, EPA's proposal lacks valid scientific and technical support.

EPA provides no biological or technological justification for the proposed performance ranges. EPA claims that the performance standards are based on a group of screening and avoidance technologies, yet the record does not demonstrate that those technologies are actually feasible, available at a reasonable price, or able to achieve the stated performance standards. To the contrary, several of them are demonstrably unusable in many instances and may be unable to achieve reductions within the performance ranges even where they can be used. EPA's supporting documents fail to establish that these technologies are BTA for existing sources.

In addition, EPA provides no credible biological justification for the performance standards or for any other aspect of its proposal. EPA's assessment of the biological impacts of entrainment and impingement misreads the available data and relies on analytical methods that have no scientific support. These errors include incorrect assumptions concerning impingement and entrainment mortality and use of invalid methods to estimate the adult equivalent losses resulting from losses of eggs and larvae. The cumulative effect of these errors is to significantly overstate the losses from Impingement and Entrainment ("I&E") and, therefore, the environmental benefits of the proposed rule. EPA's flawed biological methods provide no basis for concluding that EPA's specific proposals represent a rational approach to addressing adverse environmental impact resulting from I&E.

EPA Response

Subject Matter Code 10.02.03

Use of Replacement Costs (HRC and hatchery-based)

EPA's economic analyses are equally unsupported by sound methodology. Compounding already excessive estimates of the biological losses caused by I&E, EPA utilizes invalid valuation methods, including the Habitat Replacement Cost method and forage fish replacement costs, which impart further, and dramatic, upward biases into EPA's estimates of the "benefits" of the proposed regulation. Use of these methods has no basis in economic theory and is inconsistent with EPA's own guidelines for estimating environmental values.

EPA Response

EPA does not use the Habitat-based Replacement Cost (HRC) method in the cost benefit analysis for the final Section 316(b) Phase II rule. Please see the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003) for additional discussion of the HRC method. Please also see EPA's response to comment #316bEFR.005.035.

In the analyses for the NODA and the final rule, EPA no longer uses hatchery costs to estimate impacts on forage species. Instead EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule (DCN #6-0003). See Chapter A5: Methods Used to Evaluate I&E.

Organization PG & E National Energy Group

Subject Matter Code 10.07.02

RFC: Appropriateness of "significantly greater"

EPA's misunderstanding of economic principles is similarly reflected in its choice of the "significantly greater" cost test as an alternative to the "wholly disproportionate" cost test for existing facilities. Although the significantly greater cost test represents an improvement over the wholly disproportionate test, it reflects the same fundamental error. By requiring that facilities expend resources on technology up to the point that their costs are "significantly greater" than the benefits, this test ensures that in many, if not most, cases, the amounts expended will exceed the benefits obtained. As a result, society as a whole will be worse off.

EPA Response

Comment ID 316bEFR.060.013

Subject Matter Code 10.03.05

Brayton Point

Author Name Mark V. Carney

Organization PG & E National Energy Group

These errors are amply demonstrated in EPA's deeply flawed "case study" of Brayton Point Station. In the case study, EPA repeatedly relies on inaccurate assumptions and demonstrably incorrect calculations to conclude that the Station is having an adverse impact on Mount Hope Bay. EPA then employs invalid and biased biological and economic models to develop estimates of the significance of the economic scope of that impact that are hundreds or even thousands of times greater than those produced by any accepted approach. Relying on these grossly inflated values, EPA, not surprisingly, suggests that imposition of strict controls would be cost-justified.

EPA's reliance on such demonstrably incorrect data and invalid analytical methods is inconsistent with the requirements of the Paperwork Reduction Act and PL 106-554 (the Data Quality Act), 44 U.S.C. § 3500 et seq. In addition, EPA's use of such deeply flawed methods can provide no rational basis of support for the proposed rule.

EPA Response

The commenter argues that EPA's Brayton Point analysis is "deeply flawed" but provides no basis for this assertion. Without specifics on what the commenter considers incorrect, EPA cannot provide specific responses to this comment. However, EPA asserts that its analysis is based on sound science, and has provided responses to specific comments on the Brayton Point case study elsewhere in these responses to comments.

Subject Matter Code 17.03.02

RFC: EPA rationale to not require closed-cycle

EPA's Rejection of Closed-Cycle Cooling as the Best Technology Available is Correct

PG&E NEG wholeheartedly agrees with EPA's determination in the proposed rule that closed-cycle cooling is not the "best technology available" ("BTA") for existing sources as a whole or for any subgroup identified by waterbody type or waterbody type and flow. See 67 FR 17,155 col. 1; 17,155 col. 3; 17,158 col. 3. EPA has correctly recognized that the enormous cost, and engineering impracticability of retrofitting a large, multi-unit existing plant with cooling towers renders closed-cycle cooling completely inappropriate as a basis for the existing facility rule. This is the case whether closed-cycle cooling is required of all facilities within the scope of the rule or only those meeting specified waterbody or waterbody and flow standards. <FN 1> Rejection of closed-cycle cooling as BTA is also consistent with nearly thirty years of practice, in which EPA has repeatedly refused to require existing facilities to retrofit to closed-cycle cooling under the authority of Section 316(b).

Footnotes

1 In fact, PG&E NEG believes that the economic case for rejecting closed-cycle cooling is far stronger than EPA acknowledges in the proposed rule. EPA's analysis of the benefits and costs of closed cycle cooling includes numerous errors that enormously overstate the biological and economic benefits of cooling towers and grossly understate the economic, environmental and safety costs of retrofitting closed-cycle cooling in existing facilities. These errors have been evaluated at length by UWAG in Section IV of its comments on the Phase II Rule and PG&E NEG endorses those comments and incorporates them by reference into these comments. PG&E NEG also concurs with UWAG's analysis confirming EPA's assessment that dry cooling cannot be justified for existing facilities.

EPA Response

EPA notes that the comment supports EPA's final rule determination on recirculating cooling tower retrofit projects.

However, the Agency disagrees with the following statement, "EPA has repeatedly refused to require existing facilities to retrofit to closed-cycle cooling under the authority of Section 316(b)." When the facts specific to a particular facility justify characterizing closed-cycle cooling as BTA for an existing facility (i.e., Brayton Point Station), EPA has done so.

Require closed cycle cooling

However, PG&E NEG believes that closed-cycle cooling must be rejected for a more fundamental reason than that outlined above: Section 316(b) gives EPA no authority to impose closed-cycle cooling. By its terms, Section 316(b) only authorizes EPA to regulate specific characteristics of cooling water structures -- their design, location, capacity and construction. It is self-evident, as EPA has acknowledged, that the cooling system used by a particular facility is
part of the "intake structure." In re Central Hudson Gas & Electric Corp., Decision of the General Counsel No. 63, 378 (1977) ("A cooling tower is not an 'intake structure' within the meaning of Section 316(b)."). As a result, Section 316(b) does not authorize EPA to dictate the type of cooling system that a facility must use. See In the Matter of the NPDES Permit for Brunswick Steam Electric Plant, Decision of the General Counsel on Matters of Law, No. 41, at 181 (1976) ("Section 316(b) does not authorize the Agency to impose a particular closed-cycle cooling technology.").

Despite its acknowledgement of the foregoing, EPA claims, as it did in those cases, the ability to regulate a facility's cooling system indirectly under Section 316(b), on the theory that Congress' use of the term "capacity" authorizes EPA to restrict the volume of flow through the intake structure to the extent that closed-cycle cooling (or, presumably, dry cooling) becomes necessary. In re Brunswick Steam Electric Plant, at p. 181. This interpretation has never been upheld by any court and defies both logic and firmly established principles of statutory construction. It is blackletter law that, when interpreting a statute, every word used by Congress must be given meaning, if it is at all possible to do so. See Reiter v. Sonotone Corp., 442 U.S. 330, 339 (1979) ("In construing a statute we are obliged to give effect, if possible, to every word Congress used".). As a result, a statute must be construed so that "no clause, sentence, or word shall be superfluous, void or insignificant." United States v. Campos-Serrano, 404 U.S. 293, 301 n.14 (1971). EPA's interpretation fails under both of these principles. Adopting an unnecessary and strained reading of the single word "capacity," EPA renders meaningless the remainder of the statute's language, which, as EPA admits, limits its authority to the regulation of cooling water intake structures.

EPA's assertion of authority to regulate "volume of flow" under the "capacity" banner also lacks any basis in the legislative history of the statute, notwithstanding EPA's historical statements to the contrary. See, e.g., In re Brunswick Steam Electric Plant at 178, n. 10. The references which EPA cites as illustrating Congress' concern with the levels of entrainment resulting from high volumes of flow had nothing to do with the debate over Section 316(b). <FN 2> Indeed, to the extent that this legislative history is relevant at all, it supports PG&E NEG's position, not EPA's. Assuming Congress believed that the demands of the cooling system, and not only the characteristics of the intake, were appropriate objects of regulation, it plainly could have given EPA direct authority to regulate cooling systems under Section 316(b). Congress did not do so. Instead, it enacted a provision specifically focused on intake structures alone, using language which, given its plain and ordinary meaning, merely describes characteristics of those structures. Congress' refusal to grant EPA a broader authority over cooling systems under Section 316(b) must be respected.

For the reasons above, PG&E NEG endorses EPA's conclusion in its preferred alternative that closed-cycle cooling is not BTA for existing sources.

Footnotes

2 See William A. Anderson & Eric P. Gotting, Taken in Over Intake Structures? Section 316(b) of the Clean Water Act , 26 Column. J. Evntl. L 1, 33-34 (2001) (noting that legislative exchange in which reference was made to cooling water flows as relevant to entrainment occurred in the context of debate over whether other agencies could establish stricter effluent limits under NEPA and had nothing to do the scope of Section 316(b)). A copy of this article is provided in Appendix Ito these comments.

EPA Response

In this final rule, performance standards are not based on cooling tower technology, however, one of five compliance alternatives is the reduction of flow commensurate with the use of cooling towers, since such a level of performance meets the rule performance standards. See preamble to the final rule, particularly sections III, VII, and VIII.

Option 3--Site-specific determination

EPA Correctly Includes a Site-Specific Approach to Establishing BTA

PG&E NEG concurs with EPA's decision to provide a site-specific approach by which facilities may obtain a case-by-case determination of the best approach for reducing and/or mitigating the I&E associated with their cooling water intake structures. Until now, a case-by case application of the BTA standard has been the norm. It recognizes the unique circumstances of each facility, which dramatically affect the degree to which any particular technology will be environmentally beneficial and can be implemented at a justifiable cost. It is also the only method that is consistent with Congress' intent that Section 316 be applied in a case-by-case manner. Experience demonstrates that the site-specific determination of BTA is practicable way for EPA and delegated states to implement 316(b).

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA disagrees with the commenter's statement about the historic interpretation of 316(b). Today's rule is the first major regulation for 316(b) for existing facilities; all other § 316(b) determinations for existing facilities to date have used a best professional judgment approach. The final rule does include a site-specific compliance alternative as one of the five alternatives available to facilities, creating a flexible regulatory framework. EPA believes that today's final rule will minimize adverse environmental impact at cooling water intake structures.

Subject Matter Code 2.04

EPA's legal authority to:

The availability of a case-by-case determination is necessary as a matter of policy and law

The determination of what constitutes "best technology available" depends by its nature on unique, site-specific factors, including the age, design and location of the facility. While a "performance standards" approach may serve to expedite the review process and provide certainty to an industrial sector as a whole, by definition it will not produce a result reflecting the best science for every particular situation. Indeed, establishing BTA through uniform, nationally applicable ranges based on a pre-selected set of technologies will produce results, in many cases, that are not optimal for either the facility or the environment. In some cases, it may be that no technology is available that can meet the performance standards at any reasonable cost. <FN 3> Given the inherent limitations of the performance standards approach, it is necessary that a site-specific approach also be made available. At a minimum, the site-specific approach must, as EPA's does, provide an alternative means of compliance for facilities that cannot meet performance standards using the technologies identified by EPA or cannot do so at a reasonable cost.

Indeed, it would be unlawful for EPA to not provide for meaningful site-specific alternatives should facilities be unable to achieve the performance standards using the technologies EPA relied on in setting the standards (either because the technologies are not technically feasible or because they do not achieve the standards in a particular application). The language of Section 316(b) directs EPA to ensure the use of "best available" technologies, not to enforce compliance with performance ranges.

However, PG&E NEG believes that a site-specific approach must be available to any facility that requests it. PG&E NEG notes that a case-by-case implementation of Section 316(b) is the only method that is fully supported by the language of Section 316(b) and EPA's own past practice. By its terms, Section 316(b) requires EPA to ensure that the "location, design, construction, and capacity of cooling water intake structures" constitute BTA. Significantly, each of these terms -- "location," "design," "construction," and "capacity" -- refers to an aspect of the cooling water intake system that is highly site- and case-specific. These terms also closely interrelated -- a change in the "location" of an intake affects both the type of "design" that is possible and the type of design most able to "minimize adverse environmental impact" -- and inextricably linked to other case-specific factors, including facility cooling water needs and the geography of the facility's location. Given the clearly and necessarily site-specific nature of the terms Congress chose to use, this language itself compels the conclusion that Congress intended the "best available technology" determination to be made on a case-by-case basis.

This view is also supported by the remaining language of Section 316(b). In particular, the statute specifically states that any standard issued under Section 301 or Section 306 "and applicable to a point source shall require that the location, design, construction, and capacity of cooling water intake structures reflect the best technology available. . . ." (emphasis added). Congress clearly could have stated that the Section 301 or Section 306 standards must establish the best technology available for cooling water intakes for each class or category of point sources, but it did not do so. Instead, Congress specified that Section 316(b) concerned the application of these standards to a particular point source. Congress' requirement that cooling water intake structures "reflect" best technology available is equally significant, especially when coupled with the site-specific nature of the four terms described above. Had Congress intended to authorize uniform technology standards on a category or class basis, it could simply have required that intake structures "incorporate" or "use" best technology available. Congress' requirement instead that the four listed characteristics of the structure "reflect" best technology available indicates that Congress intended EPA to do something different here: to determine whether, in a given instance, the combination of the intake's location, design construction and capacity "reflect" -- i.e. achieve a result consistent with -- best technology available. Such a determination would clearly require a case-by-case approach.

EPA's own past practice provides additional compelling evidence that Section 316(b) requires a case-by-case approach. In 1973, less than two years after the CWA was enacted, EPA issued a proposed rule providing for a case-by-case determination of BTA. 38 FR 34,410 (1973) (stating that the proposed rule would "provide a framework for the case-by-case determination of best technology available"). This was followed in 1976 by a final regulation adopting the same approach. 41 FR 17,387, 17,388 (1976) ("Decisions relating to the best technology available are to be made on a case-by-case basis"). While the Section 316(b) rule was later invalidated on procedural grounds, EPA's adoption of the site-specific approach provides contemporaneous evidence that EPA understood Section 316(b) to require case-by-case evaluation of BTA requirements.

One year later, this understanding was again adopted by EPA in its Draft 316(b) Guidance. See Section 316(b) Draft Guidance, U.S. EPA (1977). In that Guidance, EPA stated:

"The environmental-intake interactions in question are highly-site specific and the decision as to best technology available for intake design, location, construction and capacity must be made on a case-by-case basis." Id. at p.4 (emphasis added). This same case-by-case approach continued in use for almost twenty-five years thereafter and there is no reason to change it.

For the foregoing reasons, PG&E NEG believes that EPA's inclusion of a site-specific approach is not only correct as a matter of policy, but necessary as a matter of law.

Footnotes

3 One example is the fabric filter marketed by Gunderboom, Inc., which can potentially achieve significant reductions in both entrainment and impingement, but cannot be used in a variety of circumstances. See Section III.B.1.b.

EPA Response

See preamble to the final rule, particularly sections III, VII, and VIII. The final rule does provide for a site-specific determination of BTA in specified circumstances. See, 125.94(a)(5).

Subject Matter Code 7.01.03

Option 3--Site-specific determination

Site-specific method is practicable for use by EPA and delegated states

Although EPA offers a site-specific alternative for determining BTA, EPA suggests at several points that it is concerned about the burden that this alternative could impose on EPA and the delegated states. This concern is not founded. To begin with, given Congress' clearly expressed intent that EPA recognize and address the unique circumstances of cooling water users by implementing Section 316 in a case-by-case manner, it is doubtful that EPA could appropriately refuse to offer a site-specific alternative regardless of the resulting burdens on EPA or delegated states, where the applicable statutory criteria compel a different conclusion. This is particularly the case where the practical result of EPA's unlawful approach is to shift this burden to the regulated community. Furthermore, as the result of thirty years' experience, EPA and the states have significant expertise in applying Section 316(b) in this manner. While certain aspects of the program may change -- for example, the use of voluntary mitigation measures will add a new element to be considered -- there is little to suggest that states cannot master these relatively few alterations in the program. Indeed, many states already incorporate mitigation measures in their NPDES permits. <FN 4>

Thus PG&E NEG believes that the site-specific approach provides a practical, as well as legally preferable, method for implementing Section 316(b).

Footnotes

4 As EPA notes on p. 17169 & n. 69, both the NJDEP permit for PG&E's Salem plant and the MDE permit for Potomac Electric Power Co.'s Chalk Point plant incorporate restoration measures.

EPA Response

EPA disagrees with the commenter's statement about the historic interpretation of 316(b). Today's rule is the first major regulation for 316(b) for existing facilities; all other § 316(b) determinations for existing facilities to date have used a best professional judgment approach. The final rule does include a site-specific compliance alternative as one of the five alternatives available to facilities, creating a flexible regulatory framework. EPA believes that today's final rule will minimize adverse environmental impact at cooling water intake structures.

Please refer to the response to comment 316bEFR.338.002 for more information on the site-specific compliance alternative.

Option 3--Site-specific determination

Concerns with the site-specific proposal EPA has offered as its preferred option.

While PG&E NEG fully supports EPA's determination that a site-specific approach must be included in the final regulation, PG&E NEG disagrees in a number of critical respects with the site-specific proposal EPA has offered as its preferred option. These concerns are discussed in Section III.B.3, below.

EPA Response

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

No further response is necessary, as subsequent comments have been responded to individually.

RFC: Proposed use of restoration measures

Inclusion of Voluntary Mitigation Measures as an Alternative Method of Compliance

PG&E NEG agrees in principle with EPA's proposal to allow facilities to use a variety of mitigation measures <FN 5> as an alternative means of satisfying the compliance requirements of Section 316(b) of the Clean Water Act. Mitigation measures, such as restoration or enhancement of submerged aquatic vegetation or tidal wetlands, removal of barriers to fish migration, creation of artificial reefs and fish restocking, will in many cases produce equivalent or greater environmental benefits than the use of technology to reduce impingement and entrainment (I&E) impacts. They do so at lower cost. PG&E NEG also agrees, in theory, with several elements of EPA's preferred option for implementing the mitigation alternative, including:

-EPA's decision to allow affected facilities to opt voluntarily to implement mitigation measures;

-EPA's decision to allow mitigation measures to be used either alone or in combination with other alternatives (including technology-based alternatives);

-EPA's decision to require mitigation measures to achieve a level of performance "comparable" to what could be achieved by using technology; and

-EPA's interest in developing a workable mechanism for mitigation banking.

PG&E NEG believes each of these elements is critical to a flexible, environmentally-protective and cost-effective program for offsetting I&E impacts and must be part of the final proposal. In the following sections, PG&E NEG discusses its reasons for supporting these elements of EPA's proposal and for rejecting alternative proposals on which EPA is soliciting comment.

While PG&E NEG supports much of the mitigation program EPA has laid out in its proposal, PG&E NEG believes EPA has not utilized correct methods for identifying appropriate non-technological measures. Nor has EPA utilized correct methods for determining the appropriate scale or cost of such measures. These objections are detailed below at IV.B.5.

Footnotes

5 For simplicity, the term "mitigation" in this discussion is used as shorthand for the array of restoration and mitigation measures specifically identified in the proposed rule, as well as other methods that might be used to directly or indirectly offset losses from I&E.

EPA Response

EPA believes restoration measures do not necessarily provide a lower cost alternative to cooling water intake technologies for meeting the requirements of the final rule. However, by providing additional compliance flexibility, restoration measures provide additional options to permittees seeking cost-effective solutions.

For a discussion of the extent to which restoration measures are voluntary, see EPA's response to comment 316bEFR.060.022.

All restoration measures must meet the requirements described in the final rule, including those under sections 125.94 and 125.95.

For discussion of trading programs, see EPA's response to comment 316bEFR.074.020.

Comment ID 316bEFR.060.021

Author Name Mark V. Carney

Organization PG & E National Energy Group

Subject Matter Code 11.01

RFC: Proposed use of restoration measures

The decision to implement mitigation measures should be a voluntary one made by the affected facility, not EPA

EPA's current proposal would allow a facility covered by the rule voluntarily to propose mitigation measures in lieu of, or in combination with, technological or operational measures in order to meet the applicable performance standards for I&E reductions. See 67 FR 17,166 col. 2-3; 67 FR 17,221 (proposed 40 CFR 125.94(a)(1-2)). PG&E NEG believes that making mitigation measures voluntary is correct as a matter of policy and necessary as a matter of law.

As a matter of policy, making the use of mitigation measures voluntary allows facilities the flexibility to develop the combination of measures that, in the specific circumstances under which that facility operates, will achieve the performance standards with the least amount of disruption to its operations. In some instances, mitigation measures may be able to achieve all or a part of the reductions necessitated by the rule at significantly reduced cost and/or do so without the need for, or risk of, short or long-term disruption to facility operations. In other cases, technology may prove the most reasonable means of meeting the performance standards. By permitting mitigation measures to be used where offered voluntarily, EPA allows for the important, circumstance-specific decision about how the performance standards will be met to be made by the facilities themselves, while ensuring that the regulatory performance standards are met.

EPA Response

For a discussion of the extent to which restoration measures are voluntary, see EPA's response to comment 316bEFR.060.022.

EPA believes the inclusion of the option to use restoration measures in the final rule provides permitting authorities and permittees with additional compliance flexibility. Consideration of restoration measures may lead to a more cost-effective solution. All restoration measures must meet the performance and implementation requirements of the final rule.

Comment ID 316bEFR.060.022

Author Name Mark V. Carney
Organization PG & E National Energy Group

Subject Matter Code 2.04.06
Restoration measures in place of technologies

In addition, only voluntary use of mitigation measures is consistent with the language of Section 316(b). PG&E NEG does not agree with EPA's position that mitigation measures can be required by EPA under 316(b) as an aspect of the "design" of a cooling water intake structure. To construe the creation of an artificial reef or operation of a restocking program as an aspect of intake structure "design," as EPA proposes, see 67 FR 17,169 col. 1, defies any reasonable interpretation of the word. Nor is it consistent with the historical use of the term by EPA prior to this rulemaking. <FN 6> To the contrary, when EPA issued its first regulation implementing Section 316(b), it relied on a far more logical interpretation: defining "design" as "the arrangement of elements that make up the cooling water intake structure." 41 FR 17,387, 17,390 (1976).

EPA is not allowed to use statutory construction to claim an authority Congress has not chosen to assign it. See, e.g., Lopez-Flores v. Resolution Trust Corp., 93 F.Supp.2d 834, 846 n. 34 (E.D. Mich. 2000) (noting that agency interpretations, even where entitled to deference, may not permissibly "expand the scope of an agency's authority into the external universe of topics that Congress neglected or purposefully omitted"). Here, the plain language of Section 316(b), supported by the contemporaneous evidence of the 1976 regulation, compels the conclusion that Congress did not assign EPA the authority to directly regulate mitigation measures as aspects of cooling water intake structure "design." EPA's original interpretation--that "design" of a cooling water intake structure does not include restoration of reefs--was correct.

However, PG&E NEG believes that Section 316(b) does authorize EPA to approve and to incorporate into an NPDES permit those mitigation measures voluntarily proposed by a facility, either in lieu of, or in combination with, technology. <FN 7> As discussed further in Section Ill.B.3.c.(i) below, the statutory language of Section 316(b) requires a threshold showing of adverse impact before EPA may impose technology-based requirements. To the extent that a facility proposes to implement mitigation measures to offset its environmental effects, this may reduce or eliminate altogether the "adverse impact" that forms the basis for imposing new technology. <FN 8> This interpretation of EPA's authority under Section 316(b) is consistent with that EPA and other federal authorities have adopted in implementing other, similar statutory provisions.

For example, EPA considers the effect of mitigation measures in determining under Section 404(c) of the CWA whether a project approved by the Corps of Engineers has an "unacceptably adverse effect" and thus must be vetoed by EPA. See, e.g., James City County, Va. v. EPA, 12 F.3d 1330, 1336-37 (4th Cir. 1993) (upholding EPA decision under Section 404(c) which considered mitigation measures offered by proponents of dam/reservoir project in determining whether a veto was appropriate). Courts have also affirmed that the Corps of Engineers may consider mitigation measures in determining whether a project "significantly affect[s] the quality of the human environment" and therefore triggers the Environmental Impact Statement ("EIS") requirement of NEPA. See Payette v. Horseshoe Bend Hydroelectric Co., 988 F.2d 989, 991 (9th Cir. 1993) (specifically noting that the Corps "can consider the effect of mitigation measures in determining whether preparation of an EIS is required"). These examples and others <FN 9> affirm that EPA can appropriately consider voluntarily proposed mitigation measures as offsets against requirements that would otherwise apply based on a facility's adverse environmental impact.

Because PG&E NEG believes that only voluntary use of mitigation measures is desirable policy or legally permissible as an interpretation of Section 316(b), PG&E NEG strongly endorses the voluntary approach set forth in EPA's preferred option. It opposes the alternative approaches that would make mitigation measures necessary in all or certain classes of cases, or would allow EPA (or a delegated state) to demand under 316(b) mitigation measures not identified voluntarily by the facility. See 67 FR 17,169 col. 3 -17,170 col. 1.

Footnotes

6 PG&E NEG recognizes that EPA relied on the definition of "design" proposed here in its final rule implementing Section 316(b) for new sources. See 66 FR 65,256, 65,314-15 (2001). PG&E NEG is not aware that any court has yet reviewed the new source rule and, for the same reasons outlined above, does not believe that EPA's interpretation in that context will be upheld.

7 This situation is analogous to an air emission source's accepting permit limitations to qualify as a "synthetic minor" source.

8 This argument is developed in detail in Anderson & Gotting, 26 Column. J. Evntl. L at 47-53. As Anderson and Gotting note, EPA's earliest documents relating to 316(b), including the 1973 Proposed Rule and the 1973 Development Document, specified that it was the "net" effect of a facility that determined whether there was an adverse impact and whether further technology was necessary to "minimize" it. Id at 47 & n.268.

9 Other cases involving consideration of mitigation measures under the CWA and NEPA are discussed in Anderson & Gotting, at 50-52. Anderson & Gotting also identify cases considering mitigation measures in determining whether a violation of the Endangered Species Act has occurred, id at 52-53.

EPA Response

Permittees must meet the requirements of today's rule through the use of design and construction technologies, operational measures or restoration measures. Although compliance with today's rule is not voluntary, permittees may choose which design and construction technologies, operational measures, and/or restoration measures to present in their application to the permitting authority, subject to the requirements of the final rule. Restoration measures are not required at all sites by the final rule. In some cases, the choice of design and construction technologies and/or operational measures suitable for implementation at a site will be limited, and restoration measures will sometimes be the only feasible alternative. The technologies and/or measures ultimately implemented to meet the requirements of today's rule are subject to the approval of the permitting authority. A permittee may also request determination by the permitting authority of a site-specific performance standard as described at 125.94(a)(5).

For a discussion of EPA's authority to require restoration under the final rule, see the preamble to the final rule.

For additional information on EPA's interpretation of restoration measures as an aspect of cooling water intake structure design, see the preamble to the final rule.

For a discussion of adverse environmental impact threshold requirements, see EPA's response to comment 316bEFR.029.015.

RFC: Restoration measures as supplement only?

EPA is correct to allow mitigation in lieu of, or in addition to, technology

EPA's proposed rule provides for voluntary mitigation measures to be used in lieu of or in addition to technology. See 67 FR 17,221 (proposed 40 CFR 125.94(a)(1-2)). PG&E NEG agrees that this is the correct approach. A primary justification for the use of mitigation measures is that, by allowing flexibility in how facilities may comply with a given standard, environmental improvement can be achieved more cost-effectively. Any attempt to limit flexibility by requiring, for example, that mitigation measures only be allowed as a supplement to technology, would significantly reduce, or, in some cases, eliminate, the ability of facilities to obtain the benefits of the mitigation alternative. Yet it would achieve no net environmental improvement over an appropriately designed mitigation plan. Such a result serves no policy purpose and is inconsistent with EPA's expressed concern for cost and for the impact of Section 316(b) on facility operations.

PG&E NEG therefore endorses EPA's proposed rule, which would allow for mitigation measures either in lieu of, or in addition to, technology, and opposes the alternative, under which mitigation only would be allowed to supplement technology. See 67 FR 17,146 col. 3.

EPA Response

Facilities may use restoration measures under the final rule either in lieu of or in combination with technologies that reduce impingement mortality and entrainment. All restoration measures must satisfy the requirements described in the final rule, including those in sections 125.94 and 125.95 of the final rule. One of these requirements is that permit applicants demonstrate to the permitting authority that they have evaluated the use of design and construction technologies and operational measures for their facility and have provided an explanation of how they determined that restoration would be the most feasible, cost-effective, or environmentally desirable alternative.

EPA believes the inclusion of restoration measures in the final rule provides permit applicants with additional compliance flexibility.

Comment ID 316bEFR.060.024

Subject Matter Code 11.06

RFC: Performance/effectiveness of restoration

Author Name Mark V. Carney

Organization PG & E National Energy Group

EPA correctly requires mitigation to meet a “comparable” level of performance

EPA’s preferred option would allow a facility to use mitigation measures, either alone or in combination with other methods, where it can demonstrate that it will achieve “comparable performance” to that which would result from reducing I&E in accordance with the technology-based standard, or, if this cannot be shown with precision, that the facility will maintain fish and shellfish at a level “substantially similar” to that which would be achieved if the performance standards were met. See 67 FR 17,221-22 (proposed 40 CFR 125.94(d)), 67 FR 17,223 (proposed 40 CFR 125.95(b)(5)). PG&E NEG believes that, properly applied, <FN 10> this approach represents sound policy and an appropriate exercise of EPA’s authority under Section 316(b).

As discussed above, the principal benefit of the mitigation alternative is that it allows facilities another, potentially more cost-effective, way to meet the performance standards. Insisting that mitigation measures meet a higher standard, whether by requiring mitigation to occur at a ratio of greater than 1:1, by requiring a “margin of safety” in mitigation plans, or by imposing mitigation measures to achieve performance levels in excess of those achieved by technology, would unfairly penalize the use of mitigation measures by inflating their cost relative to comparably performing technology. There is simply no apparent reason to require (for example) an extra margin of safety for mitigation measures demonstrated to be effective and good reason to treat mitigation comparably with technology: such disparate treatment would limit the use of mitigation and take away the flexibility that EPA purports to afford permittees in meeting the requirements of Section 316(b).

Footnotes

10 Although PG&E NEG frilly endorses the principle of “comparability” between the results achieved by mitigation measures and those achieved by technology, PG&E NEG does not believe that EPA’s rule, as currently formulated, will necessarily produce that result. As is discussed further in Section IV.B.4, EPA has adopted incorrect methods for evaluating the environmental benefits of mitigation measures. PG&E NEG’s endorsement of the comparability criterion is dependent on the adoption of a method evaluating those benefits that would give a facility full “credit” for all the environmental services generated by a mitigation program.

EPA Response

Any restoration measure must meet all of the requirements described in the final rule.

EPA believes restoration measures will be well suited for some sites, and not well suited for others.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

EPA believes the requirements for restoration measures in the final rule are written with a significant amount of flexibility.

Restoration measures in place of technologies

In addition, Section 316(b) does not authorize EPA to require that mitigation measures meet a more stringent standard than technology measures. Section 316(b) authorizes EPA only to require that the identified intake structures features "reflect" the "best technology available for minimizing adverse environmental impact." But that standard does not go to whether such technology should be required in the first place. Section 316(b)'s command is satisfied if mitigation measures achieve results comparable to, and thereby adequately reflect, "best technology" to offset or eliminate the need for a technological approach. It does not follow, however, that the mitigation measures themselves are an aspect of "technology" subject to the BTA standard. <FN 11> As a result, EPA has no authority to impose a standard of performance for mitigation measures that differs from that which would be applied if the facility used the technology-based alternatives on which its proposed performance standards are premised. This is the approach embodied in the "comparable performance" standard EPA has proposed in its preferred alternative.

Footnotes

11 Indeed, EPA appears implicitly to recognize this itself-- there is no suggestion in the proposed rule that the performance standards are based on the use of mitigation as though it were, itself, a "technology."

EPA Response

Under the final rule, facilities utilizing restoration measures must ensure that they perform at a substantially similar level to that which would be achieved through compliance with the applicable impingement mortality and entrainment requirements or alternative site-specific requirements. The level of performance restoration measures must meet does not consider any potentially higher performance levels possible through the sole or supplementary use of restoration projects.

For a discussion of EPA's authority to require restoration under today's rule, see the preamble to the final rule.

For discussion of EPA's interpretation of restoration measures as a technology and an aspect of the "design" of cooling water intake structures, see the preamble to the final rule.

RFC: Proposed use of restoration measures

For the foregoing reasons, PG&E NEG endorses the preferred alternative's requirement of "comparable performance" and opposes alternatives that would impose a greater than 1:1 mitigation ratio or "margin of safety" in evaluating the performance of mitigation measures or would require mitigation to achieve a higher level of performance than would be achieved by use of technology -- including any requirement that mitigation be used to offset impacts that would remain after a technology meeting the performance standards has been installed. See 67 FR 17,147 col. 1 (mitigation ratios greater than 1:1; margins of safety); 67 FR 17,169 col. 3 - 17,170 col. 1 (mitigation to compensate for impacts remaining after technology).

EPA Response

Under the final rule, it is the responsibility of the permitting authority to review a permittee's application and decide whether or not restoration measures are an appropriate means for the permittee to comply with the requirements of the final rule, including those described under sections 125.94 and 125.95. It is also the permitting authority's responsibility to determine the nature of a particular restoration measure and its implementation (performance levels, effectiveness criteria, monitoring, reporting, etc.) needed to allow it to meet the requirements of the final rule. Under section 125.95, the rule requires permittees to develop a Restoration Plan and submit several pieces of information to the permitting authority in order to aid both the permittee and the permitting authority in their consideration of the feasibility of a restoration measure. Permittee's must demonstrate the feasibility of the restoration measures to the permitting authority's satisfaction and obtain the approval of the permitting authority before they may proceed with implementation of a restoration measure. Once permittees obtain the permitting authority's approval and implement restoration measures, it is their responsibility to ensure and demonstrate to the permitting authority that the measures meet the requirements of the final rule.

RFC: Restoration banking

Author Name Mark V. Carney

Organization PG & E National Energy Group

Banking of “extra” mitigation measures should be allowed

PG&E NEG supports EPA’s consideration of mitigation banking as a mechanism for providing further flexibility in achieving environmentally-beneficial and cost-effective mitigation for I&E impacts. See 67 FR 17,170. As EPA notes, the concept of mitigation banking is already well-established under Section 404 of the Clean Water Act. <FN 12> In this context, mitigation banking has been used for wetland restoration, creation, enhancement and preservation undertaken expressly for the purpose of compensating for unavoidable wetland losses in advance of development actions, when such compensation cannot be achieved at the development site or would not be as environmentally beneficial.

One important effect of banking is that it allows for the consolidation of small, fragmented wetland mitigation projects into one large contiguous site. By consolidating compensation requirements, banks can more effectively replace lost wetland functions within a watershed, as well as provide economies of scale relating to the planning, implementation, monitoring, and management of mitigation projects.

For the foregoing reason, PG&E NEG supports EPA’s proposal to allow mitigation banking under Section 316(b). PG&E NEG notes that many of the issues that will arise in developing a successful banking program are identical to those that arise in the context of trading. PG&E NEG’s views on how those issues should be addressed are discussed in Section III.A.5.

Footnotes

12 Memorandum of Agreement Between the Environmental Protection Agency and the Department of the Army Concerning the Determination of Mitigation Under Clean Water Act section 404(b)(1) guidelines (Feb. 6, 1990). Also Federal Guidance for the Establishment, Use, and Operation of Mitigation Banks, 60 Fed. Reg. 58605 (November 28, 1995).

EPA Response

In the final rule, EPA allows use of restoration to minimize or to help to minimize adverse environmental impacts that derive from impingement and entrainment of aquatic organisms. Restoration measures must meet the requirements described in the final rule.

For a discussion of trading programs, see the preamble to the final rule.

RFC: Appropriateness of "wholly disproportionate"

EPA Correctly Abandons the Wholly Disproportionate Cost Test

EPA's proposed rule takes an important step in scuttling the "wholly disproportionate" cost test for evaluating whether technologies satisfy BTA. See 67 FR 17,221 (proposed 40 CFR 125.94(c)(l). By setting an arbitrary and extremely stringent standard of economic impracticability, the "wholly disproportionate" cost test ensures that in many, if not most, cases costs are imposed on affected facilities that far exceed the benefits to be achieved by the mandated projects. Such a result has no justification in economics because it makes society demonstrably worse off-- potentially by orders of magnitude -- than it would be if the I&E impacts were allowed to continue unabated. EPA is correct to jettison this criterion as a basis for determining the level of regulation that an existing facility should be required to meet.

However, while PG&E NEG agrees with the rejection of the wholly disproportionate cost test, PG&E NEG believes that its proposed replacement -- the "significantly greater cost" test, as it is described in the rule, see id. has many of the same flaws. PG&E NEG discusses those flaws, and its preferred economic criterion, in Section III.B.4.

Subject Matter Code 20.01
RFC: Should EPA include impingement trading?

Trading

PG&E NEG commends EPA for having taken note of the potential of market-based instruments for achieving resource protection and for having begun the process of thinking about how such an initiative could be incorporated within an existing regulatory program. See 67 FR 17,190 col. 1, PG&E NEG believes that a well-designed trading program can provide greater flexibility to permittees and so facilitate the achievement of reasonable targets (not those contained in the current rule) at substantial cost savings by providing greater incentives for voluntary reductions and technology innovation. Experience with trading programs, both in the United States and elsewhere, indicates that a program is particularly likely to be effective in achieving these results where:

-Clear legal authority for trading is provided;

-Well-defined units of trade are established;

-Transaction costs are minimized by avoiding requirements for prior government approval of trades;

-Clear protocols established to quantify units to be traded; and

-Reasonable mechanisms for compliance are established.

Although EPA indicates on page 17,170 that the proposed trading program "differs from previous trading strategies implemented by EPA because it involves trading living resources rather than pollutant loads," PG&E NEG does not believe that trading within the context of entrainment and impingement presents problems that are unique or particularly difficult to resolve. Tradable permit programs have a very long history of use in the natural resources realm - in tradable development rights (TDRs), wetland mitigation banking, and individual transferable quotas (ITQs) for fisheries. Wetlands mitigation banking provides a particularly close analogy, given that there, as here, alteration or loss in one ecosystem is offset by enhancement or creation of another. Many of these programs predate more recent applications of trading mechanisms to reducing pollutant emissions, and a careful review by EPA of those applications would be prudent before it begins to develop an I&E trading program.

EPA Response

RFC: Should EPA include impingement trading?

Entrainment Only or Impingement and Entrainment

EPA has asked for comment on whether the trading program should include entrainment only or impingement and entrainment. 67 FR 17,170 col. 2-3. PG&E NEG believes that both entrainment and impingement should be included and that trades between impingement and entrainment should also be allowed.

It is clear that implementation of technologies in certain cases may affect both entrainment and impingement impacts. In some cases, the technology may reduce both I&E, while in others one impact may be reduced while the other is increased. Allowing trading of both entrainment and impingement, as well as trading between the two, will significantly increase the cost savings available through the trading program by allowing maximal flexibility to achieve beneficial trades -- including intra-plant trades.

It should also be noted that EPA's arguments against the inclusion of impingement in the trading program are mistaken. EPA suggests that impingement trading may not be necessary, because of the comparatively low cost of making impingement reductions. However, this is precisely why impingement trading and trading between impingement and entrainment should be included. The fact that impingement reductions may generally be less costly suggests that there will frequently be highly beneficial opportunities for trading impingement reductions for entrainment reductions.

EPA's concern that the transaction costs of impingement trading may outweigh the benefits is also misplaced. To the extent that EPA is concerned about facilities' transaction costs, these decisions will be made by the facilities themselves, who presumably will not engage in trading where the costs of participating outweigh the benefits.

EPA Response

Please see response to comment 316bEFR.034.027 regarding the role of trading in today's final rule.

Subject Matter Code 20.03

Spatial scale for entrainment trading

Spatial Scale of Trading

EPA considers various alternatives: limiting trading to specific water bodies, specific watershed, or general waterbody types. 67 FR 17,171 col. 1-2. While there are arguments in favor of each approach, the rebuttable presumption ought to be to establish the largest geographic limits feasible in order to provide maximum flexibility and, as a result, greater cost-effectiveness. Imposition of geographic constraints, limiting the universe of potential trading opportunities, will inevitably result in the price of offsets rising. In some cases, it may make them unavailable altogether. Thus, of the three options proposed for comment, PG&E NEG would favor trades being allowed on the basis of general waterbody type over the more restrictive alternatives. However, adopting any of the constraints as currently proposed in the regulation could hinder market development and diminish the benefits to be achieved from trading.

EPA Response

Please see response to comment 316bEFR.077.051 for the discussion on the appropriate spatial scale of trading. Due to difficulties and uncertainties involved in determining the potential effects of a trading program on ecosystem function, community structure, biodiversity and genetic diversity, EPA believes that it is unlikely to approve any trading programs under § 125.90(c) unless the program limits trades among numbers of the same species within individual watersheds. Although these constraints may reduce the number and type of trades allowed, EPA believes that they are appropriate to ensure that the trading program will result in environmental performance within a watershed that is comparable to the reductions of impingement mortality and entrainment that would otherwise be achieved under the requirements established at § 125.94.

RFC: Potential trading units/ credits

Unit of Trading

EPA has requested comment on the appropriate unit of trading. 67 FR 17,171 col. 2-3. This issue arises within the context of any environmental regulation, not just within the context of trading. At one extreme, risks associated with environmental end-points might seem to be the appropriate units for regulation and thus for trading with any environmental problem. But this is virtually never done, because the implementation costs are excessive. As a result, in the pollution context, regulation typically shifts to the units of regulation prior to risk, which include, first exposure, then ambient concentration, then emissions, then inputs (such as the lead content of gasoline).

Here, EPA has suggested three options -- species density, species counts and biomass --as potential trading units. Each of these has potential advantages and disadvantages, as EPA notes. However, PG&E NEG believes that trading should be chosen not because it is closest to what might seem to be the theoretical ideal of the environmental end-point, but because that level of trading will result in achieving given targets at the lowest cost over time, taking into account not only technological costs of meeting the program requirements but also monitoring feasibility and enforcement costs.

In PG&E NEG’s view, the units of trading most likely to be successful are those that are least restrictive and thus allow for the greatest number of potential trades. An appropriate unit for achieving this result could be based on biomass, perhaps divided into functional groups (i.e. forage fish, piscivores). However, to most accurately reflect the differential impact of entrainment and impingement reductions on populations, this should be measured in terms of age-one equivalents.

EPA Response

Please see response to comment 316bEFR.077.052 for the discussion on the appropriate unit for trading. Trading units in terms of age-one equivalents may prove to be the most implementable solution that takes into account the different life stages entrained; however, the specifics of any potential trading program will be left to the discretion of the permit director, subject to EPA's approval.

RFC: Include Phase I facilities in trading program

New Facilities and Non-316(b) Facilities/Other Stressors

The scope of trading is another question that arises with virtually any trading program. In general, the more facilities and/or types of impacts that are allowed to engage in trade the better, for precisely the reason that EPA notes in discussing the ability of new facilities to engage in trading: the greater scope for trading will have the effect of lowering compliance costs, which will make it easier for sources to meet performance requirements. The same logic argues for the further extension to other "major environmental stressors" of the water bodies in question, including: habitat alteration, dredging, coastal development, over-fishing, industrial pollution, nutrient pollution, wastewater runoff and climate. If the desire is to achieve real environmental improvements while keeping costs down, then surely greater cost-effectiveness could be achieved by expanding trading beyond power plants to include potential offsets from other sources of the major environmental stressors.

EPA Response

Please see response to comment 316bEFR.005.045 regarding trading among new facilities, comment 316bEFR.077.051 for the discussion on the appropriate spatial scale for trading, and comment 316bEFR.005.046 regarding trading with other stressors.

General Statement of Opposition

Aspects of Proposal PG&E NEG Opposes

As the foregoing indicates, PG&E NEG supports many aspects of EPA's proposal, at least at a conceptual level. However, PG&E NEG cannot agree with a number of elements of EPA's preferred option as they are presently articulated. While PG&E NEG lauds the concept of including a variety of options for facilities to achieve compliance, the proposed rule is in a number of important respects inconsistent with the language and purpose of Section 316(b), unworkable and overly restrictive.

In addition, EPA has completely failed to provide a valid biological or economic underpinning for its proposed approach. EPA ignores critical information, relies on incorrect data, and repeatedly and without explanation relies on invalid analytical models or misapplications of valid models. Reliance on such defective data is inconsistent with the requirements of the Paperwork Reduction Act and PL 106-554 (the Data Quality Act), 44 U.S.C. § 3500 et seq. In addition, EPA's cumulative errors make it impossible to find that EPA's approach represents a rational, reasoned response to the environmental concerns EPA is authorized to address under Section 316(b). The following discusses in detail aspects of the proposal that PG&E NEG opposes, as well as the flawed assumptions on which the proposal relies.

EPA Response

Organization PG & E National Energy Group

Subject Matter Code 7.02
Performance standards

EPA's Proposed Mandatory Performance Standards are Unjustified and the Implementing Regulations are Fundamentally Flawed

Central to EPA's proposed approach is the concept of establishing a performance range for reductions in entrainment and impingement rather than dictating a specific technology or a specific performance number. This approach acknowledges that different technologies (or combinations of technologies and other measures) may be appropriate at different facilities and that even the same technologies may yield different results at different facilities. However, PG&E NEG does not concur with either EPA's selected range of mandated reductions or the performance approach EPA is proposing to implement. PG&E NEG does not believe that 316(b) authorizes EPA to apply the performance standards to all facilities, regardless of the existence of adverse impact, and to make compliance mandatory. Furthermore, the actual performance ranges established are wholly unsupported as a biological matter and unrealistic in practice. Finally, the regulations implementing the proposed standards are rife with ambiguities and are unworkable.

Because the performance standard approach proposed by EPA is inconsistent with Section 316(b), wholly unsupported by biological evidence and unworkably vague as drafted, it must be substantially modified or set aside.

EPA Response

Please see response to comments 316bEFR.307.064 and 316bEFR.311.002. With respect to the legal portion of this comment, EPA believes that the framework it has adopted fully implements the requirements of section 316(b) and ensures that each facility will implement what is, for that facility, the best technology available for minimizing adverse environmental impact.

Comment ID 316bEFR.060.036

Author Name Mark V. Carney

Organization PG & E National Energy Group

Subject Matter Code 2.04.02

Apply 316(b) before a det. of impact/AEI

Imposition of mandatory standards for all facilities is not a permissible implementation of Section 316(b)

Under EPA's proposal, the performance standards would be applicable to all facilities and compliance with the standards would be mandatory except for those qualifying for site-specific evaluation. This approach exceeds EPA's authority under Section 316(b) and must therefore be rejected.

As is discussed in Part III.B.2.c.(i) of these comments, Section 316(b) requires that an actual adverse environmental impact be found before imposition of new technology. In addition, EPA bears the burden of showing (or predicting) the existence of any actual adverse impact. See In the Matter of Public Service Company of New Hampshire, NPDES Appeal No. 76-7, 1 E.A.D. 332, 339 (June 10, 1977) (noting that, under Section 316(b), "the Agency must identify or predict adverse environmental effects and then select the most effective means of 'minimizing' . . . the adverse effects"). By making the performance standards applicable to and mandatory for all dischargers within specified categories, EPA ignores these burdens, imposing technological retrofit requirements on facilities without regard to the existence of adverse environmental impact. As a result, facilities currently having no significant level of adverse impact would nonetheless be forced to engage in expensive retrofits of new technology in an attempt to reduce those already non-significant impacts.

EPA Response

See preamble to the final rule, particularly sections III, VII, and VIII, and supporting documents.

Comment ID 316bEFR.060.037

Author Name Mark V. Carney

Organization PG & E National Energy Group

Subject Matter Code 7.02

Performance standards

Furthermore, because the performance ranges are fixed and access to the site-specific alternative is limited, many facilities will be denied the opportunity to obtain a case-by-case determination of what technology is truly “best available” under their circumstances. Yet Congress intended that a case-specific balancing of the circumstances of each facility was the appropriate way to implement Section 316(b). See Part III.A.2.a.

PG&E NEG believes that the only permissible way EPA could implement the performance ranges is on a voluntary basis. Facilities wishing to avoid the complexity, cost and uncertainty of a formal demonstration process should be permitted to demonstrate compliance by showing that they currently do, or will, achieve a level of performance falling within an appropriate range. However, any facility should also have the option of obtaining a site-specific determination of BTA.

Because EPA’s proposed performance standards would be mandatory and applicable whether or not EPA has demonstrated any actual adverse environmental impact, they exceed EPA’s authority under Section 316(b).

EPA Response

EPA disagrees with the commenter's assertion that the performance standards exceed its authority under the Clean Water Act. For a further discussion of EPA's authority under the Act, please see section III of the preamble to today's final rule.

EPA disagrees with the commenter's characterization of the performance ranges as "fixed". EPA adopted ranges instead of a single value limit for the performance standards in recognition of the fact that there exists a degree of variability between waterbodies and facilities. EPA also disagrees that today's final rule somehow restricts the determination of Best Technology Available (BTA) for a specific facility. EPA has deferred any decisions regarding BTA for a particular facility to the Director, who is in a better position to make such a determination based on the many variables present at the facility.

Organization PG & E National Energy Group

Subject Matter Code 7.03

Available I&E technologies

EPA has not demonstrated that the technologies it relies on are "available" for all facilities or that they will achieve performance within the specified ranges

Were EPA to decide to retain mandatory performance standards in the final rule -- which PG&E NEG opposes -- it would have to reconsider the approach it has taken to developing the performance ranges. In the proposed rule EPA states the proposed performance standards are based on the results that can be achieved using a specified group of technologies. <FN 13> However, EPA has failed to provide an adequate demonstration that the technologies in question are actually "available" -- that is, available commercially at an economically practicable cost <FN 14> -- or that they will be effective to achieve the performance standards at many facilities. To the contrary, it is clearly the case that several of the selected technologies may not be feasible for implementation in many cases. <FN 15> Even where they can be used, they will not necessarily produce performance falling within the range.

The ability to reduce I&E depends on site-specific factors: the shape of the shoreline, the time of year, the existence of natural currents and/or tidal cycles and especially the species present at the site. For example, whether a particular fish becomes impinged can depend on a myriad of factors, including: the swimming ability of the species, the physical condition of the individual fish, the velocity to which it is exposed, avoidance response, visibility, habitat preferences, tidal stage, season, etc. Similarly, whether a particular species is entrained depends on factors such as: seasonality, diurnal migrations, demersal vs. pelagic preferences, ability to swim, diurnal migrations, ability to adhere, etc. Facilities that use cooling water are sited on different types of water bodies, each with its own physical characteristics (flow, substrate, shoreline) and unique animal and plant communities. Similar facilities on the same waterbody can have different impacts depending on how the intake is designed and where it is positioned relative to where the fish spawn and how they behave.

Likewise, the feasibility, effectiveness, environmental impacts and cost of technologies to reduce cooling water intake structure impacts can vary dramatically from site to site. Some technologies cannot be used where there are strong currents, navigation routes, ice, or floating debris. For example, the lack of ambient current cross-flow in Mount Hope Bay, which is the source of cooling water for Brayton Point Station, eliminates consideration of wedgewire screens at the site. Yet, in the proposed regulation, EPA assumes that wedgewire screens can be installed nationally to achieve the performance standard for reductions in impingement. Similarly, fine mesh screens cannot be used in saltwater applications, because the high levels of solids cause them to clog. This eliminates this technology from consideration for Salem Harbor and Brayton Point Stations. EPA assumes fine mesh screens, too, will be available nationally to meet the entrainment performance standard.

In addition, after making site visits to both Brayton Point Station and Salem Harbor Station, the manufacturer of a fabric filter barrier concluded the technology could not be employed at either station. According to Gunderboom, Inc., the manufacturer, the mile-long filter barrier "could not be deployed [at Salem Harbor Station] without enclosing a significant portion of Salem Harbor, interfering with the normal ship traffic, shoreline and shallow water uses of the area." [Gunderboom Inc., May 20, 2002]. With respect to Brayton Point Station, the manufacturer reported that the two and one-half mile long filter barrier “could not be deployed without either occupying the shoreline for over two miles or extending into waters occupied by the shipping channel” and would constitute an “unacceptable blockage” for ship traffic in the Taunton River.” [Gunderboom Inc., September 7, 2001]. Yet EPA assumes that this technology will be available to reduce both I&E at all facilities. <FN 16>

EPA’s assumptions regarding the efficacy of the specified technologies are equally unjustified. In deciding what performance ranges could be achieved, EPA apparently relied on data submitted by various facilities in connection with the regulation for new sources. Nothing in the current rulemaking indicates that the facilities providing the information analyzed their own experiences in a way that would make them valid for general application to existing sources. In particular, there is no indication that the facilities’ calculations utilized the assumptions on which EPA’s rule is based, including EPA’s assumptions as to the I&E baseline and EPA’s apparent interpretation of the ranges as being achievable for all species.

Finally, as is discussed more generally in Part III.B.5 of these comments, EPA has also failed to provide a credible demonstration that that the technologies it has identified can be implemented at an economically practicable cost, even in those circumstances where they can be utilized.

The complete absence of information showing that the specified technologies are generally available, can achieve performance within the ranges under the definitions and conditions imposed by the rule and can be implemented at an economically practicable cost precludes EPA’s reliance on these technologies in establishing the performance standards.

Footnotes

13 The identified technologies for impingement mortality reduction are: fine and wide mesh wedgewire screens; aquatic filter barrier systems; barrier nets; and a group of technologies combining screening with fish diversion and fish return systems. The identified technologies for entrainment mortality are: aquatic filter barrier systems; fine mesh wedgewire screens; and fine mesh traveling screens.

14 Legislative History at 264 (statement of House floor manager Rep. Don H. Clausen) (stating that “best technology available is intended to be interpreted to mean best technology available commercially at an economically practicable cost”).

15 See discussion of feasibility of Gunderboom barriers at Salem Harbor, Brayton Point and Manchester Street below.

16 In fact, to PG&E NEG’s knowledge there is only one large facility currently using the Gunderboom successfully.

EPA Response

EPA has selected performance standards to facilitate a more streamlined approach to the permitting process and to provide a more consistent mitigation target on a national level. By opting for performance standards instead of requiring the deployment of specified technologies, EPA maintains a desired flexibility in the implementation of the rule, thus allowing a facility to select measures that are appropriate to the site conditions and facility configuration.

Additional documentation has been collected and reviewed by EPA to further augment support for the performance standards and added to the Technology Efficacy database. This database, originally designed to act as a centralized bibliography of data EPA has reviewed during the course of the development of the final Phase II rule, has been expanded to allow users to query and compare basic data on technology performance and applicability. EPA recognizes that some may disagree with basing the performance standards on the wide range of data available in the database. While many documents do show some level of success in reducing impingement mortality or entrainment, other studies have shown the deployed technology to be unsuccessful or at best inconclusive. EPA did not view the varying degrees of success in regards to a specific technology as problematic, but rather as evidence that some technologies work in some applications but not in others.

It is for this reason and those set forth in this comment that EPA authorizes various compliance alternatives, including the use of a Technology Installation and Operation Plan. EPA believes that there are economically practicable technologies available that can be used to meet the performance standards at the majority of facilities subject to the final Phase II rule. Because site-specific factors do come into play, EPA has also authorized site-specific BTA determinations based on cost-cost or cost-benefits tests. Adopting requirements that allow for flexibility in implementation instead of technologies also simplifies the process by which compliance can be measured.

EPA notes that many of the studies reviewed during the development of this rule were not analyses of "out-of-the-box" technologies. That is, many of the installations of the various technologies were modified or adjusted to better suit the unique conditions, species, and configurations present at the facility. A key factor in the long-term success of a particular technology is the monitoring, maintenance and adjustments made during the course of its deployment.

Organization PG & E National Energy Group

Subject Matter Code 7.02

Performance standards

EPA has not demonstrated the biological need for the proposed performance standards.

EPA's performance ranges lack a defensible biological basis. Numerous errors in EPA's analysis result in a gross overestimation of the number and economic value of I&E losses attributable to cooling water intake structures. This overestimation is then used by EPA to detail in PG&E NEG's analysis of the Brayton Point case study, include the following:

-EPA's calculations improperly assume no survival of any life stage of any species that is impinged. EPA's assumption is erroneous. Many species do survive impingement. (See the discussion under the BPS case study at Section IV.A.4.a below for specific detail on this point.) Therefore, EPA has overestimated the impingement losses.

-EPA's calculations also improperly assume no survival of any life stage of any species that is entrained. As with impingement, the eggs, larvae and juveniles of many finfish species do survive entrainment. The assumption that no organisms survive entrainment results in overestimates of entrainment losses. (See the discussion under the BPS case study at Section IV.A.4.b below for specific detail on this point).

-EPA input erroneous data into the production foregone model it used to calculate a portion of the economic losses associated with I&E. I&E result in losses of individuals of different life stages. Because the ages of individuals within life stages are not known, a defensible method must be used to assign a weight to the individuals in each life stage. EPA incorrectly used the average weight at the midpoint of life stages to compute growth rate for individuals and starting biomass in the production foregone model. This results in inflated estimates of economic losses associated with the impingement and/or entrainment of early life stages of organisms. The standard --and correct approach -- is set forth by Ricker (1975). EPA not only ignored Ricker, but also ignored the available scientific literature. The weights used by EPA for midpoints of the early life stages are also inflated as compared to values reported in the scientific literature and computed from organism volumes and densities. For example, based on data from Buckley et al. 1991, the weight of a winter flounder egg calculated using three separate methods ranges from 2.25 to 2.68 x 10-4 gram wet. USEPA used a weight of 0.997 gram wet, or over 4,000 times heavier. Using data from Buckley 1982, the weight of a winter flounder yolk-sac larvae at first feeding is 1.13 x 10<-4> gram wet (actually less than the egg weight). Yet, USEPA used an average weight of 2.00 gram wet. This is over 12,500 times heavier than the observed weight.

-Finally, it should be noted that EPA used different life history parameters in different case studies, resulting in inconsistent analysis. This is most glaring in the HRC calculations, where the same studies were used to determine the densities of individuals in a given habitat but then different survival rates were used to calculate the number of age-1 equivalents. There is simply no justification for using different survival rates for the same habitat in different case studies.

EPA Response

For a discussion of the basis for the performance standards, please see the preamble to today's final rule, as well as response to comments 316bEFR.311.002 and 316bEFR.074.005.

The language proposed for implementing the new rule includes numerous ambiguities

The foregoing fundamental errors in the substantive requirements of the performance range option are compounded by numerous ambiguities and errors in the proposed regulatory language implementing EPA's performance standards approach. These errors include the following:

(i) Calculation baseline. EPA's definition of the calculation baseline fails to explain how the baseline level of I&E should be estimated. The definition should specifically provide that the baseline level of I&E -- i.e. that which would occur if the plant were open cycle, with a shoreline intake and using no I&E controls -- is to be calculated in light of current, local environmental conditions, not historical conditions or hypothetical future conditions. It should also make clear that the level of operations assumed is that which the facility would maintain in the absence of any operational controls implemented, in whole or part, for the purpose of reducing I&E. <FN 17>

Footnotes

17 As is discussed below, PG&E NEG does not believe that EPA has authority under Section 316(b) to impose operational restrictions on a facility. However, PG&E NEG recognizes that some facilities have voluntarily adopted operational measures as a result of negotiations with regulatory agencies. The purpose of this comment is to clarify that such operational measures are not part of the "baseline" as the term is used in the proposed rule.

EPA Response

For discussions on the basis for and implementation of the calculation baseline, please see response to comments 316bEFR.308.014 and 316bEFR.063.022, as well as the preamble to today's rule.

Performance standards

The language proposed for implementing the new rule includes numerous ambiguities

The foregoing fundamental errors in the substantive requirements of the performance range option are compounded by numerous ambiguities and errors in the proposed regulatory language implementing EPA's performance standards approach. These errors include the following:

(ii) Species analyzed for compliance with performance standards. The current regulations are ambiguous as to whether the performance standards are intended to apply in the aggregate to all species that are impinged or entrained at existing facilities or to each individual species that is impinged or entrained. PG&E NEG believes that a demonstration of reductions for each individual species would present enormous practical problems and also, because of the wide variability in how species are affected by I&E, make it virtually impossible for many facilities to meet the performance standards. The rule is also unclear about how variations based on time of year (or year to year fluctuations) are to be accounted for. <FN 18>

PG&E NEG believes that UWAG's proposal to allow demonstrations of impingement performance to be made in terms of Representative Important Species ("RIS") or Critical Aquatic Organisms ("CAO") and of entrainment performance to be made in terms of biomass represents a promising alternative method for measuring compliance with the performance standards and also may be a more appropriate method for monitoring performance, including the performance of mitigation measures. In addition to reducing the burden on facilities, use of an RIS or CAO to measure impingement performance would allow distinctions to be made between impacts to biologically important species and impacts to less significant or even nuisance species. <FN 19> However, PG&E NEG believes that the use of traditional methods for selecting RIS and CAO may need to be altered for use in the context of Section 316(b). In particular, PG&E NEG believes it is important that forage species -- which are often more sensitive to impingement -- not be over-represented RIS or CAO. Similarly, use of the biomass standard should not lead to forage species being over-represented.

Footnotes

I8 In the vicinity of Brayton Point Station, for example, the abundance of Atlantic Menhaden can vary by an order of magnitude or more from one year to the next.

19 PG&E NEG also agrees with UWAG that an averaging time of at least two years is necessary to address seasonal and year-to-year variation, with a longer period allowed if the past two years are not representative of the levels of I&E typically experienced.

EPA Response

Please see response to comment 316bEFR.063.005.

The language proposed for implementing the new rule includes numerous ambiguities

The foregoing fundamental errors in the substantive requirements of the performance range option are compounded by numerous ambiguities and errors in the proposed regulatory language implementing EPA's performance standards approach. These errors include the following:

(iii) Definition of "Entrainable". The proposed regulation does not clearly differentiate between "entrainable" and "impingeable" organisms. In order to provide consistency and certainty to the process, the proposed regulation should define "entrainable" as any organism that will fit through a standard 3/8 inch intake screen.

EPA Response

EPA has modified the definition of calculation baseline to include 3/8-inch mesh traveling screens to provide a more certain means of distinguishing between "entrainable" and "impingeable" organisms.

The language proposed for implementing the new rule includes numerous ambiguities

The foregoing fundamental errors in the substantive requirements of the performance range option are compounded by numerous ambiguities and errors in the proposed regulatory language implementing EPA's performance standards approach. These errors include the following:

(iv) Level of performance within range. The proposed regulation leaves open the question of whether, or under what circumstances, a facility might be required to demonstrate performance exceeding the lower end of the performance range. PG&E NEG does not agree that this decision should simply be left to the discretion of the director. 67 FR 17,142. The appropriate economic criterion for making this determination would require performance exceeding the lower end of the performance range only where the environmental benefits would justify the costs of the incremental reduction in I&E. See Part III.B.4.

EPA Response

For a discussion on the performance ranges and a facility's obligations to meet them, please see the preamble to today's rule.

RFC: Performance/effectiveness of restoration

The language proposed for implementing the new rule includes numerous ambiguities

The foregoing fundamental errors in the substantive requirements of the performance range option are compounded by numerous ambiguities and errors in the proposed regulatory language implementing EPA’s performance standards approach. These errors include the following:

(v) Measurement of mitigation performance. The regulations as currently drafted are ambiguous as to how mitigation performance will be measured, especially where a facility must make a “qualitative demonstration” that the mitigation measures will maintain the “community structure and function” at a level “substantially similar” to that achievable by application of technological alternatives. PG&E NEG believes that the appropriate way to understand comparability in the mitigation context is at the level of ecosystem services. <FN 20> Thus, the language should be modified to clarify that a facility will meet the comparability criterion if the mitigation measures will provide comparable services and will not require the replacement of every species affected by I&E to the same level as would a technological alternative.

Footnotes

20 See Part IV.B.4.b for further discussion of the use of ecological services as the appropriate unit for measuring mitigation performance.

EPA Response

For a discussion of the basis for EPA's authority to include restoration measures in the final rule, see the preamble to the final rule.

Any restoration measure must meet all of the requirements described in the final rule.

For a discussion of the roles and responsibilities of the permitting authority and permit applicant for determining what is required to ensure a restoration measure meets the performance requirements in the final rule, see EPA's responses to comments 316bEFR.060.026, 316bEFR.212.001, 316bEFR.034.029, and 316bEFR.002.009.

Organization PG & E National Energy Group

The language proposed for implementing the new rule includes numerous ambiguities

The foregoing fundamental errors in the substantive requirements of the performance range option are compounded by numerous ambiguities and errors in the proposed regulatory language implementing EPA's performance standards approach. These errors include the following:

(vi) Operational measures. The regulation is ambiguous as to whether EPA is reserving the right to require operational controls in certain instances. For the reasons discussed at length in Part III.A.1., above, PG&E NEG believes that Section 316(b) does not authorize EPA to impose mandatory operational requirements. Section 316(b)'s delegation to EPA to regulate the "location, design, capacity and construction" cooling water intake structures cannot logically be construed to allow regulation of a facility's operations. However, like mitigation measures, operational measures may be offered voluntarily as an alternative means of complying with the performance standards. See Part III.A.3.a. The regulation should make this clear.

EPA Response

EPA agrees and believes today's final rule sufficiently address the concerns of the commenter. EPA has not designated any particular design and construction technology or operational measure as Best Technology Available for minimizing adverse environmental impact, does not mandate any technology or suite of technologies.

More Stringent Requirements

Alternative Proposals for More Stringent Requirements are Poorly Defined and Unjustified

Although not part of its preferred approach, EPA proposes for comment several alternatives that would impose generally, or allow EPA (or a delegated state) discretion to impose, more stringent requirements for I&E reductions under specified circumstances. These proposals are, in most cases, only vaguely defined, and little attempt is made to explain the rationale for allowing or imposing the additional requirements. Furthermore, imposition of these additional requirements must be viewed with skepticism, given the significant costs that Phase II facilities are already being asked to bear and the fact that the impacts of concern -- primarily to fisheries -- have numerous other causes, including, most significantly, over fishing and pollution. PG&E NEG believes these other causes must also be addressed before significant additional costs can justifiably be imposed on electricity generators. For these reasons and those discussed in more detail below, PG&E NEG opposes the adoption of these alternatives to the proposed rule. <FN 21>

Footnotes

21 Although its relevance is unclear, PG&E NEG notes that, in addition to the proposals discussed in the text, EPA's proposed rule states that "it is unacceptable to impact more than 5% of the organisms within the area of an intake structure." 67 FR 17,151 col. 2. To the extent that EPA intends this as a general statement of policy, PG&E NEG believes it would create yet another avenue for imposing more stringent requirements -- a facility that is unable, for example, to reduce its impacts below this level using the technologies identified by EPA could be required to take additional steps until this level is reached. There is no support provided for the 5% cutoff and PG&E NEG would oppose implementation of such a requirement.

EPA Response

Organization PG & E National Energy Group

Subject Matter Code 13.0

More Stringent Requirements

More stringent regulation where a waterbody is affected by multiple stressors cannot be justified as an implementation of Section 316(b)

On page 17,151 of the proposed rule, EPA requests comment on language that would specify that more stringent requirements could be imposed where compliance with the performance standards or, where applicable, a site-specific determination based on the cost-cost or cost-benefit tests, would “not adequately address cumulative impacts caused by multiple intakes or multiple stressors within the waterbody of concern.” Section 316(b) provides no authority for using BTA determinations as a vehicle for addressing impacts other than those caused by the facility seeking to renew its permit. By its terms, Section 316(b) authorizes EPA specifically to ensure that the location, design, construction and capacity of any particular cooling intake structure uses the best technology for minimizing the structure’s adverse environmental impacts. Imposing requirements that are based on impacts of other activities beyond that structure is inconsistent with the language of Section 316(b).

Nor is such an approach likely to be effective. In many, if not most cases, the cumulative impacts from other stressors will be of significantly greater magnitude than those of the affected facility. The impacts also may be the result of years, if not decades, of unregulated or under-regulated activities, as well as lack of enforcement. To the extent that state and local regulatory bodies believe that power plants will be required to take steps to “make up” for impacts caused by other activities (i.e., do more than their fare share to make up for the impacts of others’ activities), there is likely to be little incentive to address those activities.

Finally, Section 316(b) does not authorize, and cannot be reasonably read to authorize, such a profound change in the orientation of the NPDES program. The focus of the NPDES program is on regulating specific point sources through standards and requirements applicable to that source’s specific activities that will reasonably reduce the impact of that source’s activities on the environment. Nothing in the NPDES program authorizes the EPA to use the NPDES process to require a permit holder to shoulder a disproportionate responsibility for the larger environment in which the permit holder operates.

For the foregoing reasons, PG&E NEG opposes EPA’s proposal that more stringent regulation be allowed where a waterbody is affected by multiple stressors.

Organization PG & E National Energy Group

Subject Matter Code 13.0

More Stringent Requirements

More stringent regulation to promote recovery of fish stocks is equally unjustified

A second, closely related proposal would allow EPA (or a delegated state) to require more stringent technologies “where not doing so would delay recovery of an aquatic species or community that fish and wildlife agencies are taking active measures to restore, such as imposing significant harvesting restrictions.” 67 FR 17,151. This proposal is unjustified and must be rejected for the same reasons as explained in (a) above -- it ignores the requirement in Section 316(b) that there be a causal connection between the conditions being imposed on the cooling water intake structure and the adverse environmental conditions attributable to that particular source. The language of Section 316(b) is clear on this point -- EPA is to identify BTA to address the adverse impacts of the affected facility’s own cooling water intake structure on the waterbody. Congress did not authorize EPA to require affected facilities to compensate the system for any stresses other than the I&E attributed to that facility from cooling water intake.

PG&E NEG also notes that, based on EPA’s one sentence proposal, it is difficult to see how a test of the kind EPA suggests could be implemented in a manner that is not speculative. PG&E NEG opposes a rule that would authorize EPA or a delegated state to impose potentially draconian additional limits on I&E impacts on the basis of the mere suspicion that those impacts might contribute in some way to a “delay” in that recovery.

For the foregoing reasons, PG&E NEG opposes this proposal.

EPA Response

Organization PG & E National Energy Group

Subject Matter Code 17.02

Option: Reduce capacity comm. with closed-cycle

EPA's proposals to impose closed-cycle cooling based on waterbody type or waterbody type and flow are unjustified

Two further alternatives to the preferred rule EPA has proposed for comment would require certain facilities, identified by waterbody type or waterbody type and flow, to meet a performance standard based on closed-cycle cooling. Under the first proposal, all facilities on oceans, estuaries and tidal rivers would be required to adopt this performance standard. 67 FR 17,155 col. 2. Under the second, only those meeting certain flow levels would have to do so. 67 FR 17,156 col. 1. For facilities on estuaries or tidal rivers, the standard would apply to facilities withdrawing more than 1% of the volume of one tidal excursion; for facilities on oceans it would apply to facilities withdrawing more than 500 MGD.

EPA has failed to provide adequate biological or economic justification for either proposal. In particular, EPA provides no explanation for why the cutoff levels it identifies are biologically relevant in the waterbody and flow alternative. In addition, as EPA acknowledges, the incremental costs of imposing additional requirements based on waterbody or waterbody and flow would far exceed the incremental benefits of doing so

However, these proposals fail on a more fundamental ground: EPA simply has no authority under Section 316(b) to require closed-cycle cooling. See Part III.A.1. As a result, PG&E NEG opposes both proposals.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

Organization PG & E National Energy Group

Subject Matter Code 7.01.03

Option 3--Site-specific determination

EPA's Site-Specific Alternative is Too Limited and Poorly Defined

Although EPA correctly recognizes the importance of retaining a case-by-case alternative for demonstrating compliance with Section 316(b), the specific site-specific approach EPA adopts in the proposed rule is fundamentally flawed. Before a facility could hope to have EPA consider a site-specific analysis, it would have to demonstrate that its costs of meeting EPA's generic performance standards would either be significantly greater than the costs by EPA in developing the standard or that it proposes significant greater benefits from its site-specific approach. But, even if an applicant can show that its costs are significantly greater than those EPA has determined generically should be spent, the baseline cost for the site-specific standard is the level of costs EPA determined should be spent, not zero. EPA thus will assume in what purports to be a site-specific analysis that there is a benefit to spending what EPA determined should be spent with regard to any site-specific considerations and that the only costs to be justified within the context of the site-specific analysis are those "significantly greater" than those EPA already determined should be spent. The effect of these restrictions and assumptions renders the "site-specific" nature of the determination illusory. EPA has also failed to provide useable definitions of critical terms used in its site-specific alternative.

For these reasons, discussed in more detail below, PG&E NEG opposes the site-specific alternative proposed by EPA and endorses the alternative proposed by UWAG.

EPA Response

EPA disagrees. The commenter incorrectly assumes that the rule will always require a technology to be installed or some expense incurred to meet the performance standards. A facility may choose to seek a site-specific determination of BTA using the cost-benefit test.

Comment ID 316bEFR.060.051

Author Name Mark V. Carney
Organization PG & E National Energy Group

Subject Matter Code 7.01.03
Option 3--Site-specific determination

EPA's proposal improperly limits the availability of site-specific alternative

Under EPA's proposal, a facility can only obtain a site-specific determination of BTA if it can demonstrate that the costs it would incur to comply with the performance standards would be "significantly greater" than either: (i) the costs considered by EPA in developing the standards; or (ii) the benefits of complying with the performance standards. 67 FR 17,221 (proposed 40 CFR 125.94(c)(1). PG&E NEG does not believe that EPA can properly limit access to a case-by-case determination of BTA in this manner. As was discussed in Part III.A.2.a. above, the statutory language, legislative history of 316(b) and EPA's own consistent interpretation compel the conclusion that Section 316(b) must be applied on a case-by-case basis. The rule, as currently drafted, makes access to a site-specific determination of BTA effectively illusory for many, if not most, facilities.

EPA's approach also runs afoul of settled precedent by placing the burden of demonstrating significantly greater costs on the facility seeking a site-specific determination of BTA. As EPA has long acknowledged, the burden of establishing BTA in a Section 316(b) determination lies with the Agency. See In Re Central Hudson Gas and Electric Corporation, Opinion of the General Counsel No. 63 at 382 (July 29, 1977) ("[U]nder 316(b) EPA has the ultimate burden of persuasion."). This burden includes the burden of demonstrating that there is a technology available that can be implemented at an economically reasonable cost. Id at 383 (discussing agency's burden to show cost test is met); Legislative History at 264 (Statement of Rep. Clausen) (explaining that "best technology available is intended to be interpreted to mean best technology available commercially at an economically practicable cost").

Nothing in the text of Section 316(b) supports this shifting of EPA's burden to the permit applicant and PG&E NEG opposes EPA's attempt to limit access to the site-specific alternative by the cost-benefit and cost-cost test.

EPA Response

Please refer to the response to comment 316bEFR.060.050 for information about the cost tests.

EPA disagrees regarding the burden of proof. The burden of proof lies with the permittee. This is reflected in the choice of words used in the rule language and in the preamble. For example, the rule may say "you [the facility] must demonstrate to the Director" when stating a requirement.

Comment ID 316bEFR.060.052

Author Name Mark V. Carney

Organization PG & E National Energy Group

Subject Matter Code 7.01.03

Option 3--Site-specific determination

EPA's proposed rule imposes an unjustifiably stringent level of control

In addition to requiring that an applicant seeking a site-specific determination demonstrate that its costs would be "significantly greater" than those considered by EPA or than the benefits of complying with the performance standards, EPA allows an applicant to receive an alternative determination of BTA only "to the extent justified by the significantly greater costs." 67 FR 17,221 (proposed 40 CFR 125.94(c)(3)). However, requiring a facility to make reductions within the range of performance standards up to the point that costs are "significantly greater" than benefits has no economic justification and will make society worse off. See Part III.B.4.

Because a facility seeking a site-specific determination on the basis of the cost/benefit test would necessarily be required to achieve an unreasonably stringent level of control — one that has no economic justification -- PG&E NEC opposes EPA's requirement that a site-specific termination only be allowed "to the extent justified by the significantly greater costs."

EPA Response

Please refer to the response to comment 316bEFR.060.050 for information about the cost tests.

Comment ID 316bEFR.060.053

Author Name Mark V. Carney

Organization PG & E National Energy Group

Subject Matter Code 7.01.03

Option 3--Site-specific determination

EPA's proposal is wholly ambiguous as to the decision criteria to be applied

As currently drafted, EPA's site-specific alternative is ambiguous in several critical respects. Most importantly, it lacks an appropriate definition of the term "adverse environmental impact," which is central to how the provision will be implemented. In addition, it provides virtually no guidance to the agency or regulated community as to the decision criteria EPA plans to use in determining whether the cost tests are met and, if they are, what level of reduction will be required. These omissions and ambiguities, discussed in more detail below, render EPA's site-specific alternative unworkable.

EPA Response

No response is required, as the issues raised in this comment are summary in nature and are addressed in individual responses.

Comment ID 316bEFR.060.054

Author Name Mark V. Carney

Organization PG & E National Energy Group

Subject Matter Code 18.01

RFC: Definition of "adverse environmental impact"

Adverse Environmental Impact is undefined

As currently drafted, the regulation includes no definition of adverse environmental impact. Instead, EPA has identified several different possible definitions and solicited comments on how it should approach defining the term. In particular, EPA has asked for comment concerning:

-Whether the definition of adverse environmental impact (AEI) should include any I&E impacts or whether AEI should be determined in light of effects observable at a higher level (i.e. population or ecosystem effects); and

-Whether the definition of AEI should incorporate an explicit threshold determination of whether AEI is occurring.

See 67 FR 17,164 col. 2-3. PG&E NEG believes that EPA's site-specific proposal should define AEI as occurring when the loss of fish or other organisms has actual adverse effects at the population or community level and should incorporate a specific threshold level of impact below which I&E effects are presumed not to be adverse.

Such a definition reflects the reality that: (1) as a matter of basic biology, large losses occur naturally and even very large losses may have little or no effect on the vigor of the aquatic populations or community and (2) such losses often have little or no effect on the public's use and enjoyment of aquatic resources. It is also consistent with the concepts relied on by fishery managers charged with the management of fish stocks. This approach views the fishery as a renewable resource that can be managed. It recognizes that the federal government need not try to protect every fish, let alone every fish egg, but should instead preserve the fishery resource itself.

A definition of AEI based on population-level effects is also fully consistent with the language and purpose of Section 316(b). Indeed, EPA's early guidance and permitting decisions strongly support the view that AEI was understood to require that there be a significant impact at the population level before new technological requirements would be imposed. <FN 22>

Footnotes

22 See Anderson & Gotting, 26 Column. J. Envtl L. at 41-42 (discussing guidance documents reflecting EPA's understanding that "adverse impact" meant significant, population-level impacts). In this context, PG&E NEG notes that it could be argued that the requirement of population level impacts is required by the interaction between Section 316(a) and Section 316(b). Under this reasoning, Congress' acknowledgment in Section 316(a) that it is only necessary to protect a "balanced, indigenous population" reflects an upper limit on the scope of Section 316(b) as well -- it would make no sense for Congress to have deliberately established a unique, population-level standard for steam electric generators under Section 316(a) only to re-impose a more stringent level of control under Section 316(b).

EPA Response

Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define "adverse environmental impact" in today's final rule.

Subject Matter Code 10.07.02

RFC: Appropriateness of “significantly greater”

Author Name Mark V. Carney

Organization PG & E National Energy Group

Lack of Decision Criteria for Cost Tests

As currently drafted, the regulations provide no guidance as to how determinations under the site-specific alternative will be made. Completely missing is language interpreting the meaning of the “significantly greater” criterion, which is used to establish both eligibility for the site-specific alternative and the level of control required of a facility granted a site-specific determination. PG&E NEG is concerned that the absence of clear standards will be read as according EPA and delegated states virtually unfettered discretion to determine in individual cases whether or not to perform a site-specific determination and to decide what level of I&E reduction to require. Such a result is both unfair to the regulated community and incompatible with EPA’s stated intent to provide some measure of consistency and regulatory certainty in the proposed rule.

EPA Response

See responses to 316bEFR.006.003 and 018.009. With regard to the level of control required, see 40 CFR 125.94(a)(5)(i) and (ii), which specify the requirements applicable to site-specific determinations. These provisions are discussed in section VII and IX of the preamble to the final rule. EPA believes that the state Director is in a better position that EPA to account for the various physical, biological and other conditions that would be relevant to a site-specific determination of BTA.

Organization PG & E National Energy Group

Subject Matter Code 17.08

Option: UWAG's recommended approach

PG&E NEG endorses UWAG's proposed site-specific rule

In stark contrast with EPA's site-specific approach, UWAG's suggested alternative would make available to all facilities a clearly defined and economically justified method for making site-specific BTA decisions. UWAG's proposal includes definitions of all relevant terms and comprehensively articulated decision criteria. UWAG's alternative also includes provisions that appropriately focus on the circumstances in which regulation is most justified, by, for example, providing minimum thresholds for regulatory action under Section 316(b) and defining adverse impact based on population-level effects.

For the foregoing reasons, PG&E NEG endorses UWAG's proposal for making site-specific determinations of BTA. 67 FR 17,164 col. 2.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Subject Matter Code 10.07.02

RFC: Appropriateness of "significantly greater"

EPA's Chosen Economic Criterion, the "Significantly Greater Cost Test," Will Make Society as a Whole Worse Off

As noted above, PG&E NEG supports EPA's abandonment of the "wholly disproportionate cost" test as the economic baseline for determining the level of technology that constitutes BTA. However, EPA's alternative economic "bottom line" for this regulatory effort - the "significantly greater cost test" -- is only marginally less inappropriate. Under the proposed test, the alternative that provides the greatest environmental gain would be chosen from a set of alternatives for which the costs are not "significantly greater" than the benefits. In essence, EPA puts a couple of rabbits in the hat and then claims that picking the cheapest rabbit will lead to a rational cost-benefit analysis. But whether the cost of any of the rabbits can be justified is never really part of the analysis. It remains possible, indeed likely, that the set of alternatives (all of the rabbits) considered under this rule could all have costs exceeding their benefits. In that case, all alternatives would make the society at large worse off than would no regulation -- including the one that would be chosen for implementation. <FN 23>

Footnotes

23 Yet another test, "economic practicability," discussed briefly on pages 17,144-17,145, is equally flawed. Concluding that a particular cooling water technology — or any other investment — is or is not "economically practicable" or "affordable" based on its costs relative to an individual firm's or facility's revenues could not be based upon a decision criterion with any normative standing in economics. Such an approach would tell us nothing about whether the technology helps to achieve specific objectives, whether it does so at minimum cost (cost effectiveness), or whether an alternative investment would provide greater net benefits to the company, the environment, or society as a whole. EPA would in essence determine how much money a firm or facility should make by determining how much money (whether in capital or operating costs) a firm or facility should spend on cooling water technology.

RFC: Test: benefits should justify the costs

Author Name Mark V. Carney

Organization PG & E National Energy Group

This is not a rational cost-benefit criterion and for that reason, PG&E NEG opposes it. Instead, the appropriate test for determining the appropriate level of I&E reduction (if any) would be one which protects the natural resources involved to the point where the incremental benefit from increased protection equals the incremental cost of the increased protection. The alternative chosen under such a test will produce the maximum net benefits to society as a whole.

EPA has requested comments on a test employing precisely this criterion, which it describes as “a test based on the concept that benefits should justify costs.” See 67 FR 17,166 col. 2. This is the approach endorsed by PG&E NEG. Requiring that the benefits justify the costs in the manner described in the Proposed Rule will lead consistently to decisions which make society as a whole better off, and will identify the alternative that does so in the greatest magnitude, that is, the alternative that produces the largest net benefits. In economic terms, this is known as the social net present value criterion. It is in everyone’s interest that a technology be adopted if the present discounted value of anticipated net benefits (including environmental benefits) is greater than the anticipated net benefits of alternatives, including the status quo.

For these reasons, EPA should adopt the benefits justify costs criterion as its preferred criterion.

EPA Response

For EPA's response to comments on application of the cost-benefit test to assessing the value of alternative CWIS technologies, please see comment #316bEFR.005.020.

Use of Replacement Costs (HRC and hatchery-based)

The HRC and the Forage Fish Replacement Cost Method of Estimating Benefits are Invalid and Cannot be Used

In addition to adopting an economically unsound decision criterion in its proposed 316(b) rule, EPA's estimation of the benefits of the rule contains numerous errors which preclude a rational assessment of whether the rule can be justified under any cost-benefit test. PG&E NEG has reviewed EPA's economic analysis with particular reference to the Brayton Point case study and the majority of its comments on EPA's economic methods therefore appear in Section IV, which discusses that case study in great detail. <FN 24> However, because EPA used the Habitat Replacement Cost method ("HRC") and forage replacement costs to estimate benefits in a number of the case studies relied upon to develop national benefit estimates for the rule, they also merit a more general comment.

In several of the case studies, including the Brayton Point case study, the Pilgrim case study, the J.R. Whiting case study and the Monroe case study, EPA uses estimates of habitat replacement cost as an alternative method of valuing I&E losses. The HRC method uses the cost of restoring or replacing ecological resources at a level sufficient to offset I&E losses -- i.e. through restoration or construction of habitat, stocking of forage fish, installation of fish ladders, etc. -- as a measure of the value of those losses. In addition, in case studies including the Delaware Estuary case study, the Ohio River case study, the Tampa Bay case study and the Brayton Point case study, EPA uses the forage fish replacement cost approach. The forage fish replacement cost method estimates value by the cost necessary to stock lost forage fish due to impingement and entrainment. Both approaches to valuing I&E losses are wholly invalid.

As should be self-evident, the value that resources have to people is unrelated to the costs of restoring or replacing those resources. In fact, such thinking can lead to incorrect conclusions that are damaging to the environment. The fact that it might be quite costly to replace the habitat of the anopheles mosquito in drought-stricken areas, or of the deer tick in Manhattan, does not mean that the mosquito or the tick must each therefore have great value. It might be quite inexpensive to restock a species that is highly valued for commercial or recreational fishing or non-use (i.e. the value that people may derive simply from knowledge of the species' existence in some area), and likewise it may be relatively expensive to restore another species that has been little studied with respect to restoration methods precisely because of its low commercial, recreational, and non-use value. Using HRC or a replacement cost to measure the value would lead to exactly the wrong conclusion: the implication would be that the high-value species has "low value" because of the low costs required to restore it, and the low-value species has "high value" simply because it is relatively costly to restore it.

Use of these demonstrably invalid methods also has no substantive support in EPA's prior practice. Indeed, their use here represents a dramatic departure from prior practice and EPA's own current guidance documents. EPA's official guidance document, "Guidelines for Preparing Economic Analyses" (Office of the Administrator, September 2000), cannot be used to justify either approach. Indeed, the Guidelines specifically discuss the narrow circumstances in which an avoided cost measure may be used to estimate benefits. <FN 25> None of them is present here. Nor has PG&E

NEG found any meaningful support for using these approaches to estimate benefits in the technical support documents developed for this rulemaking. The complete absence of support underscores the irrationality of using these methods to calculate benefits.

Equally telling are the absurd results from application of the HRC method in the Brayton Point case study. The HRC-based analysis of the value of I&E losses at Brayton Point produced an estimate of benefits that was more than 200 times larger than the benefits that EPA calculated using more justifiable (although improperly applied, as is discussed in part N.B.3) valuation methods. The result would have been another two orders of magnitude larger still but for EPA's apparently arbitrary exclusion of one type of restoration (reef construction) which by itself would have added in excess of $1 billion per year to the total. Inclusion of the forage fish replacement cost values likewise introduces a clear upward bias to EPA's estimates.

Because these invalid methods are used to develop the benefits figures relied upon in the national benefits estimate, one result of their inclusion is to dramatically inflate EPA's estimate of the benefits of the regulation. In addition, to the extent that these methods are used to develop benefits estimates in order to demonstrate eligibility for a site-specific evaluation under the benefit-cost test, they will have the effect of improperly denying many if not most facilities a site-specific determination of BTA. As the analysis of the Brayton Point case study shows, the "benefits" estimates produced by the HRC method are truly staggering. Using these estimates, virtually any conceivable level of technological control would be found to be cost-justified and, as a result, a request for a site-specific determination under the benefit-cost test would be denied. This would result in precisely the one-size-fits-all approach (albeit one dressed-up in cost-benefit garb) that Congress specifically did not have in mind when it adopted Section 316(b).

In short, the HRC and the forage fish replacement methods simply have no place in a rational analysis of the benefits of the proposed rule. Nor has EPA even attempted to justify its use of them, in place of the various conceptually valid approaches EPA has approved for use in this context. The "values" calculated based on these methods must be eliminated from all benefit estimates, including those carried out for the Brayton Point Station case study. Further, the HRC and Forage Fish Replacement methods used by EPA should not be used to support the final rule or NPDES permits at any PG&E NEG stations.

Footnotes

24 PG&E NEG has also reviewed the analysis performed for UWAG, which found numerous errors in the choice of facilities used as the basis for the national estimates and in the biological and economic assumptions used to develop national benefits estimates for the proposed rule. See UWAG comments, Section V.D.-E. PG&E NEG endorses those comments.

25 The Guidelines identify two circumstances in which "averting behavior" may be appropriately used to estimate the value of an environmental benefit. The first occurs where individuals have actually proven willing to pay (voluntarily) a certain amount to substitute for environmental services. See Guidelines, p. 99. The second occurs where an individual or entity, again voluntarily, undertakes an action that exempts it from a pre-existing environmental obligation. See id In this latter circumstance (also not applicable here), the avoided cost of the environmental obligation can provide an estimate of the value of the action taken by the individual or entity.

EPA Response

EPA does not use the Habitat-based Replacement Cost (HRC) method in the cost benefit analysis for the final Section 316(b) Phase II rule. Please see the document entitled "Habitat-based Replacement Cost Method" (DCN #6-1003) for additional discussion of the HRC method. Please also see EPA's response to comment #316bEFR.005.035.

In the analyses for the NODA and the final rule, EPA no longer uses hatchery costs to estimate impacts on forage species. Instead EPA translates foregone production among forage species into foregone production among harvested species that are impinged and entrained using an assumed trophic transfer ratio, and then translates foregone production among these harvested species to foregone yield. Further information on the methods EPA used to estimate forage losses is provided in the regional study document prepared for the analysis for the final Phase II rule (DCN #6-0003). See Chapter A5: Methods Used to Evaluate I&E.

Facility & firm-level costs/Econ. Practicability

EPA Fails to Provide a Credible Demonstration that the Proposed Rule, as a Whole, is Economically Practicable, Especially for Nonutilities

As EPA acknowledges, Section 316(b) requires EPA to demonstrate that its rule implementing the statutory provision is economically practicable. See 67 FR 17,144-45. In the proposed rule, EPA states that it has considered the costs of its proposed rule both in terms of revenues generated by facilities affected by the proposed rule and in terms of revenues generated by the firms that own such affected facilities. It concludes that the costs of compliance with the proposed rule would be very low and that "the proposed rule would not lead to the early retirement of any existing generating capacity, and would have very small or no energy effects." 67 Fed. Reg. 17145, col. 2-3. PG&E NEG questions both EPA's methods and its conclusions.

With respect to EPA's approach, PG&E NEG notes that EPA's cost test based solely on percentage of revenues required to meet the standards or any other requirement under 316(b) provides no indication about whether the expenditures are warranted or worthwhile in terms of the environmental benefits achieved. Nor is it a reliable guide to whether the costs are affordable. Indeed, if that were the test of whether a facility could bear the cost of an additional regulatory burden, EPA could easily justify burdens that in the aggregate force the company out of business, by "dedicating" only one or a few percent at a time. For such a measure to have any meaning at all, it would have to take into account existing and sustainable margins in the market segment and the aggregate of other incremental costs that may be imposed on the enterprise, including those necessary to meet additional regulations such as air emission controls, site security upgrades, toxics use reduction, and others. EPA has not done this. And even if it had, such a test would fall short of establishing that the cost is "economically practicable," a term used by Congress to convey the need that the benefits justify the costs. CF section 304(b)(1)(B) ("best practicable" must include "consideration of the total cost of application of technology in relation to the effluent reduction benefits to be achieved); See also 118 Cong. Rec. 33,696 (1972).

Furthermore, PG&E NEG believes there is simply not sufficient data in the record to support the conclusions EPA draws. While EPA acknowledges that its proposed rule affects both traditional steam electric utility and steam electric nonutility power producers, EPA glosses over the significance of this distinction in terms of its proposed rule. Traditional steam electric utilities own and operate rate-based facilities; their costs are generally disclosed; and so long as those costs are prudently incurred, they are recovered by the utility through its rates. Steam electric nonutility power producers own and operate competitive generating facilities (that they in many cases bought from traditional utilities); their capital and operating costs are generally not public; and whether and the extent to which they recover those costs are a function of market conditions, including access to capital. EPA has not adequately taken account of these important differences between utility and nonutility power producers.

This important gap in the record is to an extent acknowledged by EPA itself. It stated with respect to its survey of nonutility power producers, "EPA did not utilize company-level data from Form EIA-

867 because the confidential nature of this data prevented EIA from releasing it." 67 Fed. Reg. 17132, col. 3. It would seem that under these circumstances EPA was required to articulate in its rulemaking record a proxy for it (by, for example, aggregating the data). Nor did EPA perform any meaningful analysis as to whether current market conditions are such that the investment contemplated by the proposed rule would more likely than not be made by affected nonutility power producers in light of uncertainties surrounding their ability to recover those costs from the market, including a reasonable rate of return on their private investment. In the absence of any recognition of real-world market conditions, how could EPA conclude that the proposed rule would not lead to the early retirement of any existing generating capacity? In short, the record does not support the conclusions EPA attempts to draw.

EPA Response

Please refer to the response to comment 316bEFR.005.021 in subject matter code 9.01 for a discussion on EPA's use of a cost-to-revenue test to determine economic practicability.

EPA also notes that in the context of Section 316(b) of the Clean Water Act, the concept of economic practicability refers, among other things, to the rule's impacts on the economic viability of facilities and firms subject to the regulation. Benefits are irrelevant to the determination of economic practicability for Section 316(b) regulation. The commenter's reference to "best practicable" is drawn from the context of "Best Practicable Technology" as defined in the Clean Water Act; this concept of "practicable" is not the same concept as "economic practicability" as considered herein for the development of the Section 316(b) regulation.

The commenter further states that EPA did not properly take account of differences between utilities, which own and operate rate-based facilities, and nonutilities, which own and operate competitive generating facilities. EPA disagrees with this comment. EPA believes that in a deregulated market, the distinction between utilities and nonutilities is no longer relevant. While such a distinction may have been important in the past, when only a few unregulated nonutilities competed with regulated utilities, this is no longer the case. The share of Phase II facilities that are owned by unregulated entities has increased from 2 percent in 1997 to 31 percent in 2001. By the time the final rule will take effect, even more Phase II facilities that currently operate under a rate-based system will be operating in a competitive market. Furthermore, EPA does not believe that nonutilities will be differentially impacted compared to utilities, even in the case that deregulation might not have taken effect in all markets by the time this rule is implemented. Competitive pressures, even in regulated environments will reduce the ability of utilities to pass on costs to their consumers.

EPA further notes that the IPM used to conduct the energy market analyses in support of the Phase II rule is based on the assumption of deregulated wholesale markets. As a result, uncertainties surrounding the ability to recover compliance costs from the market are explicitly incorporated into the model and accounted for in EPA's analysis.

The commenter alleges that there is a "gap in the record" with respect to nonutilities because EPA did not use company-level data from Form EIA-867. EPA disagrees with this comment. EPA notes that not using Form EIA-867 data did not create a gap in the record. Rather, the refusal by the Energy Information Administration to release this data to EPA resulted in the need to collect similar data through an industry survey. EPA did just that. As a result, EPA used a different data source, rather than no data, in the Phase II analyses.

For these reasons, EPA disagrees with the assertion that the record does not support EPA's conclusions.

Brayton Point

COMMENTS ON BRAYTON POINT STATION CASE STUDY

The Brayton Point Station case study prepared by EPA in support of the proposed regulations is premised on numerous faulty assumptions, erroneous analytical methods, and flawed calculations. It places undue -- but substantial -- reliance on several reports prepared by Mark Gibson of the Rhode Island Department of Environmental Management which, among other flaws, use and present data in a misleading way that distort the impacts of the Brayton Point Station, misrepresents the actual condition of Mount Hope Bay, and mischaracterizes the recovery of winter flounder in Narragansett Bay. Beginning from this flawed premise, it employs invalid and improperly applied methods to calculate the losses attributable to I&E at Brayton Point Station and then estimate the economic value of those losses.

The cumulative effect of EPA's errors is to produce a grossly excessive estimate of the benefits of the proposed performance standards for Mount Hope Bay that has no basis in sound science. Reliance on such defective data is inconsistent with the requirements of the Paperwork Reduction Act and PL 106-554 (the Data Quality Act), 44 U.S.C. § 3500 et seq. In addition, EPA's use of such deeply flawed methods can provide no rational basis of support for the proposed rule or the Station's pending permit renewal application. The principal flaws are discussed below.

A. Erroneous Factual Assumptions

The conclusions set forth in the case study flow from numerous factual assumptions. Unfortunately, most of these "facts" are demonstrably wrong.

1. The winter flounder in Mount Hope Bay did not decline due to the conversion of unit 4 to once-through cooling.

On p. F1-2 of the case study, EPA states that the decline of winter flounder in Mount Hope Bay was caused by the conversion of Unit 4 to once-through cooling in 1984. The Unit 4 conversion was not completed and operational until 1985. During this time, each of the other three units were off-line for various reasons. It was not until 1987 that all four units were running simultaneously. Hence, it was not until 1987 that the effects of the unit 4 conversion (thermal and flows) began to be experienced in Mount Hope Bay. <FN 26>

By 1987, the winter flounder were already steeply in decline. <FN 27> The steep decline was apparent not just in Mount Hope Bay, but in Narragansett Bay, Peconic Bay, Niantic Bay and numerous other water bodies up and down the entire coast of the United States. There can be no argument that Brayton Point Station affected any waterbody other than Mount Hope Bay -- in fact, Mr. Gibson, whose work is repeatedly cited in the "case study," plainly agrees that Brayton Point Station does not affect these other water bodies. That is precisely why he compares the abundance of winter flounder in Mount Hope Bay with their abundance in Narragansett Bay and adjacent coastal waters. In short, it is wrong to conclude that the winter flounder in Mt. Hope Bay declined due to the conversion of Unit 4 to once-through cooling.

2. Winter flounder have not fared much better in Narragansett Bay than in Mount Hope Bay and are not experiencing a superior recovery in Narragansett Bay

Contrary to the assumptions in the case study and in Mr. Gibson's reports, <FN 28> there is not a significant difference between winter flounder abundance in Mount Hope Bay and in Narragansett Bay. This becomes obvious when one examines closely the sampling stations throughout Mount Hope Bay and Narragansett Bay, as has been done by Professor Joseph DeAlteris, Ph.D. <FN 29> Using the same analytical methods as were used in Gibson (2002), <FN 30> Professor DeAlteris compared data collected in the immediate vicinity of Brayton Point Station ("upper Mount Hope Bay" or "UMHB") with data collected from the lower 2/3 of Mount Hope Bay ("lower Mount Hope Bay" or "LMHB"), Professor DeAlteris then compares the data from those sites with data collected from Narragansett Bay.

Professor DeAlteris analyzed the data over several different time periods between 1972 and 2000. His analysis reveals that during some time periods the rate of increase in winter flounder abundance was higher (positive) in UMHB than in either LMHB or Narragansett Bay. Similarly, for some time periods, the trend in abundance of winter flounder was lower (negative) in UMHB than in LMHB or Narragansett Bay. Most striking, however, was Professor DeAlteris' finding that winter flounder abundance trends in Lower Mount Hope Bay resemble those in Narragansett Bay. These findings flatly refute key assumptions in Mr. Gibson's work and in the case study. Contrary to what Mr. Gibson claims, only in an area of 5 square miles of Mount Hope Bay (UMHB) is there is any evidence that flounder declined more steeply there than the lower 10 square miles of Mount Hope Bay and the 146 square miles of Narragansett Bay, and even that was observable only in the longest of the time series analyzed, 1972-2000. <FN 31>

As Professor DeAlteris explains, the errors in Mr. Gibson's work flow from a mischaracterization and misuse of data. Mr. Gibson uses only a small subset of available data (that collected by Marine Research Inc. in UMHB) to reach a conclusion about the trend of winter flounder abundance in all of Mount Hope Bay. He then misleadingly compares that data with data collected in Narragansett Bay, Rhode Island Sound, and Block Island Sound combined. <FN 32> In short, Mr. Gibson's comparison is completely unreliable and misleading.

3. The abundance trends of other groundfish near the Station resembles their abundance trends elsewhere in Mount Hope Bay and in Narragansett Bay

In a subsequent report, Mr. Gibson takes his erroneous conclusions about winter flounder abundance and hypothesizes that it extends to all groundfish in all of Mount Hope Bay. <FN 33> This hypothesis is based on sheer speculation and is in fact refuted by the data. Professor DeAlteris again used Mr. Gibson's own method of analysis and Mr. Gibson's own agency's data to perform an independent analysis comparing abundance trends between UHMB, LHMB and Narragansett Bay for winter flounder, windowpane, hogchoker, tautog, and scup. That analysis found no meaningful difference between the trends for windowpane, tautog, or scup abundance in UMHB, LMHB, or Narragansett Bay. For winter flounder and scup, there was limited evidence of a differential decline in UMHB, but no evidence of a differential decline in the lower two-thirds of Mount Hope Bay. Overall, the clear weight of evidence eliminates Brayton Point Station as a factor in the declines of all species in the lower 2/3 of MHB. It also casts serious doubts on Mr. Gibson's claims that the station has seriously impacted the abundance of these five species in UMHB. In fact, in a few instances the trends were more favorable for UMHB --closest to the Station -- than for Narragansett Bay, farthest from the Station.

Mr. Gibson and the case study have overestimated the impacts of Brayton Point Station on Mount Hope Bay. Furthermore, there is no support for the statement at page F1-1 of the case study that winter flounder experiencing a superior recovery in Narragansett Bay compared to Mount Hope Bay. In fact, Mr. Gibson's own data demonstrates that the abundance trends of winter flounder in two-thirds (10 square miles) of Mount Hope Bay resemble their abundance trends in Narragansett Bay.

4. EPA erroneously assumes that no organisms survive either impingement or entrainment

EPA's analysis assumes that no organisms survive either impingement or entrainment. Yet Brayton Point Station and other power plants have provided EPA over the years with data and studies proving conclusively that substantial percentages of organisms can and do survive I&E. EPA's assumption of zero survival grossly overstates losses from I&E.

a. Impingement Survival

The capacity for organisms to survive impingement at any station's intake is dependent on a number of factors, including the general hardiness of the species, the age of the individual impinged, the construction of the traveling screens, and station operation. PG&E NEG (1987) measured survival of impinged organisms at Brayton Point Station during 1984 — 1986. The study found that many finfish species have very high rates of impingement survival (>90%; e.g., winter flounder, windowpane, hogchoker, bluefish, tautog, and threespine stickleback). Numerous other species were found to have high rates of survival (>50%; e.g., American sand lance, scup, seaboard goby, weakfish, and white perch), although some of the less hardy species did not survive impingement well (<10%; e.g., alewife, Atlantic menhaden, bay anchovy, and rainbow smelt). PG&E NEG also measured survival of impinged organisms at Manchester Street Station from January 1996 to February 1997. <FN 34> Latent (48-hour) survival rates for all finfish observed, excluding Atlantic menhaden, averaged 71.8%; survival rates ranged from 38.0% for Atlantic Silverside to 97.4% for three-spined stickleback. The survival rate for Atlantic menhaden was approximately 6%; menhaden have long been recognized to be very sensitive to any type of handing, particularly impingement. Winter flounder initial survival rates at the low pressure (LP) return line ranged from 96.6% to 98.2% and 93.5% at the high pressure (HP) return line. Latent survival rates were 95% at the LP return line and 92.2% at the HP return line.

In light of the above, EPA's decision to not consider impingement survival in the calculation of impingement losses likely resulted in gross overestimation of the station's impacts on the ecosystem and potentially misguide mitigation efforts.

b. Entrainment survival

Similar to impingement, the capacity of an organism to survive entrainment is dependent upon the age/size of the organism, the species' hardiness, biocide use at the station, abrasion and pressure changes during station passage, and the temperature of the water. Survival of organisms entrained at

Brayton Point Station was assessed during 1997 (May-August) and 1998 (March-July) using state-of-the-art sampling equipment (induced flow larval table). Over the 1997 and 1998 study periods, a total of 29,830 fish representing 26 taxa and 17 families were identified. High rates of survival were observed for a number of species held 96 hours after passage through the Station's cooling water system. For example, approximately 30% of post-yolk sac winter flounder that passed through the Station's cooling water system were alive four days after passage. In fact, a number of late-season sample dates showed better than 80% survival of postyolk sac winter flounder. Many species exhibited even better survival, including: Atlantic cod (50%), Atlantic silverside (50%), northern pipefish (36-79%), sculpins (43%), and Unidentified (52%). Alternately, some species exhibited low rates of survival after passage through the Station. This group includes some of the less hardy species, such as American sand lance (0.4%), Atlantic herring (0.0%), bay anchovy (0.0%), and clupeid (0.0%).

In addition, EPRI (2000) reviewed 36 discrete entrainment survival studies from 21 power stations. It documented high rates of survival (>50%) for some species (e.g. striped bass and white perch) and lower rates (~25%) for other more fragile species (e.g. herring and anchovies). Macroinvertabrates were found to have high survival rates (70-90%).

As the foregoing makes clear, an accurate assessment of entrainment losses must be based on entrainment mortality and not the total number entrained. To not consider entrainment survival in the calculation of entrainment losses would grossly overestimate the Station's impacts on the ecosystem.

B. Erroneous Analytical Methods

1. EPA used data not representative of current I&E at Brayton Point Station

In its case study, EPA used I&E data collected prior to 1985 to calculate current losses attributable to the Station. This approach overestimates I&E losses for many species because abundance of most demersal fishes has decreased significantly since 1984. Furthermore, in most cases the data to perform a correct analysis exists. Entrainment data for winter flounder collected between 1993 and the present is available to estimate current entrainment losses and impingement data is available for all species from 1972 to the present.

As justification for refusing to base its analysis on current I&E impacts, EPA offers two explanations: 1) it assumes that the station should be responsible for possible future losses, and 2) it assumes that populations will recover to past levels in the future. <FN 35> These statements are without basis and are contradicted by statements in EPA's proposed rule. For example, on page 17143 of the preamble of the proposed rule EPA states "Owners and operators may use existing data for the Study as long as it adequately reflects current conditions at the facility and in the waterbody from which the facility withdraws cooling water." Because fish abundance has declined since 1985 -- for many reasons that are unrelated to Station operations -- the numbers EPA used are not representative of current levels of impacts. EPA's failure to adjust the numbers to reflect the general decline in fish abundance in the area creates an upward bias on EPA's measurement of I&E. Incredibly, on p. F3-1 of the case study EPA claims that these inflated numbers may underestimate the true levels because the fishery was already in decline by 1984. This represents a blatant attempt to mislead the reader as to the impacts under consideration. There is simply no basis under 316(b) for considering any impacts other than those that would be caused by a facility under present environmental and ecological conditions.

2. EPA incorrectly used the average weight in its production foregone model

In applying the Production Foregone Model, EPA made two critical errors in their application of the production foregone model. <FN 36> EPA apparently used average weights at the midpoints of successive life stages to compute growth rate, and EPA used the midpoint weight to compute initial biomass. Both of these errors tend to inflate the estimates of production foregone. Ricker (1975) shows the correct form of the production foregone equation. In addition to ignoring Ricker, EPA also ignored the scientific literature and used overestimated average weights at the midpoints of life stages for nearly all early life stages (eggs and larvae) of entrained organisms. As compared to values reported in the scientific literature and computed from organism volumes and densities, weights of many early life stages used in EPA's production foregone model are in some cases 30, 95, and even 40,000 times higher than is biologically reasonable. This has, in turn, led to highly inflated estimates of lost production. EPA needs to re-evaluate its production foregone estimates with biologically realistic measures of life stage weights.

The magnitude of errors in EPA's implementation of the production foregone model become quite apparent when they are compared to those calculated correctly -- i.e., using the initial and final weights of a life stage to compute growth rate, using initial weight to computer initial biomass, and using biologically reasonable early life stage weights. This analysis demonstrates that EPA overstated the total production foregone losses for fourteen of the sixteen fish species analyzed, often by tens to hundreds times higher than the correct values. EPA must re-calculate its production foregone estimates.

3. EPA uses invalid economic methods to estimate the value of losses due to I&E

EPA's errors in estimating the production foregone from I&E at Brayton Point Station are compounded by numerous errors developing an estimate of the economic value of the losses. <FN 37> The appropriate methods for estimating losses to fishery resources are well understood. These begin by translating raw estimates of losses into losses of species and life stages that are actually valued by society. <FN 38> Once I&E losses have been converted to losses of species having societal value, appropriate methods are chosen to assign an economic value to those losses. This value is typically understood to have two components: use value, which captures the value society places on fish caught for commercial or recreational purposes, and non-use value, which captures other values people may actually place on the existence of a fishery resource, apart from any intent to catch or otherwise directly use the fish.

Use value for commercial fishing is analyzed in terms of the values the market assigns to the fish, while use value for recreational fishing can be determined using one or more methods that seek to derive an implicit value from the behavior of recreational fishermen. By contrast, nonuse values generally are derived by the use of (contingent valuation and other related) survey methods, which seek to elicit what people would be willing to pay for knowledge of the existence of the eggs, larvae and fish, apart from their use.

Although EPA's benefits analysis mentions the foregoing concepts, it fails to apply them or misapplies them in a manner that results in gross overestimation of the value of Brayton Point Station's losses and thus of the benefits that would result from I&E controls on the Station. First, as discussed above, EPA's economic analysis is premised on a biological analysis that is emphatically not accurate and which in fact dramatically overestimates actual current losses of socially valuable species due to I&E. EPA then compounds those errors by employing invalid economic methods, or misapplying valid methods, as discussed below. <FN 39>

a. Use values for commercially caught fish include unjustified estimates of economic surplus

For fish that are commercially fished, valuation begins with the value the market assigns -- that is, the dockside price. EPA begins by deriving this value, but then attempts to convert the dockside market value of reduced commercial landings into estimates of lost economic surplus. This is, in theory, defensible; however it is, as EPA notes (on page A9-5 of the Case Study Analysis), "an extremely complex process..." -- one which, in this case, EPA does not bother to perform. Instead, EPA employs a flawed substitute approach based on a set of rules-of-thumb that have no justification in economic theory. The results overstate the economic losses to the commercial fishery.

EPA first estimates that the producer surplus (benefits to fishermen) fall in the range of 40-70% of dockside revenues. This estimate is far too high. EPA completely ignores the most relevant study (Norton et al., 1983), which found producer surplus in Atlantic Coast fisheries to be closer to 15% of dockside revenues. Furthermore, given that commercial fisheries are known to pay between 40-60% of their revenues to labor alone, EPA's figures make no sense.

Having derived this inflated value, EPA then purports to estimate additional impacts up the market chain (i.e. to processors, consumers, etc.); however the numbers EPA employs are entirely arbitrary. Using unsupported rules of thumb, EPA simply multiplies the price-based valuations by a minimum of 1.8 and a maximum of 3.2 to establish its estimated range of social benefits. In addition to using invalid methods, EPA fails to explain what basis it has for concluding that there will be any significant effects up the market chain. Given the miniscule size of the reductions in available fish expected to result from Brayton Point Station's I&E (particularly relative to the size of the relevant markets), there is no reason to anticipate induced price changes, and hence there is no reason to expect additional impacts up the market chain.

If EPA were unwilling to expend the time and resources to calculate economic surplus correctly, a more sensible approach would have been simply to take 15% of the incremental revenues as the initial level of benefits. Because these will be dissipated by new entry, however, the long run profit changes will be nil. Thus, the 15% should be decreased to zero over a period of years. In keeping with the spirit of EPA's approach, this reasonable estimate could represent lower bound. For an upper bound, one could simply use the new dockside revenues themselves. This would have provided a realistic upper bound -- indeed a highly conservative upper bound -- on the economic surplus lost from I&E. The approach EPA employed is arbitrary and clearly overstates the lost value by a very significant margin.

b. EPA's use values for recreational fishing rest on questionable benefits transfer methods

For purposes of valuing impacts on recreational fishing in the Brayton Point Case Study, EPA relies upon the benefits transfer approach. A benefits transfer uses the results of previous studies of recreational benefits conducted for other fisheries in other locations as a proxy for value at the site under consideration. Although the use of benefits transfer can be justified, it is critically important to use scientifically sound studies involving circumstances closely similar to those of the case in question. EPA's approach does not do this.

Of the four studies referenced by EPA in the Brayton Point Station case study only one --Hicks et al. (1999) -- is an appropriate choice for a benefits transfer approach for Mount Hope Bay. The Hicks study is particularly relevant here for a number of reasons. First, it is recent. In addition, it provides estimates of the value of a marginal increase in catch for relevant species groups and was derived using data for the affected geographic area. <FN 40>

However, while EPA acknowledges Hicks, EPA arbitrarily decides to treat the Hicks values as simply a "lower bound," Case Study, p. F4-4, and then uses three other studies, having dubious relevance -- but producing significantly higher values -- to establish the upper bound. None of these three studies cover the correct geographic range and each of them is problematic as a source for estimating values for Mount Hope Bay. <FN 41> EPA provides no explanation for its decision to include these values, which were up to six times the Hicks et al. values, when it had, in Hicks, an appropriate, methodologically sound source of values for the relevant area. <FN 42>

c. Forage fish values are exaggerated through the use of an invalid replacement cost method

As was noted at the beginning of this section, forage fish appropriately enter into the valuation process at the biological stage: losses in forage fish are converted to equivalent losses of adult species that people actually use and values. Hence the correct way to value impacts on forage species is to include these species in a properly specified stock-recruitment model of the fisheries in question.

Unfortunately, EPA relies -- in part -- on estimates of the replacement costs of forage fish, based on the cost of obtaining the fish from a hatchery, as an estimate of their value. The use of replacement costs as a measure of value has no economic justification -- like the HRC method, discussed in Part III.B.5. above, and Part IV.B.3.c., below, it is a measure of cost and cannot serve as a proxy for the value people actually accord the fish in nature. The value obtained from this method is also virtually certain to represent a dramatic overstatement of the actual value of the forage fish. These values must be excluded in calculating the benefits of I&E reductions at Brayton Point Station.

d. Nonuse values are estimated using an unjustified 50% rule of thumb

The Brayton Point case study also includes an estimate of non-use value. Here again, EPA did not attempt to conduct an appropriate, site-specific estimation of non-use value. Instead, it simply adopted a rule-of-thumb according to which non-use values are assumed to be equal to 50 percent of recreational use values.

Use of this rule of thumb, which is based on research by Fisher and Raucher (1984), cannot be defended. To begin with, the notion that there should be any consistent relationship between use and non-use values is fundamentally flawed. In theory, the ratio between use and non-use values can be any number from zero to infinity, depending on the unique attributes of the environmental good in question. Furthermore, this type of benefits transfer approach is wholly inappropriate where, as here, the study relied upon involved circumstances having no relevance to the specific application.

Although application of this rule of thumb adds comparatively little to EPA's benefits estimate it lacks any reasoned basis. There is certainly no justification whatsoever for EPA's claim that its 50% rule-of-thumb provides "conservative" estimates (67 FR 17,193). These estimates should be disregarded.

EPA takes note of another alternative (Case Study Analysis, page A9-1l) for estimating non-use values in the absence of original empirical research, and correctly rejects that approach in its 316(b) analysis. This is an additional benefit transfer approach, in which willingness-to-pay estimates for non-use value per household are employed, drawing upon the problematic 50% rule of thumb described above, but applying it on a per-person or per-household basis. Although such an approach was used some two decades ago by an environmental advocacy organization when examining a resource for which it was reasonable to believe there was significant non-use value, <FN 43> there is simply no basis in economic theory or accepted practice for this method.

As EPA itself recognizes, two critical problems with this approach are: (1) identifying the appropriate willingness-to-pay measure per household for non-use value for the specific fishery and/or other ecological impacts of concern; and (2) identifying the appropriate number of households to which the benefit-transfer number should be applied. EPA takes note of these issues, and consequently does not employ this approach. The first problem means that this approach is subject to the same problems as EPA's general use of its 50% rule of thumb, but has even greater liability because it has no basis whatsoever in economic literature. The 50% ratio was derived from aggregate use and non-use values, not from per capita or household-level measures. More important, the second issue means that any application of this approach will necessarily involve essentially arbitrary judgments which can thereby lead to results which are easily manipulated, highly biased, and hence fundamentally misleading. EPA is to be commended for having rejected this approach in its 316(b) analysis.

e. Using habitat replacement costs as a method for valuing the benefits of the rule is wholly invalid

Using the methods discussed in (a)-(e) above, EPA estimates that the annualized economic value of the losses due to I & E at the Brayton Point Station (and thus of the benefits that would result from eliminating I&E) range from $169,899 to $308,257 -- a range that, itself, likely overstates actual loss value by a factor of two. <FN 44> Apparently not satisfied with the above numbers, EPA then goes on to conduct a further estimate using the completely invalid Habitat Replacement Cost (HRC) method of analysis. Use of this method has been discussed, and, it is hoped, thoroughly discredited in Section III.B.5., above. In short, this claimed method of benefit estimation is without foundation and is completely misleading. As discussed below, it also imparts an extraordinary bias to EPA's final benefits estimate.

Table F5-39 (Case Study Analysis, page F5-35) sums up the total habitat replacement costs that would — according to EPA — be required to replace the species affected by entrainment and impingement due to cooling water withdrawals at the Brayton Point Station. The total is over $1 billion annually <FN 45>. Perhaps recognizing the absurdity of this result, EPA then eliminates (with no clear justification) the largest single component, artificial reef construction, leaving $28 million of costs annually -- a result that is nonetheless 200 times greater than that EPA obtained using more traditional (if improperly applied) methods.

EPA then merges the HRC analysis with the earlier results in Table F6-1. In this table, EPA takes the midpoint of the standard estimates of benefits from Chapter F4's benefits transfer analysis and labels these as the minima of ranges of impingement and entrainment benefits. Then it takes the annualized HRC estimates from Chapter F5, and labels these as the maxima of ranges of impingement and entrainment benefits. This makes no sense. The minima of the ranges of "benefits" are the mid-points of EPA's benefit estimates and the maxima of the ranges are EPA's cost estimates (for what is probably the most costly possible method of achieving the rule's objectives).

Significantly, the misleading results reported by EPA in Table F6-1 in the Case Study Analysis are carried over (apparently with adjustments for year 2001 dollars) into the Proposed Rule, Exhibit 19, on page 17199 of the Federal Register. There, EPA reports annual average baseline losses (for Brayton Point Station) due to impingement of $9,000 to $890,000, and $200,000 to $28.3 million due to entrainment. By contrast, the correct range -- employing the defensible aspects of EPA's first approach -- updated to year 2001 dollars, and approximated by rounding as in EPA's reported figures in the Federal Register would be $4,000 to $5,000 for impingement, and $105,000 to $131,000 for entrainment. <FN 46>

In sum, EPA's methods of valuation, premised on erroneous biology and compounded by repeated estimation errors -- capped by the inclusion of results from the indefensible, wholly invalid, and grossly exaggerated HRC method -- provide a fantastically biased and ultimately useless basis for evaluating the true benefits obtained by reducing I&E impacts at Brayton Point Station.

4. EPA's Method for Identifying Appropriate Mitigation Measures and Selecting/Pricing Habitat Restoration is Flawed

PG&E NEG supports EPA's proposal to allow affected facilities to select among appropriate mitigation measures to offset I&E losses. Such mitigation measures could include habitat restoration/enhancement projects, fish restocking projects, and the like. However, EPA's approach to identifying, costing out, and applying such mitigation techniques in the BPS case study at chapter F-5 is flawed in numerous critical respects. These errors result in the development of a set of proposed mitigation/enhancement measures that have no rational relationship to the many of the I&E impacts they are intended to offset and that, if implemented, would be unnecessarily and excessively costly. In addition, EPA's approach betrays a fundamental misconception of the value of the services mitigation measures provide. In order for EPA's use of mitigation measures in the proposed rule to be valid, EPA must address the errors discussed below. <FN 47>

a. EPA's method fails to identify appropriate habitat restoration/enhancement techniques

Before one can select a technique which will result in a net gain to the species of concern, one must first identify what ecological factors are limiting the population size and its production (i.e., the "limiting factors"). Impaired habitat may deprive some species of a critical source of food but may deprive other species of shelter for spawning or protection from predators. Until one identifies the relevant limiting factors, one cannot make an appropriate selection among restoration/enhancement projects. So, for example, as to winter flounder, EPA's choice of a mitigation project completely misses the mark. Failing to do the preliminary analysis, EPA simply asserts that restoration of tidal wetlands will help the winter flounder population in MHB to recover.

EPA is wrong. Tidal wetlands do not provide critical habitat for either winter flounder or window pane flounder. The fact that these species can be found in salt marshes does not mean they need access to salt marshes in order to thrive or survive. The flounder population has not dwindled due to a loss of tidal wetlands, but as a result of other stresses and direct causes of mortality, including over fishing and an increase of predators. Those stresses need to be reduced in order for there to be a net gain to the species. Under these circumstances, the better approach for offsetting I&E losses of flounder would be through a restocking program, not tidal wetlands restoration.

Alternatively, there may be ways to reduce loss of flounder to predation pressures by increasing the food supply for the flounder predators. Most marine animals are opportunistic feeders. Hence, increasing the productivity and availability of other fish similar in size to flounder could adequately replace that ecological service provided by the flounder.

EPA is similarly wrong in its approach to tautog. EPA once again fails to adequately analyze the problem and, as a result, identifies the wrong solution. Artificial reefs of the type established for lobster in Narragansett Bay, no matter the cost, are not useful for increasing the productivity of tautog. Only adult tautog would use this habitat, and their numbers are more likely limited by over-fishing, rather than habitat. Eggs, larvae, and juvenile tautog, which are limited by suitable habitat, prefer shallow vegetated areas such as areas of eelgrass and seaweed (SAV) that provide both a food supply and shelter from predators.

Thus, an appropriate restoration project would be to increase production of juveniles by increasing SAV habitat in shallow water. Water quality and conditions are likely more suitable for SAV in the Sakonnet River than in MHB proper.

b. EPA failed to consider the various ecological services provided by habitat restoration/enhancement projects in its case study of BPS

In the case study, EPA attempts to identify one habitat project that specifically enhances each species entrained or impinged by the station. This approach completely fails to account for the fact that each project can enhance ecological productivity in many ways. Each project has the potential to increase the food supply for a variety of organisms while also providing safe spawning areas and/or protection from predators for many other organisms. By providing multiple benefits, each project can serve a number of ecological functions. In this way, even if a particular project does not increase the productivity of one target species, it may nonetheless serve as an adequately compensatory project for offsetting the I&E losses of that species by providing the EQUIVALENT ecological services provided by that species.

For example, age-one equivalent flounder, which serve primarily as prey for other species, and secondarily as recruits to the fishery, may not be directly aided by the creation of SAV. Yet, that SAV produces other species that serve as prey for the fish predators, as well as additional food for flounders and the food web generally. Small fish production in such a habitat should be considered suitable for offsetting the I&E losses of age-one equivalents that would otherwise be taken by predators by virtue of providing the equivalent services. Only the fraction of the age-one equivalents that would otherwise be recruited to the spawning stock and make a difference to the next generation of the species would need to be replaced one-for-one. Moreover, this would only be warranted if the population is limited by the size of the spawning stock.

In short, the purpose of habitat restoration/enhancement is to provide a net improvement in fish production and not to offset each individual one-for-one with the same species affected by I&E. EPA has failed to consider provision of ecologically equivalent services to those provided by the I&E losses.

c. EPA has failed to calculate properly the net production gained by habitat restoration/enhancement techniques. EPA improperly used species abundance as a proxy for production

In the proposed regulation at page Al 1-6 of Chapter A, EPA admits that estimating the production to be gained by a mitigation project is the appropriate method for determining the necessary size/scale of the project (which in turn determines the cost of the project). But instead of conducting those estimates, it chooses an inappropriate and inaccurate proxy, using abundance estimates corrected to age-one individuals instead of production data. To do this, EPA assumed a production-to-biomass ratio of 1:1 (biomass being the standing abundance of a species at any given time). This requires EPA to make the erroneous assumption that the abundance observed at the moment in time when a sample is collected actually represents all of the individuals that will be produced that year for the age sampled. The assumption is wrong because the abundance or production of individuals at a given moment in time does not accurately reflect their abundance over time during the year.

Short-lived species reproduce multiple times in a year or at varying times during the year. This would include stickleback and other forage fish. Likewise, the abundance of species with protracted spawning seasons is not accurately represented by its abundance at a given moment in time. Furthermore, many species use different types of habitat as they grow during their first year of life. Again, an abundance sample in a single habitat at one moment of time will not accurately reflect the annual production of age-one equivalents of such species.

Young winter flounder do not preferentially use salt marshes as nursery grounds. <FN 48> Thus, EPA’s reliance in the case study on the abundance observed in salt marshes is not indicative of their production. In fact, EPA has erroneously included abundance measurements made in open water areas in its estimation of production in tidal wetlands. Hence, EPA’s conclusions about the amount of tidal wetland restoration it believes is necessary to offset BPS / I&E losses is not at all reliable.

The proper method is to compare the production foregone attributable to I&E with the production to be gained by all of a given species’ age groups as a result of the mitigation project under consideration. Even if data are lacking in the form of production rate per unit area, estimates of production can still be made using population modeling similar to the production foregone model advocated by EPA in Chapter A-5.

Footnotes

26 In fact, the additional entrainment impacts resulting from Unit 4’s operation would not have shown up until two years later still. EPA’s analysis relies on an adult trawl index which measures 2 year olds and above, yet entrainment affects eggs and larvae. As a result, additional losses of this life stage, even if they began in 1987,would not have been observable in the adult trawl index until 1989.

Rhode Island Division of Fish and Wildlife. June 1995. A copy of this article is provided in Appendix V to these comments.

29 Part of the PG&E NEG's comments is based on DeAlteris, J., Trends in Abundance of Five Fish Species in Mount Hope Bay: A Response to M. Gibson's Assessment of the Effect of Brayton Point Station on Fish Stocks in Mount Hope Bay (July 1, 2001). Professor DeAlteris' report has been separately submitted to the docket. However, a copy is provided in Appendix VI to these comments.

30 Gibson, M.R. 2002. Winter flounder abundance near Brayton Point Station, Mt. Hope Bay revisited: separating local from regional impacts using long term abundance data. Rhode Island Division of Fish and Wildlife. March 2002. A copy of this article is provided in Appendix VII to these comments

31 One of the key problems in determining whether the decline in winter flounder abundance in UMHB is different from the decline in Narragansett Bay is that no single sampling program samples all of Narragansett Bay's waters (which includes Mount Hope Bay) simultaneously. However, the program covering the largest geographic area with a single sampling gear, which includes Narragansett Bay and LMHB, shows no difference in the rate of decline of winter flounder over any time period examined in the two areas.

32 Trends in fish abundance in the coastal areas of Rhode Island Sound and Block Island Sound cannot be used as a baseline for comparison with MHB because these areas contain different habitat types and include fish spawned in other areas of New England and elsewhere along the Atlantic coast.

33 Gibson, M.R. 2002. Ex-Vessel Fishery Production Foregoing in Mt. Hope Bay as a Result of Operations at USGEN of New England's Brayton Point Station, Rhode Island Division of Fish and Wildlife. March 2002 A copy of this article is contained in Appendix VIII to these comments.

34 Letter, with report attached, from Robert E. Dehart, Jr. to Angelo S. Liberti (RIDEM) dated August 26, 1997, re: The Narragansett Electric Company, Manchester Street Station, RIPDES Permit No. RI0000434 — Post-Impingement Survival Study Report. A copy of these documents are provided in Appendix X to these comments.

35 EPA states in the Brayton Point Case Study (Page F 1-2) that in order to "evaluate the potential benefits of the proposed rule, EPA estimated expected I&E at Brayton Point under current (emphasis added) operations based on an analysis of I&E rates before the accelerated fish population declines that followed the 1984 conversion of Unit 4, as discussed in Chapter F3." Specifically, EPA combined current operations with a time series of I&E data for Brayton Point Station collected between 1974 and 1983. EPA points to their conclusions (page F3-1 of the case study) that fish populations in Mount Hope Bay are currently depressed well below historical levels as justification for the comparison (i.e. current operations to fish populations from several decades ago).

36 This Part of the comments is based on Englert, T., Comments on the 316(b) Rule (critique of EPA Production Foregone Model), August 5, 2002. Englert's comments have been separately submitted to EPA's docket. However, a copy is provided in Appendix XII of these comments.

37 This Part of the comments is based on Stavins, R., Comments on the 316(b) Rule (critique of EPA's economic analysis), July 19, 2002. Professor Stavins' comments have been separately submitted to the docket. A copy is provided in Appendix XIII to these comments.

38 For example, because fish eggs and fish larvae are not actually used, the loss of eggs and larvae must be converted into equivalent lost adults of an age that may be caught by commercial or recreational fishermen. Similarly, losses of forage species are significant only to the extent that their loss causes reductions in species that are fished.

39 One further cause for concern with EPA's economic analysis is that it is not clear that EPA appropriately took account of the role of time. Before a technological improvement to an intake can begin to have beneficial effects, it must be constructed and go on-line. Furthermore, it may take time for the effects of I&E reductions to be felt in the population. From our review of the case study, it is not clear that EPA recognized the existence of such delays, and discounted the benefit stream appropriately.

40 Hicks et. al. considered data for Atlantic states from Virginia to Maine.

41 The other studies used are: Agnello (1989), McConnell and Strand (1994) and Tudor (2002). The Agnello study, using the travel cost approach, relies on an early (about 1981) and inaccurate database and uses combined data for all states from Florida to New York. Although EPA apparently believes that the McConnell and Strand values were based on a RUM

model, they were in fact derived from a contingent valuation experiment. McConnell and Strand calculated marginal values for groups of species for each state between from Florida to New York. Significantly, these benefits are based on the square root of an "expected" catch, an approach that does not correspond directly to the historic catch rate, making them suspect for EPA's intended purpose. The Tudor study reports per-trip values for Delaware Bay sites. It is unlikely that the Tudor study would be useful to EPA because the results suggest a negative value for improvements in bottomfish (Section 316(b) Case Studies, Table B5-5).

42 if EPA used the appropriate values per fish, it will still have to correct errors in their computations. For example, EPA mistakenly values changes in recreational catch of tautog using the small game values and of weakfish using the bottom fish values. Hicks et al. properly group tautog with bottom fish and weakfish with small game. EPA also alludes to using the Tudor et al. study in subsequent analysis. If they use the existing model (Section 316(b) Case Studies, table B5-5), then the improvements in bottom fish recreational catch will have a negative value.

43 The resource in question was California's Tuolumne River, the major body of water flowing through Yosemite National Park. See: Stavins, Robert N. The Tuolumne River: Preservation or Development? Berkeley, California: Environmental Defense Fund, October 1983. A copy of this article is provided at Appendix XVI to these comments.

44 If the most questionable elements are removed from EPA's calculations, the range becomes $95,731 to $112,565, for a midpoint value that is less than half of the EPA midpoint. These numbers reflect elimination of the following questionable elements from EPA's calculations: EPA's 50%-rule-of-thumb non-use value estimates; the multiplier for extrapolating economic surplus from dockside revenues; and EPA's use of hatchery costs and foregone production ratios for estimates of forage species value in lieu of direct estimates of these values as part of an overall stock-recruitment model (which would feed directly into commercial and recreational valuations). If EPA's production foregone estimates of forage fish values are included, then the range would be $99,204 to $117,469. If EPA's 50% rule-of-thumb for non-use value are included, then the range becomes $107,579 to $133,371.

45 The average value of a tautog based on artificial reef costs is approximately $32,000 per age 1 equivalent.

46 In Table F6-4, EPA provides what it characterizes as a summary of omissions, biases, and uncertainties. Incredibly, EPA concludes that every simplifying assumption and omission has led to understatement of benefits (or to irresolvable uncertainty). This is not at all accurate. To the contrary, the upward biases involved in EPA's reported estimates of the annual economic values of losses caused by impingement and entrainment at Brayton Point Station (and thus the benefits of reducing those losses) are massive.

47 Part of the comments relies on French McKay, D., Comments on the Section 316(b) Rule (critique of EPA's Habitat Replacement Cost method), August 5, 2002. Professor French McKay's comments have been separately submitted to the EPA rulemaking docket. A copy is provided in Appendix XVII to these comments.

48 Meng, L. and J.C. Powell, 1999. Linking juvenile fish and their habitats: an example from Narragansett Bay, Rhode Island, Estuaries 22(4): 905-916.

EPA Response

EPA disputes the commenter's assertion that its analysis of average annual I&E at the Brayton Point Station (BPS) contains "numerous faulty assumptions, erroneous analytical methods, and flawed calculations."

First, regarding the decline of winter flounder and other finfishes in Mt. Hope Bay, the Agency notes that an evaluation of population trends was not a part of its benefits analysis for the 316b Phase 2 rule. However, EPA has reviewed materials prepared by EPA Region 1 on this issue. The Agency concurs with Region 1's conclusion that Mark Gibson's analyses demonstrate that the decline of winter flounder in Mt. Hope Bay is statistically greater than the decline in Narragansett Bay. Additional discussion of this issue is provided in EPA Region 1's 2002 NPDES permit determinations for BPS and the related Responses to Comments document (available at http://www.epa.gov/region1/braytonpoint/index.html)

Regarding entrainment survival, please see EPA's response to Comment 316bEFR.306.506 and Chapter A7 of Part A of the Regional Analysis Document (DCN #6-0003).

Regarding impingement, please see response to comment 316bEFR.029.105.

Regarding the years of data used by EPA to estimate average annual I&E at BPS, please see response to Comment 316bEFR.005.037.

Regarding EPA's production foregone calculations, please see response to Comment 316bEFR.305.003.

Regarding EPA's benefits analysis, please see response to Comment 316bEFR.005.029 on commercial fishing benefits, response to Comment 316bEFR.075.504 on recreational fishing benefits transfer, response to Comments 316bEFR.005.035 and Comment 316bEFR.029.113 on replacement costs and the HRC method, and response to Comment 316bEFR.005.034 on the 50% rule of thumb, response. For discussion of ecosystem services and the HRC method, please see the document entitled "Habitat-based Replacement Cost Method" (Docket #6-1003).

Permit applications/implementation schedule

Application Requirements for Facilities Near Renewal

EPA's proposed rule would create extensive new application requirements for Section 316(b). Meeting these requirements could prove onerous for facilities that are close to their permit renewal date. This is especially important given the amount of time that will be required to produce the studies minimally necessary to demonstrate BTA under the new rule. Even where a facility already has performed a § 316(b) demonstration, where the data are still representative of current conditions in the waterbody, and where no additional construction or modification of the intake structure or installation of screens will be required, a permittee still might require six months to analyze existing data to demonstrate compliance with the performance standards.

UWAG has already commented at length on this question and PG&E NEG does not believe the issue merits extended discussion here. However, PG&E NEG does concur with UWAG that, to the extent that EPA's final rule includes some or all of these new application requirements, EPA must be flexible in making sure that facilities close to their renewal date are not faced with an impossible burden in trying to meet the new procedural requirements.

EPA Response

EPA has added many efficiencies to today's final rule since the proposal and NODA to provide options for streamlining application requirements and speeding permitting. See response to comment 316bEFR.034.005 for a discussion.

Permit applications/implementation schedule

Effective Date of Regulation's Substantive Provisions

In the proposed rule, EPA specifically states that the proposed rule "is not intended as guidance for determining the best technology available" at existing sources currently undergoing renewal of their permits. 67 FR at 17,124 col. 3. To the contrary, EPA directs permitting authorities to continue make BTA determinations on a "best professional judgment" ("BPJ") basis until the rule is final and acknowledges that those determinations "may be more or less stringent than today's proposal." Id. Given the significant changes that EPA is proposing to make in its implementation of Section 316(b), PG&E NEG questions does not believe this blanket approach is appropriate or permissible.

As courts have realized, unfairness can result when an agency, aware of imminent changes to its implementation of a statute that may be beneficial to the regulated industry, nonetheless continues to issue permits based solely on the older, more stringent standard. In Natural Resources Defense Counsel v. EPA, 863 F.2d 1420 9th Cir. 1988), for example, the court concluded that EPA correctly declined to make a "best professional judgment" determination of the best available technology for produced when it knew that a national standard would soon be issued that would likely be less stringent. Id. at 1427. Had EPA not done so, the court found, it would have created a disparity between the present applicants and those in the future that "would lack any apparent scientific or equitable basis." Id. The court found the case for delay to be particularly strong "[g]iven the large commitment of resources that would be necessary" to comply with the BPJ standard and the fact that the CWA's anti-backsliding provisions would likely preclude the facilities in question from seeking relief once the national rule became final. Id See also Puerto Rico Sun Oil Co. v. USEPA, 8 F.3d 73, 78 (1st Cir. 1993) (EPA could not rationally apply Puerto Rico's existing mixing zone standard in the face of clear evidence that Puerto Rico was in the process of repudiating the standard and adopting a different one).

A similar situation could occur here. Although the proposed performance standards may in some cases suggest a higher level of I&E reductions than have been required in BPJ permits under Section 316(b), they also suggest a greater flexibility in meeting those standards, including the opportunity to propose voluntary mitigation measures. If a facility currently in renewal were denied the benefits of these flexibility provisions, it could conceivably be forced to embark on costly technology-based measures, despite the fact that EPA has already taken the position that those measures are only one option for complying with Section 316(b).

For this reason, PG&E NEG believes that, in order to present this type of unfairness, each facility should have the option of complying with either the existing site-specific process or the new rule.

Monitoring requirements

Compliance Monitoring

If EPA retains its numeric performance standard option, there will need to be a period of time for monitoring whether the existing configuration or the new technology is meeting the 80-95% and 60-90% reduction criteria. EPA proposes at least a two-year period of verification monitoring. PG&E NEG believes a period of two years as a minimum is needlessly inflexible. At some facilities, less than two years of monitoring will be required. This would be the case, for example, if a plant had collected copious data already and if no change to the plant was required by the new rule. On the other hand, two to five years of monitoring might be required at some estuarine sites where fish populations vary widely from year to year.

As recommended by UWAG, after a verification monitoring period (up to two years for most plants, and possibly more for plants with highly variable aquatic communities), the data should be analyzed to determine whether the newly installed technology is indeed achieving 80-95% reduction in impingement mortality and 60-90% reduction in entrainment. As long as the data showed performance within these ranges, the technology should be deemed to comply with the rule. For example, if the entrainment reduction technology was predicted to reduce entrainment by 85% but in fact achieved only 80%, that should be sufficient.

Assuming the data showed performance within the ranges, then no further biological monitoring should be required. Instead, the permittee should be required thereafter simply to monitor and document that it continued to operate and maintain the technology. If, on the other hand, the initial monitoring showed that the technology was not achieving reductions with the performance standards, on the other hand, then there seems to be no fair alternative but to provide for a period of additional study to determine what went wrong and what should be done to fix it, including the replacement of the technology with something different if necessary (and if the cost is not “significantly greater” than the benefit).

Most importantly, EPA should clarify that, if the agreed-upon technology is implemented and properly operated, failure to meet the performance standards by itself would not make the facility potentially liable to non-compliance fines. Given the difficulty of predicting precisely how a technology will perform, any other result would be patently unfair.

EPA methods: age 1 equiv, yield, prod foregone

Production foregone or biomass lost due to impingement and entrainment (I&E) is a critical component of USEPA's analysis and plays an important role in USEPA's justification of the proposed 316(b) rule for existing facilities. One of the case studies used by USEPA is the Brayton Point Station. PG&E NEG and its consultants recently completed their own detailed analysis of production lost due to I&E at the Brayton Point Station in support of a permit application. USEPA states they got much of the biological information they used to compute production lost from the documents prepared and submitted by PG&E NEG.

PG&E NEG and its consultants who prepared the documents relied on by USEPA carefiully reviewed the production lost calculations performed by USEPA for the Brayton Point Station Case Study. Based on correspondence with USEPA and attempts to reconstruct USEPA's results, PG&E NEG concludes that USEPA made two major errors in their calculations of production lost. The errors by USEPA resulted in production lost estimates being overestimated for 14 of the sixteen fish species analyzed. For several species, USEPA's estimates of production lost were hundreds of time higher than the correct values.

Production lost is commonly used to quantify the losses due to I&E. Production is addition of biomass to the population. Biomass at any given time is the sum of the weights of all individuals alive at that time. Because the weights of all individuals at a given time are often not known, biomass is often computed as the number alive times the mean weight of an individual. Production is the rate at which biomass is added to a population, and is the net result of individuals dieing over time while surviving individuals increase their body weight. Production forgone or lost is the amount of biomass that would have been added to the population if the individuals had not been entrained or impinged. These individuals would have grown in body weight, while eventually dieing from other causes. There is a well-known formula for taking the numbers of individuals entrained or impinged of a given age class or life stage, and computing the future production of these individuals over their life time. Unfortunately, USEPA incorrectly implemented this formula.

The production lost formula uses information on the initial biomass of individuals and on growth and mortality rates. USEPA made two mistakes in their implementation of the production lost formula. The first mistake arose because USEPA used mean weights of individuals at the midpoint of life stages to compute the growth rate used in the formula, and used midpoint weights to compute initial biomass. The correct use of the formulas compute growth rate from the initial and final weights of the life stage, and use initial weight of the life stage to compute initial biomass. USEPA's implementation of the production lost formula is biologically wrong and mathematically incorrect. The second mistake made by USEPA was their estimates of mean weight at the midpoint of early life stages were too heavy, sometimes thousands of times too heavy, for many species.

The combined effect of these two errors by USEPA is frequent overestimation, sometimes by hundreds of times, of the production lost due to I&E for the Brayton Point Case Study. USEPA must reevaluate its production lost calculations and mean weights, replace their existing estimates of production lost with correct values, and determine how the revised estimates affect the 316(b) rule.

EPA methods: age 1 equiv, yield, prod foregone

Attachment 1: (Review of EPA's Application of Production Foregone Model) <FN1>

Introduction

In support of its new Section 316(b) regulations, USEPA developed a series of case studies. As an example of a power plant located on an estuarine system, Part F of the 'Case Study Analysis for the Proposed Section 316(b) Phase II Existing Facilities Rule" locument addresses the Brayton Point Station (BPS), located on Mount Hope Bay, Massachusetts. The owner of BPS, PG&E NEG, and its consultants have recently completed their own Section 316(b) assessment of this facility and are thoroughly familiar with the methods and data used by USEPA. Based on this familiarity, we note ;everal problems with the USEPA assessment, in particular with the findings of the production Foregone Model application (J)ages A5-6 through A5-7 and F4-8).

The Production Foregone Model (PFM) is a procedure for quantifying the amount of)roduction that would have resulted had individuals not been lost through entrainment md impingement. Production is defined as the total addition of biomass that would occur luring a specified period of time, and is based on individuals increasing their body weight via growth rate and dieing through time. Mathematically, production (P) is calculated as:

[see hard copy for equation]

The instantaneous growth rate (G) is defined as,

[see hard copy for equations]

An estimate of the mean biomass, B, may be obtained in several different ways; in principle it is the total weight of the population divided by the number of individuals alive at the time. As both weight and number of individuals change over time, both functions need to be integrated with respect to time. Ricker (1973), among other authors, gives the following:

[see hard copy for equation]

The instantaneous mortality rate (Z) is defined as,

[see hard copy for equations]

Because G and Z change over the life of a fish, accurate estimation of P requires that the calculations be carried out separately for a particular age class or size class. This can be noted by adding a subscript to Equation 1 to denote a specific age or size class,

[see hard copy for equation]

Further, as Rago (1984) notes, we are interested in the production foregone by the entrainment and impingement of fish. In other words, given that an entrained or impinged fish is of agej (or life stagej), what would that fish have produced over its remaining life span? To address this, Equation 7 may be recast as the sum of production from the current age or life stage to the final age or life stage,

[see hard copy for equation]

Our examination of the USEPA analysis suggests two serious flaws in their approach to estimating production foregone. First, we believe that USEPA incorrectly computed the instantaneous growth rate (G) and mean biomass (B) used in Equation 1. Second, USEPA used biologically unrealistic values for early life stage weights. Each of these points is addressed in detail below.

Incorrect Application of Average Weight

USEPA, after Rago (1984), used the following formula for computing production losses:

[see hard copy for equation]

Note that NiWi (the average biomass) is substituted for B0 (the initial biomass) of Equation 4. For entrainment and impingement calculations, Wi and Ni are computed recursively,

[see hard copy for equations]

Our attempts to reconstruct USEPA's production foregone estimates using Equation 9 were unsuccessful. In response to our written comments, we were provided with communications (ca. 6/17/02) which indicated that USEPA had used the average weight between successive life stages to obtain the instantaneous growth rate, i.e.,

[see hard copy for equation]

and where Wi = (wi + wi+1)/2 and Wi+1 = (wi+1 + wi+2)/2. The average weights wi, wi+1, and wi+2 are the start weights of life stages i, i+1, and i+2. Inspections of their results also suggest that Wi was also used to compute initial biomass. Thus, USEPA used Wi in two places in Equation 9: to compute G and in NiWi to estimate B. For example, if a larva was entrained, USEPA computed the average weight of the larva (Wi) as the average of the predicted mean weight at the beginning of the larval stage and the predicted mean weight at the end of the larval life stage. To obtain the average weight for the subsequent life stage, i.e., Wi+1, the average of the predicted mean weight at the beginning of the juvenile stage (= weight at end of larval stage) and the predicted mean weight at the end of the juvenile life stage were averaged. The resulting value of Wi was inserted into Equation 9 and the values of Wi and Wi+1 were used to compute G via Equation 12. This is incorrect. The correct calculation would use the starting and ending weights of the larval stage to compute G, and the starting weight of the larval stage as Wi. USEPA's erroneous use of mean weights, in some cases, greatly inflated the resulting values of production lost. Average biomass based on the weight of an individual observed at the midpoint of a life stage will invariably be greater than the weight at the inception of the life stage, and instantaneous growth rate (G) based on the midpoint weights of a life stage and the next life stage is biologically incorrect.

If this is what was actually used, then there is potential for serious error in the production loss estimates. Depending on the relative magnitude of the instantaneous growth and mortality rates, both to each other and to the preceding life stage, the resulting estimates may be substantially over- or under-estimated. (It should be noted that, because we could not reproduce USEPA's results even after their explanation, we cannot say with any certainty how they actually did the calculations. We have requested further clarification, but to date have not received any response to our request.)

Biologically Unrealistic Weights

USEPA made a series of unrealistic assumptions for the weights of individuals in the early life stages that are then used in the Production Foregone Model and USEPA failed to make use of available scientific literature. For almost all early life stages, USEPA overestimated, sometimes grossly, the average weight of the individuals at the midpoint of life stages. This, in turn, led to highly inflated estimates of lost production.

Production estimates are highly sensitive to the average weight of an individual selected for each life stage. Yet, for eggs and early larval stages these values are not readily available in a form directly usable in the PFM. Scientific studies rarely report the average wet-weight of any egg or larvae. Such weights would be difficult to measure accurately due to the overwhelming contribution of moisture. Weights for these small organisms are generally reported as dry-weight, i.e., the organisms have been dried to remove all moisture. These weights are no longer comparable to the wet-weights reported for larger organisms. It is not entirely clear how USEPA overcame this lack of comparable wetweight data. Tables F1-1 through F1 -18 of the Case Study provides wet-weights and cites the PG&E NEG's Brayton Point Station 316(b) Demonstration as the source, yet PG&E NEG did not provide wet-weights in their Demonstration.

There are several methods, however, that can yield reasonable estimates of early life stage wet-weights, particularly for eggs. These include (1) volume of the organism coupled with the assumption that the biological material has nearly the same weight as water, (2) that dry-weight is a constant proportion of the wet-weight, or (3) compute the average wet-weight by dividing the ovary wet-weight by the total number of eggs present. Additional computational details for the three methods follow.

Method #1
For eggs, volume (V) may be calculated as V = pi di d2 d3 /6 where d1 = major axis, d2 = largest minor axis, and d3 = smallest minor axis. For spherical eggs this reduces to V = pid3/6 where d = diameter. The volume of small fish larvae may similarly be computed by multiplication of length x depth x width. The volume may be expressed as weight assuming that 1 cm3 = 1 gram.

Method #2
Wet weight can be calculated from dry weight based on the fact that dry weight is approximately 20% of the wet-weight (McGurk 1986). Our analysis (see below) is in close agreement with this figure, yielding 19.3%.

Method #3
By dividing the ovary wet weight by the total number of eggs, the average egg wet weight may be obtained. The information necessary for this method is often available from studies of fish fecundity.

Some allowance should be made for the weight of the ovary tissues other than eggs. In the following example, we have assumed 10% for this weight.

An example of all three of these methods is presented in Table 1.

Table 1: Winter Flounder Egg Weight
[see hard copy for table]

Using the average weight from all three methods, the expected weight of a single winter flounder egg is 0.000244 grams or 0.000000538 lbs. USEPA's reported value in Table F1-18 was 0.0022 ibs, or over 4,000 times heavier than the actual weight!

As newly hatched larvae do not feed exogenously, but rely on yolk reserves, it is expected that the initial yolk-sac larvae weight will be similar to that of the egg stage. As the yolk-sac is absorbed, larval weight may actually decrease somewhat. For winter flounder, data from Buckley (1982) illustrate this point (Table 2).

Table 2: Winter Flounder Yolk-Sac Larvae Weight
[see hare copy for table]

Buckley et al. (1991b) reported that the initial average weight of laboratory reared winter flounder yolk-sac larvae from upper Narragansett Bay was 29.7 microg, while those from lower Narragansett Bay averaged 25.6 microg. Assuming that dry weight is 20% of wet weight, corresponding wet weights would be 0.000160 g and 0.000128 g, (or 3.53x10^-7 and 2.82x10^-7 lbs) respectively. USEPA assumed an average weight of 0.00441 lbs for Stage 1 (= yolk-sac larvae). This is approximately 12,500 to 15,600 times heavier than the actual weight.

Weight at length relationships for post yolk-sac winter flounder larvae are available from several sources, including Laurence (1979), Beyer and Laurence (1980), and Rose et al. (1996). Using the relationship,

[see hard copy for equation]

from Lawrence (1979), the expected weights for post yolk-sac larvae (ca. 3.1 to 8.2 mm) may be calculated and compared to the values assumed by USEPA (Table 3).

Table 3: Winter Flounder Post Yolk-Sac Larvae Weight
[see hard copy for table]

The comparison in Table 3 demonstrates that USEPA grossly overestimated the weights for all post yolk-sac larvae stages of winter flounder. The largest discrepancy is for the Stage 2 larvae, surpassing the discrepancy for the yolk-sac larvae (Stage 1).

By re-arrangement of Rose et al.'s Equation 9, the expected weight for juvenile winter flounder (ca. 9 to 137 mm) may be obtained:

[see hard copy for equation]

This equation yields an expected weight for an averaged size juvenile (ca. 73 mm) of 0.942 g or 0.00208 lbs. The USEPA value of 0.033 lbs is 15.8 times greater than the actual value.

Discrepancies in early life stage weights are not restricted to winter flounder, but appear in nearly all species. Below (Table 4) are several examples of this problem in other pecies (winter flounder is sometimes included for comparisons).

Table 4: Comparison of Expected Egg Weight with Values Assumed By USEPA
[see hard copy for table]

Of the eighteen species modeled by USEPA, egg weights for fifteen (83%) were overestimated. In some cases, such as the previously examined winter flounder and tautog, this overestimation was by several orders of magnitude. Only butterfish, silver hake, and striped killifish egg weights were underestimated.

Larval stages were also overestimated. For example, the expected weight for tautog larvae is shown in Table 5.

Table 5: Tautog Larvae Weight
[see hard copy for table]

Assuming an average size of approximately 15 mm (size range is 2.2 mm at hatch to 30 mm TL at end of PYSL), the average weight is 0.000233 lbs (the average of 10 mm and 20 mm weights in Table 5). The weight used by USEPA, 0.022 lbs, is almost 95 times heavier that the actual weight.

A similar analysis may be conducted for scup larvae (Table 6):

Table 6: Scup Larvae Weight
[see hard copy for table]

Scup hatch at about 2 mm in length and become juveniles at about 20 mm in length. Assuming an average size of approximately 11 mm for larvae, Laurence's equation predicts an average weight of 0.0163 g or 0.000036 lbs. The assumed USEPA weight of 0.0011 lbs for scup larvae is 30 times heavier. (Even assuming the weight for the 20 mm individual, the USEPA weight is over 3 times heavier.)

USEPA needs to re-evaluate its Production Foregone estimates with biologically realistic measures of mean weights of individuals.

Combined Influence of Errors

The two errors by USEPA combine to yield an overestimate of the production losses resulting from BPS. To demonstrate the magnitude of this overestimation, we have computed production losses using the correct weights in the production formula and biologically realistic values for weights at midpoints of life stages. As can be seen in Table 7, USEPA overstated total production losses by at least 300 times!

For 14 of the sixteen species, the incorrect calculations used by USEPA resulted in overestimation of the production lost. For several species, USEPA's estimate of production lost was hundreds of times higher than the production lost based on realistic weights and the correct use of the production formula.

Table 7: Comparison of USEPA and LMS 1974-83 Average Production Foregone Estimates for Brayton Point Station
[see hard copy for table]

USEPA must reevaluate its calculations of production lost and its estimates of mean weights, replace their existing estimates of production lost witlkcorrect values, and determine how the revised estimates affect the 316(b) rule.

Mkt-level impacts/Reliability/EO 13211: Energy Effects

In particular, these comments focus on the EPA's stated concern <FN 6> that the implementation of a more protective standard for cooling water intake structures at existing power plants would adversely affect national energy reliability. In the proposed rule, the EPA relies on a forecast that grossly miscalculates the rate of electric generating capacity development in the United States over the next several years. The amount of generating capacity that has either recently come online or is under active development exceeds even the long-term estimates relied upon by the EPA in this rulemaking. The Agency's concerns about the effect a protective Phase II CWIS rule would have on energy reliability are therefore misplaced, as they are founded on completely obsolete projections.

Footnotes

6 See, e.g., 67 Fed. Reg. 17121, 17188 (April 9, 2002).

EPA Response

EPA agrees that more recent capacity developments exceed the estimates embedded in the IPM. Please refer to section VII of the preamble for information regarding EPA's decision to reject cooling towers as the basis for today's rule.

Subject Matter Code NEW

Comment on new (Phase I) facility rule

Under an agreement reached by the parties in the ongoing case of Riverkeeper, Inc. v. Whitman, <FN 10> the rulemaking process under Section 316(b) was divided into three phases. <FN 11> Phase I of the rulemaking, which pertained to CWIS at new power plants and industrial, facilities, was proposed in August 2000 <FN 12> and finalized in December 200l. <FN 13> As mentioned above, the Clean Air Task Force and ten other organizations submitted comments on the Phase I proposed rule. The EPA's Phase I proposal would have required closed-cycle recirculating cooling systems only at the most ecologically sensitive waterbodies and would have allowed once-through cooling everywhere else. We urged the Agency to require all new facilities to install dry-cooling or its functional equivalent and wrote that the proposed regulation failed to comport with the Clean Water Act's requirement that cooling water intake structures employ the best cooling technology available for minimizing adverse environmental impact. In the final version of the Phase I rule, the EPA adopted uniform protections for all types of waterbodies, but failed to establish dry cooling as the Best Technology Available (BTA) as required by Section 316(b) of the Clean Water Act.

Footnotes

10 No. 93-Civ.0314 (AGS) (S.D.N.Y.)

11 Under Phase I, the EPA is required to issue a final rule governing new facilities that employ a cooling water intake structure by November 9, 2001. Under Phase II, the EPA must propose regulations for existing utilities and non-utility power producers whose intake capacity levels exceed a given minimum threshold by February 28, 2002; final regulations are due August 28, 2003. Finally, under Phase III, a proposed rule governing any remaining unregulated facilities that employ a cooling water intake structure is due June 15, 2003, and a final rule is due December 15, 2004.

12 65 Fed. Reg. 49060 (August 10, 2000) (notice of proposed rulemaking for Phase I (new facilities)).

13 66 Fed. Reg. 65255 (December 18, 2001) (final rule for Phase I (new facilities)).

EPA Response

EPA appreciates the commenter's concerns regarding the Phase I rule. The rule was finalized on November 9, 2001 and is no longer open for public comment. Please refer to the Phase I docket (W-00-03) and the Phase I Comment Response Document (DCN 3-0091) for further information.

RFC: Three-option framework for determining BTA

The Phase II CWIS Rule: Existing Power Plants

The EPA proposed Phase II of the CWIS rule on April 9, 2002. <FN 14> The Phase II rule applies to existing facilities that (a) both generate and transmit electric power or that generate electric power for sale to another entity for transmission; (b) use one or more cooling water intake structures to withdraw water from the waters of the United States; (c) require a Clean Water Act NPDES permit; and (d) withdraw at least 50 MGD and use at least 25% of water withdrawn solely for cooling purposes. <FN 15> Eligible facilities are required to comply with performance standards established by EPA as the best technology available for minimizing adverse environmental impact. In its proposed rule, the Agency offers three alternative methods by which an eligible facility can demonstrate compliance with those standards: <FN 16>

-A facility may demonstrate that its existing design and construction technologies, operational measures, and/or restoration measures already meet the EPA's proposed minimum performance standards. <FN 17>

-A facility may select design and construction technology, operational measures, restoration measures, or some combination thereof, and then demonstrate that the selected approach would meet the performance requirements proposed by the EPA.

-A facility may calculate the cost of complying with the presumptive standard and compare those costs either to the EPA's estimated compliance costs or to a site-specific determination of the benefits of meeting the presumptive standard. If the facility's costs are significantly greater than the EPA' s estimated cost or the site-specific benefits, the facility would become subject to a site-specific BTA determination.

An existing power plant would be allowed to use any of these three approaches to demonstrate compliance with the proposed rule.

Footnotes

14 67 Fed. Reg. 17121.

15 Id. at 17128.

16 Id. at 17143.

17 To comply with the performance standards proposed by the EPA, a facility must either demonstrate that its intake capacity is commensurate with the use of a closed-cycle cooling system or seek to comply with limits on the net impingement mortality and entrainment caused by the facility. Id. at 17140. The second choice, which is considerably less stringent, represents the actual minimum performance standard.

EPA Response

Please refer to the response to comment 316bEFR.038.007.

Organization Clean Air Task Force

Subject Matter Code 8.0

Waterbody Type

Under the EPA's Phase II proposal, the performance standard required of eligible facilities will differ according to the type of waterbody from which a given facility withdraws its cooling water. Oceans, estuaries, tidal rivers and the Great Lakes will benefit from stricter limits on impingement and entrainment than will freshwater rivers, streams, and other lakes. In the Phase I rule, the EPA proposed a similar scheme that would have regulated facilities differently depending on the type of the source waterbody. In our comments on the Phase I proposal, we joined other environmental organizations in criticizing this approach, recognizing that all - waterbodies have ecological value and support potentially vulnerable ecosystems. <FN 18> EPA wisely abandoned this method in its final Phase I rule and we urge the Agency to do the same here.

Footnotes

18 Clean Air Task Force, et al., "Phase I Comments," supra note 5, at 6-7.

EPA Response

EPA recognizes that all waterbodies have some ecological value, but disagrees that all waterbody types merit the same level of protection. Today's rule implements performance standards that would apply different requirements for facilities located upon different waterbody types. EPA considers location to be an important factor in addressing adverse environmental impact and one expressly included in the language of section 316(b). When cooling water is withdrawn from sensitive biological areas, there is a heightened potential for adverse environmental impact, since these areas typically have higher concentrations of impingeable and entrainable aquatic organisms. Therefore, the final rule includes performance requirements that vary, in part, by waterbody type. For example, estuaries and tidal rivers have a higher potential for adverse impact because they contain essential habitat and nursery areas for a majority of commercial and recreational species of fish and shellfish. Therefore, these areas warrant a higher level of control that includes both impingement and entrainment controls.

Organization Clean Air Task Force

Subject Matter Code 17.02

Option: Reduce capacity comm. with closed-cycle

Moreover, in the Phase II rule, the EPA has failed to propose performance and technology standards that truly reflect the best cooling technology available for existing power plants. For all of these facilities, <FN 19> BTA must be the functional equivalent of a closed-cycle recirculated cooling system. Closed-cycle cooling systems offer substantial protection against adverse environmental impact and can be installed at existing power plants at a reasonable cost. If the EPA adopts a technology-based BTA standard, it must designate closed-cycle cooling as that standard. Likewise, if the Agency defines BTA according to a performance standard, the resulting standard must require power plants to reduce their cooling water intake capacity to a level commensurate with closed-cycle cooling.

Footnotes

19 We believe that the EPA should develop a single BTA standard, to be applied uniformly to all eligible existing power plants. Existing facilities that are eligible for regulation under Phase II are described above and at 67 Fed. Reg. at 17127-128. The EPA defines an "existing" facility as "any facility that commenced construction before January 17, 2002 and (1) any modification of such a facility; (2) any addition of a unit at such a facility for purposes of the same industrial operation; (3) any addition of a unit at such a facility for purposes of a different industrial operation, if the additional unit uses an existing cooling water intake structure and the design capacity of intake structure is not increased; or (4) any facility constructed in place of such a facility if the newly constructed facility uses an existing cooling water intake structure whose design intake flow is not increased to accommodate the intake of additional cooling water." Id. at 17128.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

Subject Matter Code 17.04

Option: Closed-cycle for oceans, tidal rivers or estuaries

In the proposed rule, the Agency discusses — but ultimately rejects — two alternative BTA standards. The first alternative standard, referred to in the preamble as the “waterbody/capacity based option,” <FN 20> would require facilities that withdraw water from an estuary, tidal river, or ocean, and that meet specified intake flow requirements, to reduce their intake capacity to a level that can be attained by a closed-cycle cooling system. <FN 21> Although the “waterbody/capacity based option” would represent a significant improvement over the proposed rule, we are concerned about its failure to protect all waterbodies.

EPA Response

EPA believes that today’s final rule represents the best option for minimizing adverse environmental impacts brought by cooling water intake structures (see final rule preamble section VI. Basis for the Final Regulation for more details). For EPA’s rationale behind rejecting the waterbody/capacity based option, please refer to the final rule preamble.

Option: Reduce capacity comm. with closed-cycle

Author Name Jonathan Lewis

Organization Clean Air Task Force

The second alternative BTA standard considered by the EPA would require all eligible Phase II existing facilities to reduce intake capacity commensurate with the use of closed-cycle, recirculating cooling systems. <FN 22> We urge the EPA to adopt this standard, also described as the “all closed-cycle option,” <FN 23> when it finalizes the Phase II rule. <FN 24>

Footnotes

Mkt-level impacts/Reliability/EO 13211: Energy Effects

According to the Agency's own calculations, a rule which requires closed-cycle cooling at all existing power plants would have only minor economic consequences, <FN 25> and when inspected closely, it becomes clear that the EPA's analysis of the market-level impacts on energy production overstates the matter. The Agency's analysis overestimates the effect that the few plant closures that would be attributable to a closed-cycle rule would have on energy reliability because it does not fully and accurately account for the current boom in electric generating capacity development. The EPA suggests that an additional 6560 MW will be retired if it requires existing plants to install closed cycle cooling (or its functional equivalent). <FN 26> But that amount of retirement is rendered almost inconsequential when considered against the flood of new electric capacity that will come online over the next five years — nearly 177,593 MW according to one conservatively derived estimate. <FN 27>

Footnotes

25 See 67 Fed. Reg. at 17 187-17189.

26 As compared to the Agency's proposed rule. 67 Fed. Reg. at 17188 (Exhibit 13).

Option: Reduce capacity comm. with closed-cycle

The Agency's proposed rule does not reflect the best technology available as required by law. None of the various compliance options will ensure that existing power plants will reduce intake capacity to levels commensurate with those that would be achieved by closed-cycle, recirculated cooling systems. <FN 28> It has been demonstrated that reducing the intake capacity of a facility is typically the most important factor in minimizing adverse environmental impact. <FN 29> "When water is extracted from healthy natural waters, to an overriding degree the numbers of organisms killed. . . increases with the volume of water pumped." <FN 30> Accordingly, in order to minimize adverse environmental impact, the BTA standard for existing power plants should require that those facilities reduce their intake capacity to levels commensurate with closed-cycle cooling systems. Closed-cycle cooling systems can reduce mortality from entrainment and impingement by 98% when compared to conventional once-through cooling systems. <FN 31> The proposed rule, by contrast, requires that plants reduce impingement mortality by only 80% and entrainment by only 60%.

Footnotes

28 A facility that demonstrates that its intake capacity is commensurate with the use of a closed-cycle cooling system meets the requirements of the proposed rule as a matter of course. 67 Fed. Reg. at 17140. However, such reductions in intake capacity are not required. Facilities may instead seek to comply with less stringent limits on impingement mortality and entrainment. Id.

Option: Reduce capacity comm. with closed-cycle

Pursuant to the Phase II proposal, the determination of what technologies and processes constitute BTA would hinge on the type of waterbody used by a facility as the source of its cooling water. The EPA proposes, for example, to afford most freshwater bodies only minimal protection. If a facility located on a freshwater river or stream consumes five percent or less of the annual mean flow of the source river or stream, that facility must reduce fish and shellfish impingement mortality by 80-95% (as compared to conventional once-through cooling systems). <FN 32> If the intake flow is greater than five percent of the annual flow, the facility must also reduce entrainment by 60-90%. <FN 33> Similarly, a facility that withdraws it cooling water from a lake or reservoir would have to reduce impingement mortality by 80-95% for fish and shellfish, and, if it expands its design intake capacity, the increase in intake flow must not disrupt the natural thermal stratification or turnover pattern of the source water. <FN 34> The Great Lakes and saltwater bodies benefit from standards that are somewhat stronger, albeit still inadequate. Existing power plants that withdraw cooling water from the Great Lakes, tidal rivers or estuaries, or from the ocean must reduce fish and shellfish impingement mortality by 80-95% and to reduce entrainment by 60-90%. <FN 35>

When measured against the reductions available from closed-cycle cooling, the Agency's targets for impingement and entrainment limits are impermissibly lax. According to EPA data, "closed-cycle, recirculated cooling systems (e.g., cooling towers or ponds) can reduce mortality from impingement by up to 98 percent and entrainment by up to 98 percent when compared with conventional, once-through cooling systems." <FN 36> The proposed Phase II rule, in contrast, permits unlimited entrainment at most freshwater sources, and would require only a 60% decline in impingement mortality (relative to a conventional once-through cooling system) at waterbodies the Agency has deemed to be particularly sensitive. Similarly, the proposed rule would require existing facilities using once-through cooling to reduce impingement mortality by only 80%, despite the fact that considerably steeper reductions are achievable using closed-cycle systems. Due to the staggering number of organisms that are impinged and entrained by the cooling systems at existing facilities, the quantitative difference between an 80% reduction in impingement mortality and a 98% reduction is significant. Furthermore, under the proposal, facilities will have the option of using restoration measures "in lieu of or in combination with reductions in impingement mortality and entrainment." <FN 37> As long as facilities takes steps to maintain fish and shellfish populations at a level "comparable" to that which would be achieved with the installation of closed-cycle cooling, the actual numbers of organisms impinged and entrained are irrelevant to the Agency. <FN 38>

By mandating that intake capacity levels reflect the true BTA for existing power plants - i.e., closed-cycle cooling or its functional equivalent — the EPA would ensure that intake capacity levels are reduced by 96% when compared with once-through cooling systems. <FN 39> As a result, mortality from impingement and entrainment at that class of facilities would be reduced by as much as 98% - a significant improvement over the current proposal. Furthermore, it is only by doing so that the EPA will satisfy its statutory obligation to establish a standard that minimizes adverse environmental impact.

These significant reductions in mortality associated with closed-cycle cooling or its functional equivalent could be achieved with negligible effect on the supply and reliability of electricity around the country, as discussed in Part IV below.

Footnotes

RFC: EPA rationale to not require closed-cycle

The EPA's Reliance on Capital and Operating Costs as a Basis for Rejecting the All Closed-Cycle Cooling Option is Misplaced.

A.Cost Is Not a Valid Consideration in Establishing the Best Technology Available

Congress intended Section 3l6(b)'s Best Technology Available standard to be highly protective of the nation's waterways. With respect to each of the criteria listed in Section 316(b) - location, design, construction, and capacity — the standard of protection selected by the EPA as BTA must in fact be the best cooling technology available to existing power plants for minimizing adverse environmental impact. Notably, cost is not among the factors enumerated in Section 316(b), and may not be considered by the Agency when setting BTA. The EPA, however, impermissibly compared the capital and operational costs of various regulatory options while determining BTA for existing power plants. In fact, the EPA wrote that it "did not select closed-cycle, recirculated cooling systems as the best technology available for existing facilities because of the generally high costs of such conversions." <FN 40>

Section 3 16(b) of the Clean Water Act, 33 U.S.C.S §1326(b), reads:

(b) Cooling water intake structures. Any standard established pursuant to section 301 or section 306 of this Act § 1311 or 1316] and applicable to a point source shall require that the location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact.

The conspicuous absence of cost from the list of factors for which the EPA must determine BTA is neither trivial nor accidental. Congress has repeatedly demonstrated that it knows how to direct the EPA to consider costs when establishing a control standard. Section 316(b), on the other hand, requires the EPA to identify the best technology available without reference to economic considerations. <FN 41> In Whitman v. American Trucking Associations, the Supreme Court ruled that the projected cost of compliance is not a relevant factor in environmental rulemaking unless the underlying statute explicitly enumerates cost as a valid consideration. <FN 42> The Court's unanimous decision validated a similar position taken years earlier by the D.C. Circuit Court of Appeals in Lead Industries Association v. EPA. <FN 43> The underlying statute here, Section 316(b), lacks any clear "textual commitment of authority to the EPA to consider costs. <FN 44> Accordingly, the EPA' s is not authorized to consider cost when establishing BTA. <FN 45>

RFC: EPA rationale to not require closed-cycle

Section 316(b) Requires the EPA to Establish BTA According to Location, Design, Construction, and Capacity

The straightforward language of Section 316(b) clearly requires the EPA to set BTA so that the location, design, construction, and capacity of cooling water intake structures reflect the best technology available for minimizing adverse environmental impact. Intake capacity, or the volume of cooling water pumped by a facility, varies significantly depending on the type of cooling technology utilized. As discussed in Part II above, a reduction in intake capacity is the most effective method by which a facility can minimize adverse environmental impact caused by its cooling water intake structures. <FN 46>

Therefore, the cooling system that most effectively reduces intake capacity is also the most likely to minimize adverse environmental impacts. Compared with once-through cooling systems, closed-cycle cooling systems offer reductions in intake capacity on the order of 96-98%. <FN 47> Reductions in capacity generally result in reduced impingement and entrainment, thereby minimizing adverse environmental impact. <FN 48> The "all closed-cycle option" discussed (but rejected) in the EPA' s proposed Phase II rule would require power plants to "reduce their design intake flow to a level that can be attained by a closed-cycle recirculating cooling water system." <FN 49> By reducing intake capacity by as much as 98% as compared to once-through cooling, closed-cycle cooling can truly minimize the adverse environmental impact associated with cooling water intake structures at existing power plants.

Under the EPA's proposed CWIS standard for existing power plants, facilities are not required reduce their intake capacity. Instead, the proposed rule would permit existing power plants to continue using once-through cooling, provided they use alternative means such as ecosystem restoration to meet the rule's targets for impingement mortality and entrainment. <FN 50> The Agency's proposed standard simply fails to meet the Act's requirement that the CWIS standard itself must reflect the best technology available for minimizing adverse environmental impact. Technologies and processes that offer greater environmental protection not only exist, they are commonly used. Numerous power plants around the country employ closed-cycle cooling water intakes structures, leaving no question that closed-cycle cooling is a readily available technology. Because a rule that requires closed-cycle cooling or its functional equivalent would provide more protection against adverse environmental impacts, the EPA's proposed standard, by definition, does not reflect the best technology available.

The Agency's "all closed-cycle option," by comparison, would satisfy Section 316(b)'s requirement that the EPA implement a stringent BTA standard for existing power plants. Closed-cycle cooling systems significantly reduce intake capacity, thereby ensuring that the environmental impacts caused by cooling water intake structures are minimized. Unlike the various stratagems allowed under the proposed rule, the "all closed-cycle option" would require significant reductions in intake flow, thereby taking advantage of the direct relationship between an intake structure's capacity and the number of organisms that are entrained and impinged. <FN 51>

Footnotes

47 See OTTINGER, ETAL., supra note 39, at 281.

48 Section 316(b) requires the EPA to select the best technology available to minimize adverse environmental impact. According to the Agency, "minimize means to reduce to the smallest amount, extent, or degree reasonably possible." 67 Fed. Reg. at 17130. Webster's Dictionary, however, does not join the EPA in using the word "reasonably" to qualify what is "possible." See 'Webster's Ninth New Collegiate Dictionary 756 (1991) ("minimize v, 1: to reduce or keep to a minimum;" "minimum mi, 1; the least quantity assignable, admissible, or possible.") We remind EPA that the boundaries of its discretion in determining what degree of minimization is "reasonably possible" are delimited by the four criteria relevant to BTA: location, design, construction, and capacity. See Lead Industries, 647 F.2d at 1150. Cost is not one of the factors listed by Congress and is therefore irrelevant to the EPA's BTA determination.

49 67 Fed. Reg. at 17187.

50 67 Fed. Reg. at 17143.

51 See Pisces International Ltd., supra note 29, at 27.

EPA Response

The Agency disagrees with the following statement, which is the thesis of the comment: "…a reduction in intake capacity is the most effective method by which a facility can minimize adverse environmental impact caused by its cooling water intake structures."

The determination of what is the "most effective method," in the Agency's belief, must incorporate a variety of factors. As such, the Agency's determination of the "most effective method" for minimizing adverse environmental impact in the case of the Phase II existing facility rule must acknowledge the technical feasibility, the potential energy market impacts, the relative costs of technologies, and the relative effectiveness of said technologies, among other secondary factors. Although the "Location, Design, Construction, and Capacity" of an intake are the four major technical means by which aquatic impacts can be controlled, the judgment as to which means is "most effective" is based on those factors that the commenter specifically asserts are not appropriate for this regulation. The commenter's premise – that the cooling system that most effectively reduces intake capacity is also the most likely to minimize adverse environmental impacts – is unworkable. Dry cooling technology is not even a feasible technology for retrofit installations at the vast majority of power plants in the scope of the rule. As such, the "cooling system that most effectively reduces intake capacity" is inherently an improbable candidate for best technology available.

A technical oversight on the commenter's part further undermines their assertions. When the commenter asserts that closed-cycle cooling reduces water intake by 96 to 98 percent, they are mistaken. In freshwater environments the statement is a bit optimistic. However, with saltwater (that is, in the locations most in need of protective entrainment standards, in the Agency's opinion) the water intake reductions range from 85 to 92 percent. This is on par with the entrainment reduction achieved (60 to 90 percent) with the "most effective" technologies available for existing facilities, which form the basis of the final rule (see the discussion of technology efficacy in the Technical Development Document). As such, the commenter fails to realize that the Agency is promulgating a rule that will achieve entrainment reductions on the order of recirculating wet cooling tower systems without the impractical costs, technical feasibility concerns, power impacts, and aesthetic concerns.

Furthermore, the commenter demonstrates a fundamental misunderstanding of what qualifies a technology for “best technology available” when he states, “numerous power plants around the country employ closed-cycle cooling water intakes structures, leaving no question that closed-cycle cooling is a readily available technology.” This statement does not adhere to basic principles of determining candidates for “best technology available.” Through exhaustive research, the Agency determined that 4 plants had performed this engineering feat. Two of these projects occurred at plants larger than 500 MW in size. This, in no way, could be considered “numerous”. This fact alone leaves questions as to whether or not it is a readily available technology. Additionally, there are high costs, energy impacts, technical hurdles, and potential land-acquisition issues that the commenter fails to consider.

The Agency disagrees with the commenter that there exists in Section 316(b) a “requirement that the EPA implement a stringent BTA standard for existing power plants.” As the commenter pointed out in their thesis statement, the Agency must determine the most effective means for minimizing adverse environmental impact and not the “most stringent BTA standard”. The Agency refers to comment response 316b.NFR.206.014 for further discussion of its legal authority to consider cost in determining the “most effective” of the best technology’s available.

Mkt-level impacts/Reliability/EO 13211: Energy Effects

Requiring Closed-Cycle Cooling at Existing Power Plants Will Have a Minimal Effect on Electricity Reliability.

In the preamble to the proposed rule, the EPA relies partly on market projections for the electric generating industry in its attempt to explain why two alternative regulatory approaches, the “waterbody/capacity-based option” and the “all closed-cycle option,” were not adopted despite the additional protection they would provide against adverse environmental impact. <FN 52> The Agency’s predictions about how these alternative options would affect the electricity market is an impermissible attempt to analyze their compliance costs. <FN 53> Moreover, as set forth in greater detail below, the Agency’s own data suggest that the market impacts of implementing a rule that required closed-cycle cooling at all eligible facilities (the “all closed-cycle option”) would be insignificant, particularly with respect to electric generating capacity. Furthermore, the EPA overstates the impact of such a rule because its analysis is based on a flawed and outdated market forecast that fails to accurately account for the enormous growth in generating capacity currently under development.

Mkt-level impacts/Reliability/EO 13211: Energy Effects

The EPA‘s Own Projected Market Impacts from a Closed-Cycle Cooling Rule Are Minimal and Are Not a Sufficient Basis for Rejecting the “All Closed Cycle Option” as BTA.

According to EPA data, a rule that “requires that existing facilities with a design intake flow [of] 50 MGD or more reduce their total design intake flow to a level that can be attained by a closed-cycle recirculating cooling water system” would have only a minimal impact on the electricity market in the United States. In the preamble to its Phase II proposal, the Agency estimates that the “all closed-cycle option” would result in the closure of only 6560 MW of capacity by 2013 — less than one percent of the total baseline capacity. <FN 54> In its description of the market impacts associated with the “waterbody/capacity-based option,” <FN 55> the EPA describes regional capacity closures of 1.1% and 1.3% as “an insignificant percentage of total baseline capacity in those regions.” <FN 56> Certainly, then, the closure of less than one percent of total capacity under the “all closed-cycle option” (as projected by the EPA) is also insignificant.

Using the EPA’s projections, it is nearly impossible to accurately compare the market impacts associated with the “all closed-cycle option” to those market impacts associated with the proposed rule. The EPA relied on ICF Consulting’s Integrated Planning Model (1PM 2000) to project compliance-related data for both of the alternative regulatory options discussed Section VIII. B. of the proposal — the “waterbody/capacity-based option” and the “all closed-cycle option.” <FN 57> As discussed in the preceding paragraph, the Agency used 1PM 2000 to estimate capacity closures of 6560 MW by 2013 under the “all closed-cycle option.” <FN 58> Due to time constraints, however, the EPA was unable to develop comparable projections for the performance standards it actually proposed. <FN 59> Instead, the Agency concluded, rather crudely, that based on data it collected for the alternative options, “there would be no significant impacts on any NERC region associated with the proposed rule” in 2008. <FN 60> Even if we assume that by “no significant impacts” the EPA means that electrical capacity closures attributable to the proposed option would be zero, the “all closed-cycle option” would result in capacity closures of no more than 6560 MW — less than 1% of baseline capacity— when compared with the proposed rule.

The Agency’s analysis of facility-level impacts further demonstrates that the effects of the “all closed-cycle option” on plant closures would be benign. According to the EPA, a net of only five facilities would close as a result of the rule. <FN 61> The Agency again fails to provide similar facility-level data for its proposed option. Assuming that the proposed option would result in zero plant closures, however, the facility-level impacts projected by the EPA under the “all closed-cycle option” — i.e., the closure of five facilities that generate less than 1% of total baseline capacity — would still be negligible.

Footnotes

54 The EPA projects a total baseline capacity in 2013 of 922,740 MW, of which 6560 MW is 0.7%. 67 Fed. Reg. at 17188 (Exhibit 13).

55 The “waterbody/capacity-based option” would require facilities that withdraw water from particularly sensitive waterbodies (i.e., estuaries, tidal rivers, or oceans) and which meet minimum intake flow requirements, to achieve intake

capacity levels commensurate with those levels attained by a closed-cycle, recirculating cooling systems. Id. at 17185.

Mkt-level impacts/Reliability/EO 13211: Energy Effects

The EPA Overstates the Market Impacts that Would Be Attributable to a Closed-Cycle Cooling Rule.

The EPA, furthermore, overestimates the market impacts of a Phase II rule that requires closed-cycle cooling. The model used by the EPA to evaluate projected market impacts of the various regulatory options underestimates the dimensions of the remarkable surge in power plant development currently underway in the United States. While the Agency figures that an additional 6560 MW of capacity would be retired if all eligible existing power plants were required to install closed-cycle cooling or its functional equivalent, that loss in generating capacity is significantly less than the amount by which EPA underestimates long-term total capacity.

The EPA bases its projections on IPM 2000, "a long-term general equilibrium model of the domestic electric power market which simulates the least-cost dispatch solution for all generation assets in the market given a suite of user-specified constraints." <FN 62> In 2000, when the IPM 2000 began its modeling run, the full scale of the current power plant development surge was not yet apparent. As a result, the amount of new development projected by the model is far too low.

The pace of recent construction demonstrates the extent to which IPM 2000 has underestimated the enormous, unprecedented surge in power plant development. The RDI NEWGen database is a proprietary database that contains detailed information on the status of new plant development projects across the country. The database is updated monthly and provides the most timely and accurate method of tracking actual power plant development. According to the April 2002 update of the RDI NEWGen database, 77,690 MW of capacity has come online since the beginning of 2000, when the IPM 2000 was developed. <FN 63>

Furthermore, future capacity development can be accurately projected based on actual construction and development information. By analyzing data from the April 2002 update of the RDI NewGen database and taking into account various project and business criteria, the NorthBridge Group <FN 64> has assessed the likelihood that power plant development projects across the country will be completed. NorthBridge assigned a probability of completion to each category of new projects and included low, base, and high scenario estimates that cover a range of plausible market conditions over the next several years. The projections developed by NorthBridge assume that many of the projects under active development will be delayed or abandoned due to market or regulatory factors.

NorthBridge's conservative analysis of the NewGen database demonstrates the problem with IPM 2000's projections. The EPA's IPM 2000 Base Case projects that 97,519 MW of new capacity will be added between 1999 and 2005. <FN 65> In stark contrast, as of April 2002, 88,328 MW of capacity has become operational since the beginning of 1999 and a further 122,829 MW of capacity is currently under construction. An additional 49,160 MW generating capacity is under advanced development and is likely to go online by the end of 2005. <FN 66> In all, 260,317 MW of additional generating capacity will have been developed between the beginning of 1999 and the end of 2005, which is 162,798 MW greater than the amount of additional capacity projected by IPM 2000 to come online during the same period. <FN 67> The development of generating capacity has accelerated dramatically over the past few years and is expected to peak at over 60,000 MW per year in both 2002 and 2003. <FN 68> In each of these peak years (2002-2003) the amount of new generating capacity that will be added exceeds the total amount of capacity brought online over the entire decade of the l990s. <FN 69>

NorthBridge's projected new capacity additions — based on the RDI NEWGen database and checked by Energy and Environmental Analysis, Inc. (EEA) <FN 70> — indicate that national electrical generating capacity additions through 2006 will exceed the additions projected by IPM 2000 through 2015. <FN 71> More to the point, the amount of new capacity almost certain to be online by 2006 exceeds IPM 2000's projected total capacity additions through 2013 by an amount— 95,000 MW — that is more than fourteen times larger than the amount of capacity the EPA estimates would be retired under a Phase II CWIS rule that required the installation of a closed-cycle cooling system or its functional equivalent. <FN 72>

The decrement that the EPA attributes to the "all closed-cycle option" — 6560 MW — is miniscule in comparison to the amount by which the Agency is underestimating generating capacity additions over the next several years. Even under IPM' s erroneous generating capacity projections, the "all closed-cycle option" would have only a minimal impact on the electricity market. The recent surge in power plant development, reflected in NorthBridge's analysis of the RDI NEWGen database, has rendered the retirement of 6560 MW by 2013 insignificant. The EPA should revise its analysis of the "all closed-cycle option" to recognize that the electricity market can readily afford the negligible loss in generating capacity that would result from a Phase II CWIS rule requiring closed-cycle cooling or its functional equivalent.

Mkt-level impacts/Reliability/EO 13211: Energy Effects

Closed-Cycle Cooling Would Have Little Negative Effect on System Reliability

The retirement of 6560 MW of generating capacity nationwide will not threaten the reliability of the national electricity system. In fact, the rapid addition of new capacity will ensure that reserve margins continue to grow. The NorthBridge Group estimates that in 2006 there will be 971,289 MW of installed capacity nationwide. The growth in installed capacity will correspond to increases in the reserve margins — i.e., the difference between installed capacity and projected peak demand — in each of the ten North American Electric Reliability Council (NERC) regions. <FN 73> Moreover, in all but two of the ten NERC regions, projected 2006 reserve margins will exceed 20%. <FN 74>

Accordingly, the reliability concerns of the 1990s have been largely rectified by the surge in power plant development. The pace of development has allowed all NERC regions to project adequate planning margins for 2002. <FN 75> Regional reserve margins will further benefit from the additional capacity generated by power plants that have come online in the past year, plants that are under construction, and plants that are in advanced development, and are projected to be substantial in most regions by 2006. <FN 76> The retirement of 6560 MW of generating capacity over the next eleven years — the amount which the EPA estimates would be attributable to the implementation of the "all closed-cycle option" — will not threaten these margins in any appreciable manner.

In the preamble to its Phase II proposal, the EPA estimates that 0.7% of the projected total installed generating capacity in 2013 would be retired under the "all closed-cycle option." <FN 77> This percentage was derived by dividing 6560 MW (the estimated amount of retired capacity by 2013 under the "all closed-cycle option") by 922,740 MW (IPM's projected total capacity in 2013). Accordingly, the EPA had exaggerated the ratio of estimated capacity retirements to projected total capacity-because, as discussed above in Part IV.B., its model, IPM 2000, severely underestimates capacity additions. Actual total capacity in 2013 will far exceed the IPM 2000 projection of 922,740 MW; consequently, 6560 MW will account for even less than 0.7% of total capacity in 2013.

The EPA cannot responsibly rely on IPM 2000 projections in its analysis of the market-level impacts of a rule that would require existing power plants to reduce their intake capacity to levels commensurate with closed-cycle cooling systems (i.e., the "all closed-cycle option"). Actual installed capacity will already have surpassed IPM's 2013 projections by end of 2003. <FN 78> The amount of capacity the EPA expects would be retired under its rejected "all closed-cycle option" is dwarfed by the amount the Agency, using IPM data, underestimates future installed generating capacity. An analysis of more realistic capacity projections will demonstrate to the EPA that the electricity system's reliability will not be negatively impacted by the loss of 6560 MW.

Mkt-level impacts/Reliability/EO 13211: Energy Effects

The Energy Penalty Associated with Closed-Cycle Cooling Is Not Significant.

The EPA has expressed concern about the energy penalties associated with cooling systems that use less water, including closed-cycle cooling. <FN 79> The use of a different type of cooling system can affect the temperature maintained at a facility's steam condensing surface. Everything else being equal, an increase in the temperature of the condensing surface generally corresponds to a decrease in the generating efficiency of a plant. <FN 80> Although there is a slight energy penalty associated with closed-cycle cooling as compared to once-through cooling, that difference is so small as to be irrelevant to the Agency's rulemaking process.

The EPA estimates that the national average energy penalty for fossil fuel plants is only 1.7% of plant output for facilities using closed-cycle cooling when compared to facilities using once-through cooling. This difference is not significant enough to justify the EPA in finalizing a rule that would allow power plants to continue using once-through cooling systems that withdraw hundreds of millions of gallons per day.

The estimated energy penalty of 1.7% is so low that it poses very little threat to energy reliability. As discussed in Part IV.C above, regional reserve margins will exceed 20% in eight of the ten NERC regions by 2006. <FN 81> As a practical matter, then, energy reliability is not at issue here, and the larger environmental requirements of the Clean Water Act should govern the EPA's decision. Rather than relying on false assertions of reliability issues as an excuse to avoid n-more stringent environmental controls, the Agency should instead focus on adopting a CWIS rule that truly minimizes the adverse environmental impacts associated with cooling water intake structures. <FN 82>

Option: Reduce capacity comm. with closed-cycle

Conclusion: EPA Should Require Closed-Cycle Cooling as BTA for Existing Power Plants.

We look forward to reviewing more detailed, more protective standards for cooling water intake structures at existing power plants. As a technical matter, EPA's proposal currently lacks the specificity and the analysis befitting a rule of this importance. In particular, the Economic Analysis in Section VIII of the rule needs to be expanded so that all of the options being considered by the Agency are subject to the same level of scrutiny. <FN 83> Those options, moreover, should be analyzed using accurate data about the amount of actual and projected installed generating capacity.

Substantively, the Agency's proposed rule fails to satisfy EPA's statutory mandate to implement CWIS standards that reflect the best technology available to minimize adverse environmental impact. The proposal does not require facilities to reduce their intake, capacity, but instead allows them to continue using outmoded once-through cooling systems. Accordingly, under the proposed rule, existing power plants can continue to consume hundreds of millions of gallons of water per day provided they take steps to mitigate the resulting impingement and entrainment. Because other more protective cooling technologies are in fact readily available, EPA cannot credibly describe its proposed standard as BTA.

The EPA's own "all closed-cycle option," an option that would require power plants to reduce their intake capacity to levels commensurate with closed-cycle cooling, does satisfy the stringent requirements of Section 316(b). Closed-cycle cooling, a process used by numerous facilities, allows a power plant to withdraw only 2-4% as much water as it would using a once-through cooling system. Reductions in intake capacity correspond to reductions in impingement and entrainment, thereby minimizing the adverse environmental impacts associated with cooling water intake structures.

Furthermore, the "all closed-cycle option" would have a negligible impact on energy reliability. Due to the enormous surge in power plant development currently underway, regional power market reserve margins are increasing and are expected to be substantial in most regions by 2006. <FN 84> The amount of electric capacity coming on-line in the near future will dwarf the miniscule loss in capacity that the EPA would attribute to the implementation of the "all closed-cycle option."

We urge the EPA to adopt its "all closed-cycle option" as BTA for existing power plants. In doing so, the Agency would fulfill its duty under the Clean Water Act "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters." <FN 85>

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

General statement of support

The proposed rule covers a wide range of legal, technical, scientific and economic issues, On the whole, Duke Energy is encouraged that the EPA recognizes that to be successfully implemented; § 316(b) regulations for existing facilities must not dictate a single technology fix. The factors affecting entrainment and impingement are site-specific, species-specific, and consequently widely varied. A one-size-fits-all categorical performance standard based solely on the type of water body, location of the intake structure, and volume of water withdrawn, would not be an appropriate or necessary response to mitigating the impact of cooling water intake structures.

EPA Response

EPA notes the comment. Today's final rule maintains the flexibility for the permittee in determining the most cost-effective approach to meeting the performance standards.

Subject Matter Code 17.06

Option: Site-specific determination of BTA

Author Name Michael W. Stroben

Organization Duke Energy

Site-Specific Approach

EPA's proposed § 316(b) rule for existing facilities is based primarily on "performance standards." The performance standards that EPA has selected correspond to an impingement mortality reduction target of 80-95% and a total entrainment reduction target of 60-90%. EPA bases these reduction targets on data from several existing facilities where various intake technologies are in use (i.e., wedgewire screens, fine mesh screens, fish returns, and aquatic filter barriers). EPA also proposes that if the costs of meeting the performance standards are significantly greater than" either the technology costs EPA considered, or the benefits to society, an alternative "site-specific" approach is justified.

It is encouraging that the EPA recognizes that site-specific conditions play an important role for power plants. Regional differences in meteorology, topography, and hydrology greatly influence the site characteristics of an existing power plant. A technology that may be suitable for one power plant may not be suitable for another. In addition, an approach that does not recognize and account for the multitude of site-specific factors that affect impingement and entrainment of aquatic organisms is not scientifically valid.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Subject Matter Code 7.02

Performance standards

Underlying EPA's proposed performance standards for reductions in impingement mortality and total entrainment is the simplifying assumption that entrainable eggs and larvae and impingeable fish are concentrated in certain areas of a waterbody; and that they are uniformly distributed through the water column in those areas. Data collected over the past 30 years indicates that this assumption is not correct. This issue is explained in detail in comments filed by the UWAG, EEl and EPRI.

The power plants that Duke Energy operates are located on various types of waterbodies and aquatic environments. These facilities employ a variety of intake structure locations, technologies, and operational characteristics. Subjecting each of these facilities to the same one-size-fits-all technology driven by a single impingement mortality or total entrainment performance standard would clearly not be a cost effective approach. A site-specific approach that factors in each facility's unique characteristics is critical to Duke Energy's and the electric generating sector's ability to cost effectively implement the § 316(b) regulations.

EPA Response

EPA believes it has presented ample evidence demonstrating a significant decrease in the level of entrainment when intake flow is minimized in relation to the flow of the source waterbody. The documents DCN# 2-013L-R15 and 2-013J support the propositions that flow is related to entrainment and organisms are distributed somewhat uniformly throughout the waterbody.

EPA has discussed the range of technologies used to establish the performance standards (see Sections VII.B.2 and B.3 of the preamble to today's rule). Available data indicate that, when considered as a suite of technologies, barrier, and fish handling technologies are available on a national basis for use by Phase II existing facilities. These technologies exist and are in use at various Phase II facilities and, thus, EPA considers them collectively technologically achievable. For example, currently, 14 percent of Phase II existing facilities potentially subject to this final rule already have a closed-cycle recirculating cooling water system. In addition, 50 percent of the remaining potentially regulated facilities have some other technology in place that reduces impingement or entrainment. Thirty-three percent of these facilities have fish handling or return systems that reduce the mortality of impinged organisms. The fact that these technologies are collectively available means that one or more technologies within the suite is available to each Phase II facility. Economic practicability is discussed in Sections VII.B and XI.B of the preamble. See also response to comment 316bEFR.041.701.

Organization Duke Energy

Subject Matter Code 7.02

Performance standards

Performance Standards

As stated above, the EPA has proposed performance standards that correspond to an impingement mortality reduction target of 80-95% and a total entrainment reduction target of 60-90%. EPA devised these ranges after examining a limited number of "case studies" across the country. Duke Energy supports detailed comments submitted by UWAG and EPRI that data from these limited number of case studies should not be extrapolated across the country. A technology installed at one power plant can perform differently than that same technology installed at a different power plant, even on a similar waterbody type. Given site-specific differences in the effectiveness of a technology, the performance standards devised by EPA should only be used as a guide when determining which technologies may be deployable and effective at a given power plant.

Permit writers should also have flexibility when implementing § 316(b) requirements, and not be required to establish numeric standards. Given natural spatial and temporal variability in aquatic populations, it would be extremely difficult for permittees to comply with a numeric standard and for state regulatory agencies to enforce numeric limits. As an alternative, compliance and enforcement should be predicated on meeting certain non-numerical requirements. For example, compliance with the installation of a technology, operational modifications, a routine maintenance plan, or the establishment of an environmental restoration program could all be enforced more readily by the permit writer.

EPA Response

RFC: Definition of "adverse environmental impact"

Definition of Adverse Environmental Impact (AEI)

The first step in a § 316(b) determination should be the determination of whether or not an Adverse Environmental Impact (AEI) is occurring due to the location or operation of a cooling water intake structure at an existing facility. The EPA's proposed rule does not define an AEI. This is a fundamental flaw because without such a definition, it is impossible to determine Best Technology Available (BTA) requirements.

EPA Response

Please see the response to comment 316bEFR.011.004 for the discussion regarding EPA's decision not to define "adverse environmental impact" in today's final rule.

Comment ID 316bEFR.062.006

Subject Matter Code 7.01.03

Option 3--Site-specific determination

Author Name Michael W. Stroben

Organization Duke Energy

Again, Duke Energy believes that the BTA determination for existing cooling water intake structures should be made on a site-specific basis taking into consideration whether or not an AEI is occurring, or is likely to occur. A BTA determination should not be based on arbitrary, one-size-fits-all performance standards that are not based on sound science.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

EPA disagrees that a determination of whether an adverse environmental impact is occurring is a preliminary step in implementing 316(b). Please refer to the response to comment 316BEFR.313.001 for more information on EPA's position on minimum impacts at existing facilities.

Comment ID 316bEFR.062.007

Author Name Michael W. Stroben

Organization Duke Energy

Subject Matter Code 18.01

RFC: Definition of "adverse environmental impact"

The need to determine if a facility is or is likely to cause an AEI is especially important when it comes to managing man-made reservoirs (for example, reservoirs built in the southeastern U.S.). It is not uncommon for state resource management agencies to stock non-native fish species for recreational purposes. In addition, "exotic" and/or nuisance species are often introduced to the reservoir system either accidentally or by an unauthorized means. The combination of these two activities creates a totally artificial aquatic ecosystem. These artificial ecosystems are subject to relatively rapid aquatic population swings as new species, or greater numbers of an existing species, are added. Therefore, the determination of whether or not an AEI is occurring should only focus on "Representative Indicator Species" (RIS), meaning certain species that are impingeable or entrainable, and representative of species in the waterbody that need to be protected. Likewise, any monitoring program that is designed and implemented should focus only on impacts to RIS. This will ensure that studies are more focused and cost effective.

In southeastern reservoirs, the forage fish population is often sub-tropical and cannot survive cold winter temperatures. Forage fish living outside of the thermal discharge area are highly susceptible to stress, weakening, and die-offs resulting from cold-shock. During this period, they are also more susceptible to being impinged or entrained because of their weakened condition. Once-through power plant cooling systems are actually beneficial in these circumstances because they provide an over-winter refuge for these forage species. Those that do survive the cold winters have such a high fecundity that they easily re-populate during the spring spawning period and the cycle starts over. This ability to compensate for the high degree of mortality experienced during the winter is totally ignored by EPA in its proposed rule. Instead, the EPA would argue that severely weakened or dead fish being collected at the intake structure is an adverse impact. From a scientific standpoint, this argument is not logical and would be counter to goals of the state resource management agencies. This also points out the need for a rule based on site-specific conditions.

A reasonable definition of AEI should be based on the consideration of all important environmental factors and should focus on the overall health of representative species on a population and community level, and not just on numbers of organisms impinged or entrained. A full discussion of this issue, as well as possible definitions, can be found in comments filed by UWAG, EEl and EPRI.

EPA Response

EPA has rejected all proposed definitions of adverse environmental impact which limit the scope to population or communality level impacts. Please see the response to comment 316bEFR.011.004 for more details. Today's final rule sets performance standards to reduce impingement mortality and entrainment of all life stages of fish and shellfish. EPA believes that the all-species approach may be appropriate under certain circumstances, while the use of representative species may be optimal in other cases. The Agency has therefore concluded that the Director must determine whether a clearly defined all-species approach or representative species approach is appropriate. The Director may choose to require evaluation of all species or of certain representative species. In the case of moribund species, the Verification Monitoring Plan includes a proposal on how naturally moribund fish and shellfish that enter the cooling water intake structure would be identified and taken into account in determining compliance with the performance standards in § 125.94. In this case, the Director will review the proposal making certain to analyze whether the operation of the cooling water intake structure is responsible for the moribund fish and shellfish.

RFC: Appropriateness of "significantly greater"

Evaluation of Economic Impact

As stated previously, EPA's proposed rule allows for a site-specific approach if: a) the actual cost of implementing BTA is significantly greater than the cost EPA estimated for that technology (cost-cost test), or b) the actual cost of implementing BTA is significantly greater than the benefit received (cost-benefit test).
EPA's proposed rule lacks a definition for the term "significantly greater than." Therefore, "significantly greater than" as it applies to EPA's proposed rule is subjective and is likely to create significant problems during a BTA determination. Duke Energy proposes that the cost of implementing a technology is "significantly greater than" its benefits if the net cost of installing and operating the technology exceeds the net benefit. This definition should ensure that net benefits to society are maximized.

EPA Response

EPA does not agree that significantly greater mean costs simply exceed benefits. See responses to 316bEFR.006.003, 018.009 and 045.012.

Performance standards

Author Name Michael W. Stroben

Organization Duke Energy

Baseline Characterization

EPA's proposed rule describes a hypothetical intake structure that is to serve as a "baseline" from which impingement and entrainment reductions are measured. The hypothetical intake structure is defined as a "shoreline cooling water intake structure with an intake capacity commensurate with a once-through cooling water system and with no impingement and/or entrainment reduction controls." The performance of an existing intake structure will then be judged against this hypothetical intake structure. In concept, this is good because existing facilities will be given a "credit" for control measures that are already in place. In practice, however, it will be difficult to come up with the "baseline condition." EPA needs to provide better guidance on how to measure the baseline level of impingement mortality and entrainment for various types of intake structures and waterbody types.

EPA Response

For discussions on the basis for and implementation of the calculation baseline, please see response to comments 316bEFR.308.014 and 316bEFR.063.022, as well as the preamble to today's rule.

Definition: Waters of the U.S.

The use of Cooling Impoundments

Many facilities have constructed cooling impoundments whose primary purpose is to provide intake water used for heat exchange and for the treatment of thermal discharges. These impoundments would not exist if not for the steam electric power plant. In these instances, and for the purposes of this rule, EPA should consider these impoundments as closed-cycle cooling and they should be exempted from further § 316(b) requirements.

EPA Response

See response to 316bEFR.006.001.

Comment ID 316bEFR.062.012

Author Name Michael W. Stroben

Organization Duke Energy

Subject Matter Code 3.01

Definition: Existing Facility

Existing Facilities with Multiple Intake Structures

The EPA needs to clarify that if an existing power plant with multiple water intake structures uses a combined total of 50 million gallons per day (MGD), or more, the entire facility should fall under the Phase II § 316(b) Rules. Without this clarification, it is conceivable that a power plant would fall under both the Phase II Rules and the Phase III Rules. An example would be a facility that had two cooling water intake structures; one with a design capacity of more than 50 MGD and one with a design capacity of less than 50 MGD. If both intake structures supply cooling water to the same facility, the facility should be included in only the Phase II Rulemaking.

EPA Response

As specified in § 125.91 of the final rule, Subpart J requirements (i.e., Phase II) apply on a facility basis, not an intake-by-intake basis. Thus, for any Phase II existing facility subject to Subpart J, all cooling water intakes at that facility are subject to regulation under Subpart J requirements as applicable. Also see definition of "facility" in 40 CFR 122.2.

RFC: Proposed use of restoration measures

The Role of Environmental Restoration

Duke Energy is encouraged that EPA recognizes that environmental restoration is one way of satisfying § 316(b) requirements. Duke Energy has a long history of using restoration at its power generating facilities to achieve net environmental benefits and we strongly encourage EPA to keep this option in the final rule; as long as it is done on a voluntary basis by the permittee. Restoration activities should include, but not be limited to support for fish hatcheries and stocking programs, wetlands restoration or creation and other types of habitat improvement, and the support of environmental studies that help state and federal resource agencies manage aquatic resources.

EPA Response

The final rule gives permitting authorities the flexibility to make decisions on the appropriate nature of a restoration measure on a case-by-case, site-specific basis. All restoration measures, however, must meet the requirements of the final rule.

For a discussion of the extent to which restoration measures are voluntary, see EPA's response to comment 316bEFR.060.022.

Implications for nuclear facilities

Nuclear Safety

Duke Energy maintains a strong presence in the nuclear energy industry through ownership and operation of three steam electric nuclear plants in North and South Carolina. The proposed § 316(b) rule for existing facilities poses retrofit and safety concerns at these power plants. Duke Energy is encouraged that the EPA recognizes these concerns and is proposing to allow the Nuclear Regulatory Commission (NRC) to intervene during the National Pollutant Discharge Elimination System (NPDES) permitting process if it finds that nuclear reactor safety could be jeopardized. Because impacts to nuclear safety from intake structure retrofits or operational changes are largely unknown at this time, it is imperative that this language remain in the final rule for existing nuclear facilities. Detailed comments on impacts specific to the nuclear industry have been submitted by the NEI.

EPA Response

Today's final rule allows for a site-specific determination of best technology available if requirements conflict with Nuclear Regulatory Commission safety requirements (see § 125.94(f)).

Permit applications/implementation schedule

Implementation of Final Rule

EPA needs to devise a well thought out plan on timing issues associated with implementation of its proposed § 316(b) rule. As an example, for permittees who have already applied for a permit renewal when the § 316(b) rule becomes final, and are in the period of agency review of the application, the permittee should not have to resubmit its application because of the new rule. Instead, the next five-year permit term should be the time in which the permittee complies with the new rule. Likewise, if a permittee is within a year of submitting a renewal application, there will not be time to complete any impingement or entrainment studies for that renewal. Therefore, the permittee should be given the upcoming five-year permit term to perform the necessary environmental or BTA assessments with compliance required in the subsequent five-year renewal period.

EPA Response

EPA has clarified timing requirements for the submittal of the required studies. See response to comment 316bEFR.034.066 for a discussion.

Subject Matter Code 21.09

Permit applications/implementation schedule

EPA has indicated that it will be developing a guidance document(s) that will aid permittees in designing and implementing impingement and entrainment monitoring plans at existing facilities. However, it is unclear as to when this information will be available. To help permittees more clearly understand EPA's intentions, implementation of final § 316(b) rules for existing facilities should coincide with the availability of this guidance document(s).

EPA Response

EPA plans to develop guidance on implementing today's final rule; however a date of availability has not yet been determined.

Burden to facilities (general)

Burden of Implementation

In the proposed § 316(b) rule for existing facilities, the EPA requests comment on the burden associated with a site-specific approach. Duke Energy believes that the majority of the burden rests on the permittee and not the permit writer. The permittee is responsible for designing and conducting any necessary environmental studies, reviewing and summarizing data, and presenting results to the permit writer for their review. The permittee is responsible for performing any cost-cost tests, or cost-benefit tests. The permittee is also responsible for the implementation of any required technologies, monitoring programs, and/or environmental restoration activities. The permit writer is responsible for ensuring compliance with agreed upon § 316(b) requirements. Clearly, the majority of the overall burden rests with the permittee.

Many states, including North Carolina, agree that the site-specific approach is the most workable for their permitting agencies. Refer to the enclosed copy of a February 22, 2002 letter from Michael P. Easley (Governor, NC) to The Honorable Christine Todd Whitman (Administrator, US EPA). In the letter, Governor Easley urges the EPA to "provide a framework for site-specific decision making — one that allows North Carolina to make the critical plant control decisions and will not arbitrarily reopen past regulatory decisions that we have found to be effective."

EPA Response

The final rule includes regulatory pathways for site-specific compliance. Therefore, the commenter's recommendation to adopt a site-specific approach has been met. However, the Agency believes that in assessing the share of burden between permittee and permit writer the commenter has underestimated the requirements and responsibilities of the permit writer. The commenter states that the sole responsibility of the permit writer is "ensuring compliance with agreed upon section 316(b) requirements." The commenter fails to acknowledge that the permit writer is responsible for reviewing and approving any necessary studies, reviewing and approving data, and analyzing the results of potentially multiple presentations from many facilities. The permit writer is further responsible for evaluating, reviewing, and approving any cost-cost tests, or cost-benefit tests. In addition, the permit writer is responsible for approving the implementation of any required technologies, monitoring programs, and/or environmental restoration activities. Clearly, the overall burden is shared between permittee and permit writer, in the Agency's opinion. Nonetheless, the permit writer lacks the resources of the majority of the permittee and the question of "equitable" burden is not addressed by the commenter. The Agency asserts that in site-specific decision making that the permit writer has greater burden than in other cases analyzed by the Agency. Regardless, the Agency determined that the site-specific alternatives were tantamount to an equitable regulation to the permittees, and has determined that the burden to permit writers is acceptable. See the Information Collection Request 2060.02 supporting the final rule.

Option: Reduce capacity comm. with closed-cycle

NPPD doesn't agree that a closed-cycle recirculating cooling system is an available technology for facilities that currently have once-through cooling water systems. For most existing facilities it is neither financially nor spatially feasible to replace a once-through with a closed-cycle cooling water system. EPA indicates in the proposed rules that it considered other technology-based options. These options are: 1. Intake Capacity Commensurate with Closed-Cycle, Recirculating Cooling Systems for All Facilities, 2. Intake Capacity Commensurate with Closed-Cycle, Recirculating Cooling Systems Based on Waterbody Type, 3. Intake Capacity Commensurate With Closed-Cycle, Recirculating Cooling System Based on Waterbody Type and Proportion of Waterbody Flow, and 4. Impingement Mortality and Entrainment Controls Everywhere. Further EPA itself notes that even for option 3 (the most limited application of closed-cycle recirculating cooling water systems), the incremental costs of this option significantly outweigh the incremental benefits.

EPA Response

EPA elected to not adopt any of the alternative technology-based options or the alternative site-specific approaches discussed in the proposed rule (67 FR 17154-17161) in today's final rule. Please refer to section VII of the preamble to the final rule for further information as to why these options were not selected.

For a variety of reasons, EPA opted not to implement a regulatory approach based solely upon closed-cycle, recirculating cooling. Please refer to section VII.E of the preamble for more information on why EPA rejected this alternative.

Subject Matter Code 7.01.03

Option 3--Site-specific determination

NPPD strongly supports the inclusion of the third method for establishing the best technology available (BTA) for minimizing adverse environmental impact. This "site-specific" determination of BTA is an important option for a facility to have available for use in cases where its costs of compliance with the applicable standards are significantly greater than EPA's estimated costs or the benefits of complying with the standards at the facility's site.

EPA Response

EPA agrees that flexibility for permittees is an important consideration and notes that the final rule contains five compliance alternatives from which a permittee may choose. Please refer to the preamble for a discussion of the framework of the final rule.

EPA notes that the final rule includes a site-specific compliance alternative, which includes a provision for a cost-cost and cost-benefit test. Please refer to the response to comment 316bEFR.338.002 for more information.

Organization Nebraska Public Power District

Subject Matter Code 7.02

Performance standards

The proposed rule, in compliance option 2, allows a facility to implement design and construction technologies, operational measures, and/or restoration measures that meet the proposed performance standards. These performance standards for reduction in impingement mortality and entrainment are expressed as a range of percentage reduction. The NPPD position is that the Director shall interpret any performance within the range for the appropriate waterbody type as meeting the proposed performance standard.

EPA Response

EPA has decided to give the Director the authority to determine methods of evaluating compliance. Thus, the Director will specify species and life stages of concern. The Director may choose to require evaluation of all species or of certain indicator species; or the Director may elect to verify compliance using biomass as a metric. The Director may also authorize compliance to be determined based on a Technology Installation and Operation Plan. EPA believes that as each situation will be somewhat unique, it should be left to the Director to determine the appropriate compliance approach.

Subject Matter Code 21.09

Permit applications/implementation schedule

The proposed rule states that 316(b) requirements for Phase II existing facilities would be implemented through the NPDES (National Pollutant Discharge Elimination System) permit program. Facilities subject to the proposed rule would comply with Phase II rules when an existing NPDES permit is reissued or, when an existing permit is modified or revoked and reissued. This implementation plan presents some significant scheduling problems for facilities where NPDES permits expire in the next several years. A NPDES permit renewal application is due 180 days prior to expiration. The proposed rule states this application would include new information requirements for a facility: physical data to characterize the source waterbody in the vicinity where the cooling water intake structures are located; data to characterize the design and operation of the cooling water intake structures; information describing the design and operating characteristics of the cooling water systems and how they relate to the cooling water intake structures at the facility; and all facilities (except those that already use a closed-cycle, recirculating system) must submit a Comprehensive Demonstration Study.

The Comprehensive Demonstration Study has seven components: proposal for information collection; source waterbody flow information; impingement mortality and entrainment characterization study; design and construction technology plan; information to support proposed restoration measures (only for facilities proposing to use restoration measures); information to support site-specific determination of best technology available for minimizing adverse environmental impact (only for facilities choosing a site-specific standard); and a verification monitoring plan. For the first component of the study, a facility would be required to submit a proposal to the Director for review and approval stating what information would be collected to support the study. Several of these components could likely require source waterbody studies conducted over multiple seasons and more than one year to obtain representative data. The data acquired will also require some time for analysis and the development of a report. The NPPD position is that any facility subject to Phase II with a NPDES permit expiring 3 years or less after the issuance of the final rule should not be subject to these requirements until the subsequent NPDES permit renewal. This staggering of the imposition of the requirements for the final Phase II rule will also allow States to better plan for the resources necessary for their implementation.

EPA Response

EPA has added many efficiencies to today's final rule since the proposal and NODA to provide options for streamlining application requirements. See response to comment 316bEFR.034.005 for a discussion.

EPA has also clarified the timing for submittal of the required studies. See response to comment 316bEFR.034.066 for details.

Comment ID 316bEFR.063.007

Author Name Joseph L. Citta, Jr.
Organization Nebraska Public Power District

Subject Matter Code 21.03
Monitoring requirements

EPA requested comment on minimum frequencies for verification / compliance monitoring, specifically, for at least two years following initial permit issuance, impingement samples at least once per month over 24 hours and entrainment samples at least biweekly over 24 hours during primary period of reproduction, larval recruitment, and peak abundance. The NPPD position is that once the best technology available to meet the required performance standards (or site-specific requirements) has been determined and installed, a facility should only have to conduct monitoring to show the equipment (or other measures) are operated or utilized in accordance with permit conditions. Verification / compliance monitoring will be satisfied by monitoring the operations of the best technology available.

EPA Response

Please see EPA's response to comment 316bEFR.021.007.

Comment ID 316bEFR.063.008

Subject Matter Code 21.09

Permit applications/implementation schedule

Author Name Joseph L. Citta, Jr.

Organization Nebraska Public Power District

The proposed rule indicates that at each NPDES permit renewal, the same Phase II information requirements will be in place. The NPPD position is that once best technology available has been implemented for a facility, unless there have been significant changes to the waterbody / aquatic community, that technology remains best technology available. To interpret otherwise would mean a facility could be faced with the design and installation of a new best available technology at each NPDES permit renewal. A facility should not be required to submit a comprehensive data study with each permit renewal.

EPA Response

EPA agrees that a comprehensive demonstration study may not need to be conducted each time a permit is renewed. See response to comment 316bEFR.041.126

Comment ID 316bEFR.063.009

Author Name Joseph L. Citta, Jr.

Organization Nebraska Public Power District

Subject Matter Code 21.01.01

Source water physical data

With respect to the source water physical data, the comprehensive demonstration study, and any other biological studies, NPPD believes that the Director should be given authority to determine which studies, and their parameters, are necessary and to determine which species are of concern.

EPA Response

EPA agrees that the Director should determine the specific study requirements after reviewing the facility's Proposal for Information Collection. Study requirements will be determined in accordance with the compliance alternative selected. EPA believes the Director is best positioned to make decisions about the specific species that should be monitored, the frequency of monitoring, averaging times, etc., that support the compliance alternative selected, however a facility may propose these parameters in the Proposal for Information Collection for review and approval by the Director.

In addition, source water physical data is required of all applicants under 122.21(r)(2). As discussed in the preamble to today's rule, source water physical data are needed to characterize the facility and evaluate the waterbody type and species potentially affected by the cooling water intake structure. The Director would use this information to evaluate the appropriateness of the design and construction measures, operational measures, and/or restoration measures proposed by the applicant. Thus, in today's final rule, EPA is requiring source water physical data to be submitted by all applicants.

RFC: Proposed use of restoration measures

Author Name Joseph L. Citta, Jr.

Organization Nebraska Public Power District

NPPD supports EPA's recognition of the importance of restoration measures in maintaining a healthy fishery. Because the State Director is the most familiar with local water body conditions and history, the NPPD position is that it be at the Director's discretion as to whether and what extent restoration is a part of best technology available for a facility to meet the performance standards of the Phase II rule. The flexibility of this option allows ample opportunity to enhance fishery populations especially in Nebraska where the source water for facilities comes from a variety of water bodies and site-specific fishery concerns.

EPA Response

For a discussion of the roles and responsibilities of the permitting authority for restoration measures, see EPA's response to comment 316bEFR.060.026.

Comment ID 316bEFR.063.011

Author Name Joseph L. Citta, Jr.

Organization Nebraska Public Power District

Subject Matter Code 3.03

Definition: Waters of the U.S.

A number of public power electric generating facilities use cooling ponds or reservoirs that have been constructed off of a main watercourse channel. Water withdrawn from the cooling reservoir is used for noncontact cooling and discharged back into the reservoir from which it can be withdrawn and recirculated. Such man-made cooling reservoirs or ponds are supplied with makeup water pumped from a nearby source, such as a river. Such cooling water ponds often provide a valued asset due to the enhanced aquatic habitat and recreation opportunities that they offer.

A cooling pond or reservoir meets the definition of a “closed-cycle recirculating system" which as set forth in Section II, Scope and Applicability of the Proposed Rule [Page 17129] section G “means a system designed, using minimized makeup and blowdown flows, to withdraw water from a natural or other water source to support contact and/or noncontact cooling uses within a facility. The water is usually sent to a canal or channel, lake, pond, or tower to allow waste heat to be dissipated to the atmosphere and then is returned to the system view source water (make up) water is added to the system to replenish losses that have occurred due to blowdown, drift arid evaporation."

Although closed-cycle, recirculating cooling is not one of the technologies on which the presumptive standards are based the proposed rules recognize that the use of a closed-cycle, recirculating cooling system would readily achieve such standards. For that reason, the proposed rule, 124.84(b)) would allow the performance standard to be satisfied by reducing the “intake capacity to a level commensurate with the use of a closed-cycle, recirculating cooling system."

Based on the above, NPPD readily concludes that those existing facilities, which are located on and use cooling water from a closed-cycle, cooling pond are in compliance with the proposed Phase II rule. This conclusion appears to be further bolstered in EPA’s assessment of ” impacted facilities [page 17142] in which EPA concludes based on an analysis of survey data that "the proposed rule would not require any changes at approximately 89 large existing facilities with recirculating wet Cooling systems (e.g., wet cooling towers or ponds).”

However, what appears to be clear cut is muddled in the discussion on cooling ponds vis a vis “waters of the United States." Under Section C, Is My Facility Covered If It Withdraws From Water of the U.S., EPA states that they "do not intend this proposal to change the regulatory status of cooling ponds." EPA further clarifies that “cooling ponds are neither categorically included nor categorically excluded from the definition of waters of the United States at 40 CFR, 122.2." Accordingly, EPA has concluded "facilities that withdraw cooling water from cooling ponds that are waters of the U.S. and meet other proposed criteria for coverage would be subject to today’s proposed rule."

In that a number of cooling ponds provide recreational and fishing opportunities for both in-state and out-of-state visitors, i.e., support interstate commerce, they often will meet the definition of waters of the United States. The issue, however, should not be whether or not they are de facto waters of the United States but, rather, are they a system that satisfies the performance standard or a system that must meet the performance standard. Or more simply put, are they part of the solution or part of the problem.

The uniqueness of a man-made, off-channel, closed-cycle, recirculating cooling pond is such that we believe they should not be lumped together with lakes and reservoirs — regardless of whether or not they are determined to be waters of the United States. More appropriately, these man-made resources, which often provide a valued habitat and fishery that otherwise would not exist and allow a cooling water intake capacity at a level commensurate with the use of a closed-cycle, recirculating cooling system, should be explicitly defined as meeting the performance standards of this rule. The presence of NPPD facilities has enhanced the sport fishery in many circumstances that normally would not be there.

EPA Response

The final rule provides that a Phase II existing facility may demonstrate that it has reduced its flow commensurate with a close-cycle recirculating system and therefore is not required to further demonstrate compliance with applicable performance standards. (see, § 125.94(b)(1)). However, whether use of a specific pond or reservoir meets the definition of a closed-cycle, recirculating system will be determined on a case-by-case basis. Also see response to 316bEFR.006.001.

Comment ID 316bEFR.063.012

Author Name Joseph L. Citta, Jr.

Organization Nebraska Public Power District

Subject Matter Code 7.02

Performance standards

With respect to the performance standard for reduction in impingement mortality of 80 - 95%, NPPD offers the comment that this level of reduction maybe possible ONLY with the use of advanced technologies that are not applicable to all water bodies. The Director should be given discretion on determining best technology available for a facility. This provides even more justification to a site-by-site determination. Tumbleweeds, corn shucks, plant debris in the spring and fall, can be devastating and very maintenance intensive to any kind of trash removal, fish removal system found in the state.

EPA Response

EPA disagrees that the impingement mortality standard may be met only with the use of advanced technologies that are not applicable to all waterbodies. Several of the technologies used to reduce impingement mortality have been widely-deployed and studied for the better part of three decades (modified ristroph screens, barrier nets) and can no longer be considered "advanced".

EPA agrees, however, that site-specific factors may render one design and construction technology or operational measure more successful at one facility than another. Today's rule leaves the determination of BTA for individual facilities up to the Director.

Subject Matter Code 10.09

RFC: Does today's proposal allow for 'backsliding'

EPA has expressed concern that the proposed performance standards could create an opportunity for "backsliding" from current impingement mortality and entrainment performance levels. NPPD does not believe this concern is justified and that facilities will not remove or disable currently installed technology from their cooling water intake structures.

EPA Response

See response to 316bEFR.021.013.

Comment ID 316bEFR.063.014

Author Name Joseph L. Citta, Jr.

Organization Nebraska Public Power District

Subject Matter Code 3.04

Applicability to facilities subject to NPDES permit

NPPD would like EPA to include a provision to cover facilities that will be decommissioned within 10 years (a period that also coincides with the timing for significant investment for air emission controls currently under consideration) after the Phase II rule becomes final. If the Director obtains necessary assurances that the facility (and its cooling water intake structure) will cease operation within a time certain, the final NPDES permit(s) should be renewed without the requirements imposed by the Phase II rule.

EPA Response

The final rule does not exclude facilities that will be decommissioned within 10 years for several reasons. First, the power generation market is dynamic and changes in the market often influence decisions to prolong the use of aging facilities. Second, the emergence of innovative technologies (e.g., combined cycle energy production) often can alter the useful life of existing facilities. Finally, there is flexibility built into this rule. Given these factors, EPA has concerns regarding what type of assurances of closure would be sufficient, whether and how a facility could "change its mind" if faced with changed circumstances, whether such agreements could be effectively enforced, and whether such an approach most effectively fulfills the objectives of section 316(b).

RFC: Entrainment vs. entrainment mortality

NPPD feels from a scientific and risk management point of view, USEPA's decision based the proposed §316(b) performance standard on entrainment, rather than entrainment survival. Detailed comments resulting from review of sections Vl.A.7 and Vl.A.8.b of the rule and the support document on entrainment survival, Chapter A7, are provided below. The major findings and recommendations resulting from the review include:

-The proposed rule's exclusion of entrainment survival from the BTA performance standard is scientifically flawed;

-The proposed rule's exclusion of entrainment survival from the BTA performance standard can be ecologically unprotective and would not provide comparability in quantifying resource impacts among facilities and waterbodies;

-To provide a solid scientific and resource management foundation for BTA determination, the performance standard should be based on realistic estimates of entrainment losses (i.e. entrainment mortality) and be linked to protection of higher biological levels of organization.

-USEPA's evaluation does not reflect consideration of the evolution of entrainment survival study methods— methods have matured and later methods do allow for valid estimates of entrainment survival with appropriate levels of precision.

-USEPA's assumption of 100% entrainment mortality is not supported by the overwhelming evidence of substantial entrainment survival of many species that has been found in studies conducted to date, and is not justified by the concerns US EPA presented in Chapter A7.

NPPD feels the Performance Standard for BTA should be based on reducing entrainment loss, as it currently is for impingement. USEPA correctly states that:

Assessment of ecological and economic consequences of entrainment is based on estimates of the number of fish and shellfish killed as a result of entrainment" (p. A 7-1) (Emphasis added.)

Despite the above statements, USEPA, instead, proposes a performance standard that requires reducing numbers entrained rather than reducing numbers killed (Vl.A.7 of the proposed rule). Their decision was based on the belief that appropriate entrainment mortality data for existing and potential intake technologies used as the basis for the rule was either absent or insufficient. However, USEPA, in reality, is not excluding entrainment mortality from consideration in choosing this approach, but rather assuming all entrained organisms die (100 percent mortality) as a result of passage through cooling water intake system (CWIS) for all of the baseline and benefits evaluations. USEPA notes in Chapter A7 (e.g. Section A7-5), that they believe this assumption of 100 percent entrainment mortality is consistent with a precautionary approach, is protective of biological resources, and implies consistency in quantifying resource impacts at different facilities and waterbodies.

It is of utmost importance that USEPA reevaluate this position, which fundamentally influences the soundness of the decision-making process for 316(b). A performance standard that is scientifically sound, consistent with risk assessment and management frameworks currently in use by USEPA, and environmentally protective should be based on numbers killed, as USEPA currently proposes for impingement, to provide better measures of potential risks at population and community levels. Our comments are elaborated in more detail below. The proposed rule should clarify terms dealing with entrainment mortality and distinguish between entrainment loss as a performance standard and estimates of entrainment mortality rate that may be used in benefits assessment. The protection requirements should be consistently based on actual risks to the ecological entities of concern for both entrainment and impingement. To assure BTA performance requirements are protective, they should be based on entrainment loss. Facility operators should be allowed to address the baseline assumption of 100% entrainment mortality by inclusion of entrainment survival estimates in the BTA assessment, as USEPA proposes for impingement. To assure BTA performance standards are protective, and to provide a basis for evaluating tradeoffs among species as part of BTA determination they should provide for consideration of risks to higher biological levels in the BTA determination. Comparability in quantifying resource impacts and determining BTA at different sites and waterbodies requires that the entrainment mortality rate be considered. The description of the entrainment vulnerability is overly broad and misleading.

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards. Please see response to comment 316bEFR.002.015 regarding the inclusion of entrainment survival estimates in site-specific benefit analysis. Please see the response to comment 316bEFR.306.506 for the discussion regarding EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule.

Comment ID 316bEFR.063.016

Subject Matter Code 12.03

RFC: Entrainment vs. entrainment mortality

Author Name Joseph L. Citta, Jr.

Organization Nebraska Public Power District

Estimates of entrainment mortality RATE CAN and should be used in Benefits Assessment.

USEPA indicates that the proposed Phase II rule does not preclude the use of estimates of entrainment mortality and/or survival rates when estimating benefits to be achieved through installation of BTA (Section Vl.A.8.b). However, USEPA expresses some reservations about the quality of existing entrainment survival data and the potential of collecting reliable survival data in the future based on its review of 13 entrainment survival studies, which it provides in Chapter A7.

We believe that it is scientifically appropriate to allow consideration of entrainment mortality rates in benefits estimation for the same reasons discussed previously above. Further, as elaborated below, previous entrainment studies, including those reviewed by USEPA, were conducted during a period when equipment and procedures for estimating entrainment survival were being refined to minimize the potential confounding influences of handling stress. Consequently, not all previous entrainment survival studies can be viewed with the same degree of scientific certainty. However, much valuable information exists (far more than “a provocative set of anecdotes”) that could and should be used as part of the evaluation of alternatives. Finally, the success of some of the most recently conducted studies clearly demonstrates that entrainment mortality can be estimated with a level of confidence comparable to that of other biological testing (e.g., bioassay testing). Thus, assuming a 100 percent entrainment mortality rate for the many relatively hardy species would clearly result in biased estimates of entrainment loss and introduce much greater uncertainty in the decision-making process than would inclusion of best available estimates of entrainment mortality rate. In such cases, an assumption of 100 percent entrainment mortality rate cannot be scientifically justified. This concept would carry over and create a flaw in the cost benefit analysis as well.

Entrainment survival is a scientifically demonstrated reality for some species. Entrainment mortality rate is estimatable with sufficient precision. Existing data has utility in benefits assessment. Although not all commonly entrained species have been studied in sufficient detail, existing information related to entrainment survival does cover many of the commonly entrained species and can have important utility for evaluating the potential benefits of CWIS alternatives. Information on entrainment survival has long been recognized as an important evaluative tool for making better decisions on the selection of technologies for minimizing impacts (Jinks et. al. 1981). In addition to the results of previously conducted field studies of entrainment survival, other available information that assessors should consider includes:

-Thermal tolerance data relevant to short-term exposures of early life stages to elevated temperatures;
-Pressure bomb and condenser simulator studies that help to define the general range of mechanical stresses tolerated by fish eggs and larvae.
-Direct release studies of through-plant survival using live hatchery-reared eggs and larvae
-Monitoring data demonstrating species and life stages obtained and seasonal distribution.

While actual entrainment survival assessments have been conducted at only a relatively small number of existing power plants, the studies to date support the transferability of results to other power plants with similar pumping and thermal regimes. Hence, the results of studies conducted at one facility can be used to support the evaluation of potential benefits of intake alternatives at other, similar facilities.

The following example serves to illustrate how existing entrainment survival information can be used to aid in the selection of potential intake alternatives to reduce CWIS impacts:

An existing steam-electric generating facility operates in load following mode at less than full generating capacity throughout most of the year. Load is typically lowest during late evening and nighttime hours. Unfortunately, the existing cooling water pumps run at a fixed speed regardless of facility generating load and cooling requirements. Therefore, it appears that a significant reduction in entrainment exposure might be achieved through reductions in cooling water withdrawal by installation of variable speed pumps that could better match the changing cooling water need of the facility. However, both the permitting authority and the facility operators are concerned that installation of variable speed pumps could result in elevated condenser discharge temperatures and higher thermal stress. This increased stress might result in a higher entrainment mortality rate that could offset potential reductions in the numbers entrained for the species being entrained. Facility operators are further concerned that flow reductions being sought with the use of variable speed pumps will result in losses of condenser efficiency resulting in severe economic penalties to operation of the facility.

A review of available information for the facility indicates that no site-specific measurements of through-plant survival are available for any of six species that are most abundant in entrainment at the facility. However, estimates of entrainment survival are available for two of the species and on a congeneric of a third species at other facilities. These data indicate that these three species could be very tolerant of the mechanical stresses of entrainment at the facility being evaluated. In addition, laboratory-based thermal tolerance data for short-term exposures to temperature elevation is also available on the early life-stages of these species. Although no entrainment survival data is available anywhere for the other three species, data for related family members indicates low (0-15 percent) entrainment survival.

All parties decide to include an analysis of the limits on flow reduction imposed by thermal mortality and condenser performance in the benefit assessment. The permitting authority and facility operators felt that the most realistic estimates of potential benefits for the three focal species that have potentially high entrainment survival would be obtained by using mechanical mortality rate estimates and thermal tolerance threshold limits available from studies conducted at other facilities. The analysis assumed 100 percent mortality rates for the other three focal species. Losses were estimated for variable speed pumps and for projected typical operation of the existing intake. By comparing these results with losses for a baseline assuming 100 percent mortality rate for organisms entrained at full capacity operation, the assessors provided information on the incremental benefits of variable speed pump
installation compared to the protection already implemented by facility operation. Further, should the assessment show significant potential benefits of installing variable speed pumps, the facility plans to incorporate site-specific studies to verify entrainment mortality rates for the entrained species as part of the overall engineering and implementation plans.

EPA Response

Please see response to comment 316bEFR.305.001 with regard to entrainment-based performance standards. Please see response to comment 316bEFR.002.015 regarding the inclusion of entrainment survival estimates in site-specific benefit analysis. Please see the response to comment 316bEFR.306.506 for the discussion regarding EPA's assumption of 100 percent entrainment mortality in the benefits analysis for this rule.

RFC: Application to "unique" facilities

Clarify that storm water permits do not subject an otherwise non-applicable facility to coverage under the Phase II rule.

The Phase II rule applies to existing power generation facilities that use a cooling water intake structure (CWIS) to withdraw certain amounts of cooling water from waters of the United States lithe facility is a point source subject to an NPDES permit. The preamble to the Phase II rule, however, discusses a hypothetical facility that discharges wastewater, storm water, and cooling water, or some combination thereof, and suggests that the permitting agency would include CWIS requirements in the NPDES permit. The preamble then goes on to state:

In the event that a Phase II existing facility's only NPDES permit is a general permit for storm water discharges, the Agency anticipates that the Director would write an individual NPDES permit containing requirements for the facility's cooling water intake structure. The Agency invites comments on this approach for applying cooling water intake structure requirements to the facility. 67 Fed. Reg. 17129.

NPPD disagrees with EPA's assertion of jurisdiction over facilities that have NPDES permits only for storm water. There are both legal and practical arguments against such an approach. First, Section 316(b) of the Clean Water Act (CWA) does not grant EPA comprehensive authority to address all cooling water intake structures. Instead, EPA is directed to develop Best Technology Available (BTA) requirements in connection with "any standard established under section 301 or section 306 and applicable to a point source." The special provisions addressing storm water discharges in CWA section 402(p) were enacted subsequent to that directive in section 316(b), and in any case they do not constitute a "standard established under section 301 or section 306." There is thus no indication that Congress intended that a facility subject only to a storm water permit would have to comply with section 316(b) standards.

In addition to the absence of CWA statutory authority for applying the proposed rule to storm water permits, there are a number of practical reasons why it would be inappropriate for EPA to do so, especially considering the potential impacts that such an action would have if similarly applied in Phase III. If EPA were to subject to section 316(b) facilities whose only direct discharge is storm water, most of which are subject to an NPDES general permit, EPA would be imposing a significant administrative burden on both the regulated community and on state and EPA permit writers. Permitting authorities would have to somehow identify such facilities and then develop, following procedural requirements that apply to NPDES permitting, individual NPDES permits for such facilities for the first time. EPA should avoid imposing this burden, in light of its lack of statutory authority and the questionable environmental benefit to be obtained from such an action.

RFC: Cooling water withdrawal thresholds of 25%

The definition of a cooling water intake structure, and the applicability threshold for the rule, should be based on a minimum of 50% of the intake water used for cooling purposes. Do not require monthly determinations of the applicability of the Phase II rule on the basis of water use.

The proposed rule states in effect that it applies to an existing facility if the facility is a point source with a water intake structure, and the facility uses for cooling purposes at least 25% of the water drawn through that intake structure. As stated in comments on the Phase I rule, there is no logical reason for asserting that an intake structure constitutes a cooling water intake structure" where the primary purpose of the intake structure is to withdraw water for non-cooling purposes. A cooling water intake structure should be one that withdraws water where more than

50% of the water is used as cooling water, i.e., where the primary purpose for the structure is to withdraw cooling water.

RFC: Cooling water withdrawal thresholds of 25%

Regardless of whether the applicability threshold is 50% or 25%, though, EPA needs to provide clearer and more practicable guidance on how to determine if the threshold is met. Section 125.91(d) of the proposed rule discusses how one calculates whether 25% or more of water withdrawn is used for cooling water. Unfortunately, the language of the proposed rule would create serious implementation problems.

The proposed rule states that the 25% threshold "is met if any monthly average of cooling water over any 12 month period is 25 percent or more of the total water withdrawn." Besides the ambiguous language used, the primary problem with this approach is that it seems to suggest that a facility make a determination every month as to whether or not it is within the scope of the rule. Applicability of the Phase II rule is a very important determination with significant financial and other resource consequences. It is both unreasonable and impracticable for the regulated entity, as well as the permitting authority, to be expected to make this determination every month. Moreover, withdrawal rates may vary from month to month due to seasonal or process variables, and facilities should not be subject to the rule simply because cooling water use percentages may marginally exceed 25% (or other applicability threshold) in a given month.

We suggest instead that the rule require that the calculation be made once at the time the facility submits its application for renewal of its NPDES permit. At that time, the facility should review the previous 12 months of flow data or, alternatively, a representative 12 month period. If the total amount of cooling water used during that period is 25% or more of the total flow for that period, then the facility would be subject to the Phase II rule. If not, the facility is not subject to the rule. This determination would be revisited each time a permit is renewed and would be based on the previous five years' worth of data.

This approach provides a high degree of certainty for both the facility and the permitting agency as to the basic question of whether a facility is subject to the rule. It is also comparable to the approach EPA has taken for applying production-based effluent limitations guidelines, where application of the guidelines and calculation of mass effluent limitations based on production occurs at the time a permit is issued or renewed, not on an ongoing basis.

Withdrawal threshold of 50 MGD

Permittees should have the option of meeting an actual flow threshold in lieu of the 50 MGD design flow threshold.

The proposed rule lists a design intake flow of 50 million gallons per day (MGD) as one of the criteria for applicability of the proposed Phase II regulations. In many cases, however, actual intake flow is below the design capacity. If a permittee is willing to accept permit limitations that restrict its actual water use to some level below 50 MGD, and thereby not be subject to the Phase II regulations, EPA should encourage such actions as a means of reducing the potential for entrainment and impingement, which the rule seeks to avoid.

Definition: Existing Facility

Remove the proposed imposition of Best Professional Judgment requirements.

The proposed Phase II rule contains a provision that is certain to cause confusion and is potentially the source of regulatory uncertainty, controversy, and litigation. Proposed 40 C.F.R. § 125.90(c) states that: "Existing facilities that are not subject to this subpart [the Phase II rule] must meet requirements under section 316(b) of the CWA determined by the Director on a case-by-case, best professional judgment (BPJ) basis." The apparent effect of this provision would be to subject any facility with an NPDES permit and withdrawal of any amount of surface water for cooling purposes to case-by-case section 316(b) BPJ determinations.

This provision unnecessarily blurs the distinction between Phase II and Phase III facilities. EPA appears to be directing permit writers to impose BPJ section 316(b) conditions on Phase III facilities (and even facilities with de minimis impacts or falling below the applicability thresholds in an eventual Phase Ill rule) before EPA promulgates the Phase Ill rule. The benefits and objectives of the phased rulemaking addressing different types of facilities in different rules would be contravened by including a provision in the Phase II rules that sweeps in all of the Phase III facilities as well.

The language in 40 C.F.R. § 125.90(c) is unnecessary. Although EPA claims that the authority for applying BPJ interpretations for purposes of section 316(b) requirements already exists, it has never included such a requirement in its regulations, including the 40 C.F.R. Part 125 Subpart A regulations on establishing BPJ permit limits. If EPA believes that its rules have always allowed imposition of case-by-case requirements for cooling water intake structures, then there is no need to modify the regulations now. By including express BPJ language in the section 125.90(c) of the Phase II rule, EPA seems to imply a greater need for BPJ requirements for Phase III intake structures now, when in fact the opposite is certainly the case: Phase III facilities will be addressed shortly in a new rulemaking, so it would be particularly inefficient and problematic to direct permit writers to begin issuing BPJ requirements for Phase III facilities that have been operating without any BPJ intake structure requirements for many years.

Moreover the proposed Phase II regulations give no guidance as to when BPJ permit conditions are required. In fact, proposed 40 C.F.R. § 125.90(c) could be interpreted to require that BPJ requirements under section 316(b) be included in every NPDES permit for any facility with a surface water intake structure where any portion of the water is used for cooling purposes. Likewise, EPA provides no guidance in the regulations or preamble as to how the permit writer should establish BPJ section 316(b) permit conditions. The absence of details or specific interpretive guidance on the applicability of BPJ requirements makes it impossible for industry to comment comprehensively or specifically on this proposal. Even more importantly, the lack of specificity would leave permit writers and permittees with the difficult and resource-intensive task of trying to develop and negotiate permit conditions in a regulatory vacuum.

Industry has both legal and practical concerns about the concept of BPJ limitations on intake structures in general. We have previously communicated some of those concerns to EPA and plan to do so in greater detail in the Phase III rulemaking. Apart from these specific concerns with BPJ, however, there is simply no justification for EPA directing consideration of BPJ limits for Phase III facilities in the Phase II rule.
